Alternatively, by selecting one of these error files in the Custom Errors tab and clicking Edit Properties, you can specify that the default HTTP status codes and messages will be returned by the server when that error occurs, or that any specified file located in either a local folder or a network share will be returned when that error occurs. Companies commonly use this feature to create error pages that contain elements like the company logo, the e-mail address of customer support, or even a search tool for finding the page the client is trying to access. This improves the overall user experience of the site, even when errors occur.

IIS uses more detailed error messages than are included in the original HTTP specification. For example, the HTTP error code 401—which in HTTP simply means unauthorized—is represented in IIS by a group of codes spanning from 401.1 through 401.5, representing various reasons why a server might deny a user's credentials.

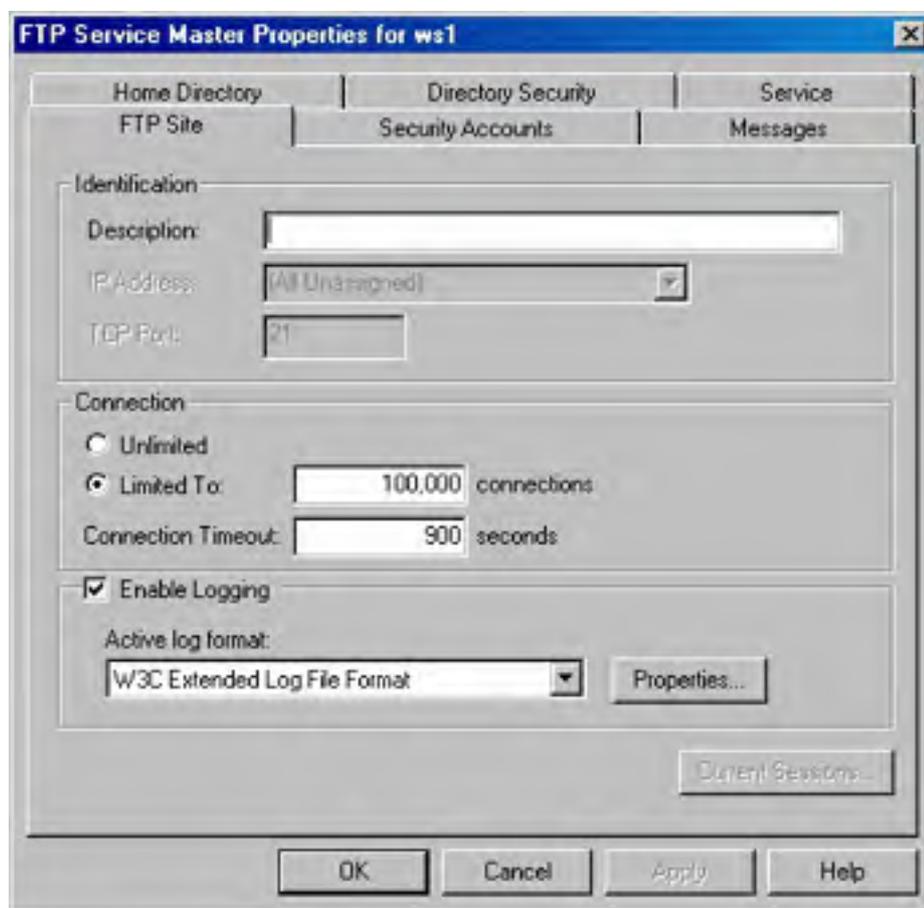

## Managing FTP Sites

The four levels of IIS administration that apply to the WWW Publishing Service also apply to the second core service of IIS, the FTP Publishing Service. Because administering servers, sites, directories, and files is similar between the two services, this section is condensed to avoid repetition.

### FTP Service Master Properties

In addition to the general server-level tasks of connecting to an IIS server to administer its services, backing up and restoring a server configuration, and throttling total bandwidth used by all IIS operations on the machine, IIS also lets you globally configure the master properties for all existing FTP sites on your server and for all new ones you might create in the future.

To configure the FTP service master properties for a particular server, simply select the node in the IIS console tree that represents the server, click the Action button on the toolbar, and choose Properties from the drop-down menu to open the Properties dialog box for that server. (See Figure 29-3 in the [Server-Level Administration](#) section earlier in this chapter. We'll continue to use server ws1 as an example.) From this dialog box, select FTP Service from the Master Properties section and click Edit to open the FTP Service Master Properties dialog box for server ws1 (Figure 29-17).

**Figure 29-17.** The FTP Service Master Properties dialog box for server ws1.

This Properties dialog box has six tabs used for configuring the default global settings for existing FTP sites. All new FTP sites you create on the machine inherit these settings. Note that some of the settings at this level are unavailable because they can't be applied to all FTP sites but only to specific FTP sites. For example, the *IP Address* field in the FTP Site tab can't be globally configured, as it is specific to each FTP site.

Of the six tabs in this dialog box, only the Service tab is unique to the server-level FTP properties. This Service tab performs a function similar to the Service tab of the WWW Service Master Properties dialog box: it allows you to specify a single FTP site on your IIS 5 machine that can be managed using the ISM included in IIS 3 on Windows NT. The other five tabs are common to site-level FTP properties and are discussed next.

## Configuring FTP Site Properties

The site-level properties for a particular FTP site are almost identical to those at the server level (Figure 29-17) except that the Service tab is absent. This section covers the various settings that you can configure using the Properties dialog box for a particular FTP site. Remember that site-level settings for a newly created FTP site are inherited from the server-level master properties previously specified, whereas modifying settings at the site level overrides similar settings configured at the server level. We'll use the properties of the Default FTP Site for this discussion.

### The FTP Site Tab

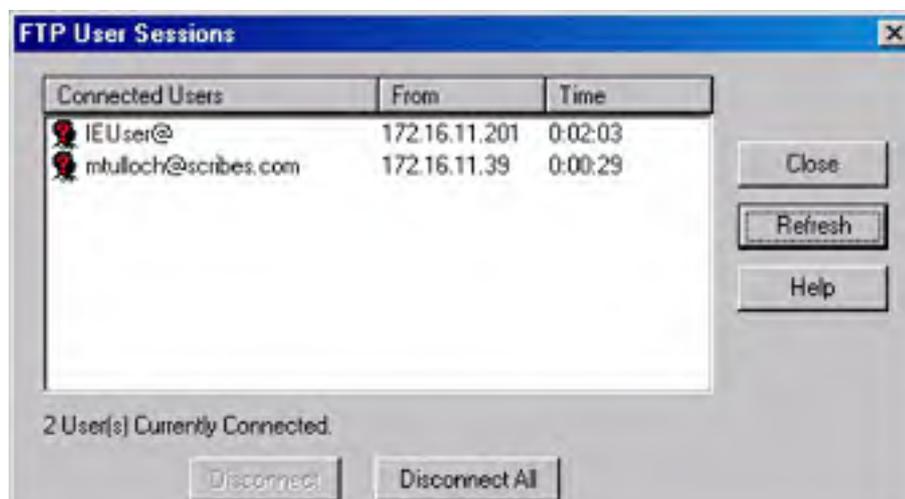

Like the Web site properties used in site-level administration, the FTP site properties allow you to specify FTP site identities, configure connections, and enable logging. The connections and logging settings work the same way as those for Web site properties, so we won't say anything more about them here. However, we'll look at identification and current sessions.

**Identification** Like Web sites, each FTP site hosted on an IIS machine must have a unique identity so FTP clients can connect to it to upload or download files. Unlike Web sites, however, FTP uses two (not three) parameters to define an FTP site: IP address and TCP port number.

The identity for an FTP site is specified in the FTP Site tab of the Properties dialog box for the particular FTP site under consideration. For FTP sites on the same machine to have unique identities, they must differ from each other in at least one of the two parameters. In other words, to host several different FTP sites on the same server, you could use one of the following methods:

- Configure multiple IP addresses on the server's network card and select a different IP address for each FTP site, leaving each site's TCP port set to 21 (the default TCP port for FTP). Clients can then connect to a specific site by using either the site's IP address or its associated fully qualified DNS name (if either a DNS server is available on the network or a local hosts file is configured on the client). This method is preferred for public FTP sites because it is the easiest way for users to connect.
- Configure only one IP address for the server's network card and use this IP address for every FTP site while assigning a different TCP port (above 1023) to each FTP site hosted on the machine. In this case, the user must know the TCP port of each site to connect to it. This method is sometimes used to hide private FTP sites from view (although FTP is inherently nonsecure anyway, as you shall soon see).

**Current Sessions** The Current Sessions button in the FTP Site tab opens the FTP User Sessions dialog box for that site, which displays all users who are currently connected to the site, the IP addresses of their clients (or of your proxy server if they're behind your firewall), and the time elapsed since they connected (Figure 29-18). You can select any user to disconnect him or her from your site, or you can click Disconnect All to terminate all sessions on your site.

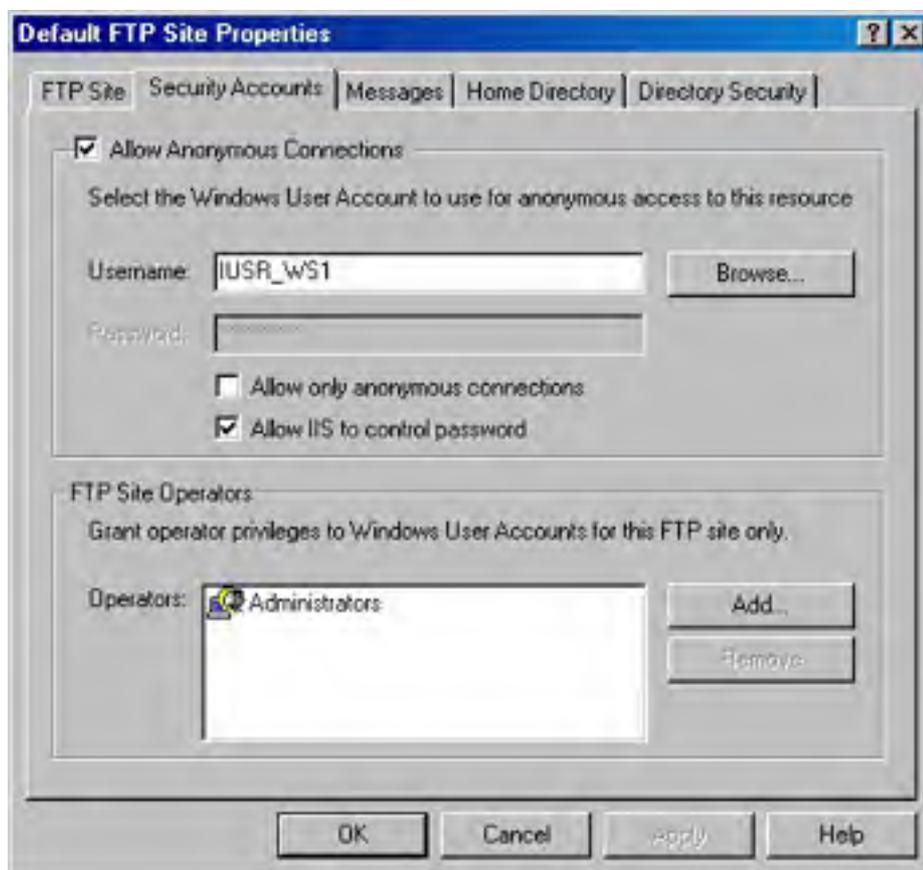

**Figure 29-18.** *Displaying the current connections to the Default FTP Site on server ws1.*

Figure 29-18 displays two anonymous users who are connected to the Default FTP Site, which is configured to allow anonymous access. The user IEUser@ accessed the site by opening the URL `ftp://ftp.scribes.com` in Internet Explorer 5, whereas the user `mtulloch@scribes.com` used the Windows command-line FTP utility and logged on with user name `anonymous` together with the voluntary (but optional) password equal to the user's e-mail address `mtulloch@scribes.com`. On the other hand, if users log on using basic authentication (described next), the FTP User Sessions dialog box shows their user names in the Connected Users column. (If they connect using Internet Explorer, this user name appears twice for some strange reason.)

## The Security Accounts Tab

The Security Accounts tab of an FTP site's Properties dialog box functions similarly to the Directory Security tab of a Web site's Properties dialog box. FTP site operators have limited administration rights on the site, similar to those granted to Web site operators discussed previously. However, authentication control is much simpler for the FTP service (Figure 29-19). Whereas the WWW service supports four levels of authentication (anonymous, basic, digest, and integrated) plus the option of enabling SSL for encrypted transmission, FTP supports only the anonymous access and the basic authentication methods.

**Figure 29-19.** *The Security Accounts tab for the Default FTP Site on server ws1.*

Because you already know about anonymous access and basic authentication, you just need to learn how to configure FTP authentication settings using the Security Accounts tab, which at first glance appears a bit confusing. Two check boxes account for this confusion:

- Allow Anonymous Connections
- Allow Only Anonymous Connections

Table 29-1 shows how combinations of selecting and clearing these two check boxes produce different combinations of anonymous access and basic authentication. If you enable anonymous access, IIS needs a user account to make this work. By default, the `IUSR_servername` account is

specified, but you can select another one if you like. (Make sure it has the right to log on locally to the server console, because this is necessary for basic authentication to work.) You can then either specify the password manually or allow IIS to synchronize the password with those set in Windows.

**Table 29-1.** Combinations of anonymous and basic authentication for FTP

Allow Anonymous Connections	Allow Only Anonymous Connections	Result
Yes	Yes	Only anonymous access is enabled.
Yes	No	Both anonymous access and basic authentication are enabled, with anonymous access being attempted first.
No	N/A	Only basic authentication is enabled.

If you must enable basic authentication on your FTP site, only users who have the right to log on locally to the IIS server hosting the FTP site will be able to be authenticated and connect to the site. Make sure you physically secure the server from misuse by these users if they are working in your organization.

### Real World

#### FTP Security

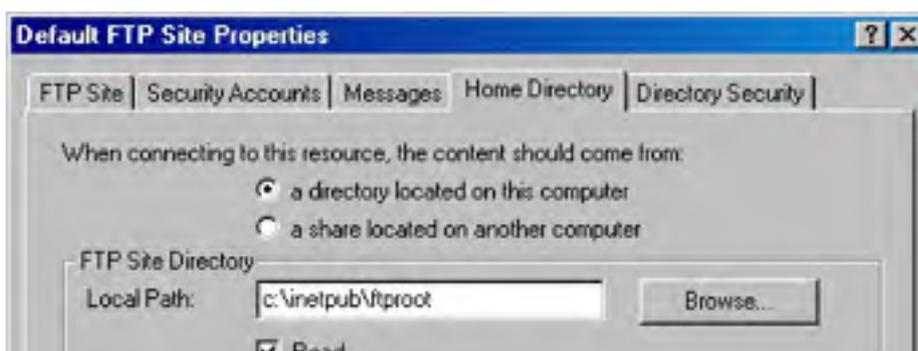

FTP is viewed as less secure than HTTP because FTP supports only anonymous access and basic authentication (that is, unencrypted passwords). For instance, if you're running an internal FTP site within a company and are using basic authentication, any person with a network sniffer could potentially obtain a trace of an FTP session and determine a user's password. Furthermore, if you connect to an FTP site using Internet Explorer and are authenticated using basic authentication (after entering your credentials into the Login As box), your user name appears in the URL as something like *ftp://mtulloch@ftp.scribes.com*. So if you leave your machine, lock your console or people will know who logged on to the FTP site.

## The Messages Tab

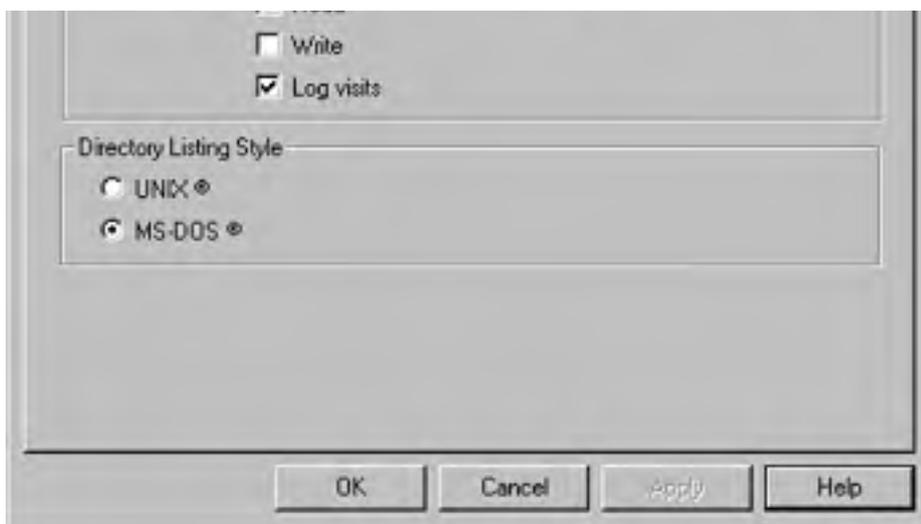

FTP sites typically have a welcome, exit, and maximum connections message that the server provides for users as appropriate. Specify the text of these messages in the Messages tab of an FTP site's Properties dialog box.

## The Home Directory Tab

FTP has two possible choices for the location of the home directory mapped to the virtual root of the site. One is a local directory on one of the server's disks; the other is a UNC path to a network share located on a file server somewhere else on the network. (Credentials must be supplied to access this share.) Specify either of these in the Home Directory tab shown in Figure 29-20. Note that FTP sites can't be redirected to a URL like Web sites can (as shown previously in Figure 29-10).

**Figure 29-20.** The Home Directory tab for the Default FTP Site on server ws1.

**Access Permissions** FTP permissions are simpler than WWW permissions:

- **Read** Selecting this check box allows users to read or download files stored in the home directory and allows users to list the contents of the directory.
- **Write** Selecting this check box allows users to upload files to the home directory.
- **Log Visits** Selecting this check box causes an entry to be added to the IIS log files whenever any file is downloaded from or uploaded to the home directory by a client. Note that Enable Logging must first be selected in the FTP Site tab before this feature works. Logging of the home directory is enabled by default.

**Directory Listing Style** When a Web browser like Microsoft Internet Explorer accesses an FTP site, provided that Read access is enabled for the home directory, the user is presented with a directory listing showing the contents of the directory. This directory listing can be presented in either the original FTP style (UNIX style) or in standard Windows style (MS-DOS style). The same information is presented either way; it's just displayed differently.

If you're hosting a public FTP site on the Internet, select UNIX style for maximum compatibility with users running older FTP client software. Some clients might be unable to interpret MS-DOS style correctly.

### The Directory Security Tab

Like Web sites, you can also control access to FTP sites according to the IP address or DNS domain name to which the remote user belongs (discussed for Web sites earlier in the chapter).

### Configuring FTP Directory Properties

In FTP directory-level administration (that is, in the administration of FTP virtual directories), Properties dialog boxes of virtual directories created within FTP sites have only the following two tabs:

- **Virtual Directory** You can configure the location of the content for the virtual directory and specify the access permissions.
- **Directory Security** You can specify IP address and domain name restrictions for the virtual directory.

Note that unlike Web sites, *physical* directories within an FTP site aren't displayed within the IIS console window. The FTP service in IIS requires no file-level administration because individual files within an FTP site aren't displayed in the console window either.

## Managing NNTP Virtual Servers

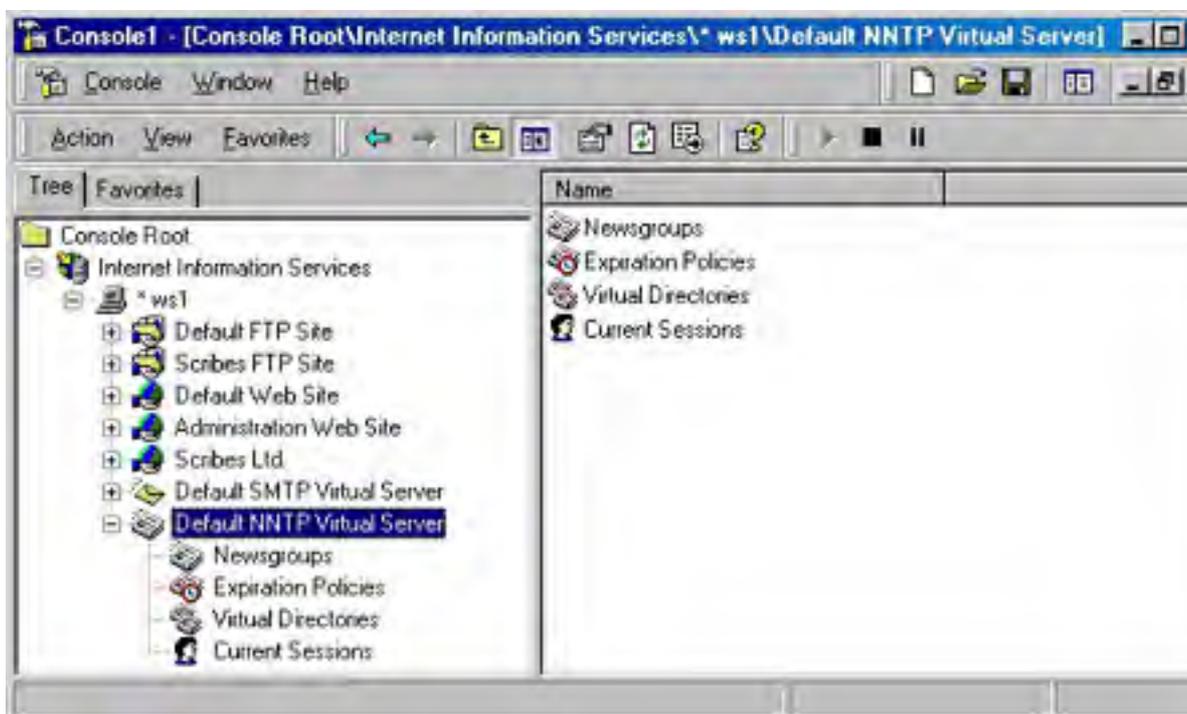

The third core IIS facility on Windows 2000 Server is the Network News Transfer Protocol Service (NNTP Service). NNTP is the application-layer protocol that underlies the worldwide USENET system of news servers on the Internet. IIS includes an NNTP Service that can be used to create news sites, which are also implemented as virtual servers like Web and FTP sites. Use Add/Remove Programs in Control Panel to install the NNTP Service subcomponent of IIS if you need to.

### What NNTP Service Does

NNTP Service on IIS fully supports both the client/server and server/server portions of NNTP and can be administered either through the IIS snap-in for the MMC or by a Web browser using NNTP Service Manager (HTML). Like other core IIS facilities, NNTP Service is fully integrated with Windows 2000 event and performance monitoring, and it integrates with the Indexing Service for full-text indexing of newsgroup content.

NNTP Service can be used to implement private news servers for hosting departmental discussion groups within your company or to implement public news servers that provide customer support resources to Internet users. It isn't designed to pull feeds from USENET hosts on the Internet, however. For that purpose, you should obtain Microsoft Exchange Server and implement the Internet News Service on it to give it NNTP capability. You can use Microsoft Outlook Express to connect to NNTP Service on an IIS machine to download a list of newsgroups, read existing messages, reply to messages, and post new messages.

When you install NNTP Service on IIS, it automatically creates the Default NNTP Virtual Server (Figure 29-21). We'll configure this virtual server in a moment, but first you should know that you can host multiple NNTP virtual servers on a single machine. In this way, several departments in your company can run separate news servers on a single IIS machine, just as they can run separate Web or FTP servers. We'll look at how to do this next and then consider other aspects of managing NNTP virtual servers. Notice that NNTP Service is managed with a combination of Properties dialog boxes and wizards, just like the other IIS core services.

**Figure 29-21.** The IIS console tree showing the Default NNTP Virtual Server on the IIS server ws1.

### NNTP Service Wizards

You can run the following wizards from the IIS console to configure and manage various aspects of NNTP virtual servers:

- New NNTP Virtual Server Wizard
- New Virtual Directory Wizard
- New Expiration Policy Wizard
- New Newsgroup Wizard

### New NNTP Virtual Server Wizard

To create a new NNTP virtual server, just select the server's node in the IIS console tree, click the Action button, point to New, and choose NNTP Virtual Server from the drop-down menu. This starts the New NNTP Virtual Server Wizard, which takes you through the following steps:

1. Specify a display name for the new NNTP virtual server that will be used in the IIS console tree.
2. Specify an IP address and port number for the server. (The standard TCP port for NNTP is 119.) The identity of the virtual server you are creating must be different from that of any existing virtual servers on the machine.
3. Specify locations for the internal server files and news content files. These can be local directories or network shares.
4. Click Finish, and a new NNTP virtual server is created on your IIS machine.

### New Virtual Directory Wizard

NNTP Service allows you to create virtual directories within your NNTP virtual server. You can use these virtual directories to store portions of the news server's content. To see how this works, follow this procedure to create a new virtual directory within the Default NNTP Virtual Server:

1. To start the wizard, select the Virtual Directories node under Default NNTP Virtual Server in the console tree, click the Action button, point to New, and choose Virtual Directory from the drop-down menu.
2. In the opening screen of the wizard (Figure 29-22), specify the newsgroup subtree whose content you want to store in the directory. For example, if you wanted to store messages for the newsgroups scribes.support.pc, scribes.support.mac, and scribes.support.unix, you could specify scribes.support in this text box. We'll actually do this now and create the three newsgroups later. Click Next.

**Figure 29-22.** Creating a new NNTP virtual directory within the Default NNTP Virtual Server on ws1.

3. Choose File System or Remote Share, and then click Next to specify a path to the local directory or network share where the content will be located. (If you choose a network share, you must enter appropriate credentials.) Choose File System and specify C:\Support as your path. Click Finish.
4. The Virtual Directories node under the Default NNTP Virtual Server node in the console tree now shows the new virtual directory listed there, along with its associated newsgroup subtree. You can double-click the new virtual directory to open a Properties dialog box where you can reconfigure its settings or configure additional settings.

## New Expiration Policy Wizard

In the New Expiration Policy Wizard, you can create an expiration policy that specifies how long articles remain in newsgroups before they expire (are deleted). Articles can expire if they surpass a specified age. Follow these steps to create an expiration policy for the scribes.support.\* newsgroups:

1. Start the New Expiration Policy Wizard.
2. Specify a descriptive name for the expiration policy, like *Expiration Policy for scribes.support.\* groups*. Click Next.
3. Specify that you want the policy to apply to only a selection of news-groups on the selected virtual server. Click Next.
4. Click Add, enter *scribes.support* as the pattern that groups need to match to have this expiration policy, and then click OK. You can add several patterns if you want, to apply your expiration policy to several disjointed newsgroup subtrees. Click Next.
5. Specify the time in hours that articles are allowed to remain in the group before expiring. (The default is 168 hours, or 7 days.) Click Finish.
6. Select the Expiration Policies node under the Default NNTP Virtual Server node in the console tree to see the new expiration policy displayed. You can double-click the expiration policy to open its Properties dialog box and reconfigure it manually if you want.

## New Newsgroup Wizard

To add a new newsgroup, select the Newsgroup node in the console tree, click the Action button, point to New, and choose Newsgroup from the drop-down menu. Specify a display name for the new newsgroup and click Next. Or you can provide a description and prettyname. Click Finish. It's that simple.

## Configuring the Default NNTP Virtual Server

To configure an NNTP virtual server, use the various tabs in its Properties dialog box. For simplicity, we'll continue to use the Default NNTP Virtual Server as our example. You'll notice some similarities between configuring NNTP virtual servers and Web and FTP sites discussed previously. Along the way we'll also create the three scribes.support.\* newsgroups mentioned earlier.

### The General Tab

Figure 29-23 shows the General tab of the Default NNTP Virtual Server Properties dialog box on the Windows 2000 server called ws1.scribes.com. In this tab, you can specify the following options:

- **Name** This is the friendly name of the NNTP virtual server in the console tree.
- **Path Header** Whatever you enter here appears in the Path line of the NNTP headers attached to messages posted to this virtual server. Typically, you might enter the fully qualified DNS name of the virtual server here, but this is optional.
- **IP Address** Like FTP sites discussed earlier in this chapter, NNTP virtual servers are uniquely identified by a combination of IP address and TCP port, and each NNTP virtual server hosted on the same IIS machine must differ in at least one of these parameters. Although you already know the advantages and disadvantages of the different ways of configuring this, note that the Advanced button allows you to configure additional identities (combinations of IP address, TCP port number, and SSL port number) for an NNTP virtual server, if you want to.

**Figure 29-23.** The General tab of the Properties dialog box for the Default NNTP Virtual Server.

Connections and logging in this tab are similar to that for Web and FTP sites discussed earlier in this chapter. You can enable logging here, but you can also enable or disable it on a directory-by-directory basis, just as you can with Web and FTP sites.

### The Settings Tab

The Settings tab contains a variety of settings related to how NNTP functions for the selected virtual server. Specifically, you can set the following options:

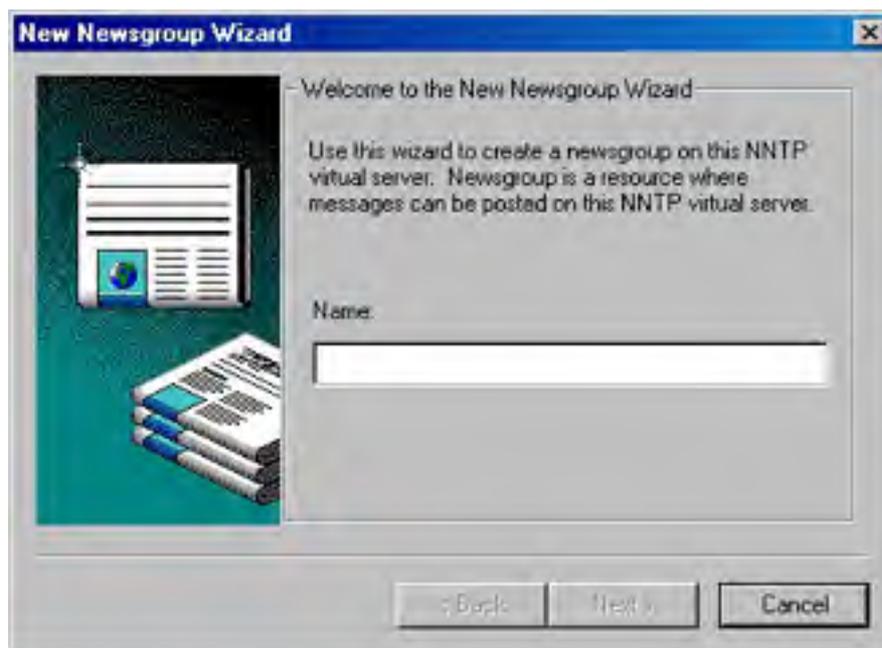

- Enable or disable posting to the virtual server by NNTP clients. For example, you might disable posting when you are performing maintenance on the server.
- Limit the maximum size of a message that can be posted. This is usually a good idea.
- Limit the maximum amount of data that can be posted by a user during a single connection. This is also a good idea.
- Allow other NNTP servers to pull newsfeeds from this virtual server. This option does not enable pulling from other IIS servers because the NNTP Service on IIS doesn't support this—rather, this option applies to USENET hosts and Exchange Servers running the Internet News Service.
- Allow newsfeeds to post articles to this NNTP virtual server.
- Allow control messages. This allows clients and servers to issue special commands to the virtual server for performing tasks like creating new newsgroups or deleting existing ones.
- Specify the DNS name of an SMTP mail server to be used for moderated newsgroups hosted on the virtual server.
- Specify the fully qualified DNS name to which the moderator belongs.

- Specify the e-mail address for the administrator of the virtual server so that this person can receive any error messages generated by the NNTP Service when messages posted to a moderated newsgroup can't be delivered to the specified SMTP mail server.

## Managing Newsgroups

To view the list of existing newsgroups on the virtual server, to modify the properties of a group, to create new groups, or to delete existing ones, use the NNTP server's Newsgroups node. Note that a number of default newsgroups already exist within the Default NNTP Virtual Server. Let's create the three newsgroups described earlier. Follow these steps to create the group `scribes.support.pc`:

1. Select the Newsgroups node, click the Action toolbar button, select New, and then select Newsgroup on the drop-down menu. This opens the New Newsgroup Wizard, shown in Figure 29-24.

**Figure 29-24.** The New Newsgroup Wizard.

2. Type `scribes.support.pc` for the name of the newsgroup. Click Next.
3. Enter a description, if you want.
4. Enter a newsgroup prettyname. (Some clients support this feature.)
5. Click Finish, and the new newsgroup should appear in the right pane of the console.

Repeat these steps to create the `scribes.support.mac` and `scribes.support.unix` groups. We'll test these groups in a moment.

If you have hundreds (or thousands) of newsgroups defined on your virtual server, you can use the Limit Enumeration option on the Newsgroups shortcut menu to locate newsgroups with properties you want to modify. In the Find Newsgroups dialog box, just specify a portion of the newsgroup name and the maximum number of results you want returned.

## The Security Tab

In the Security tab you can specify an NNTP operator who can perform limited administrative tasks on the virtual server, just as you can for Web and FTP sites discussed earlier.

## The Access Tab

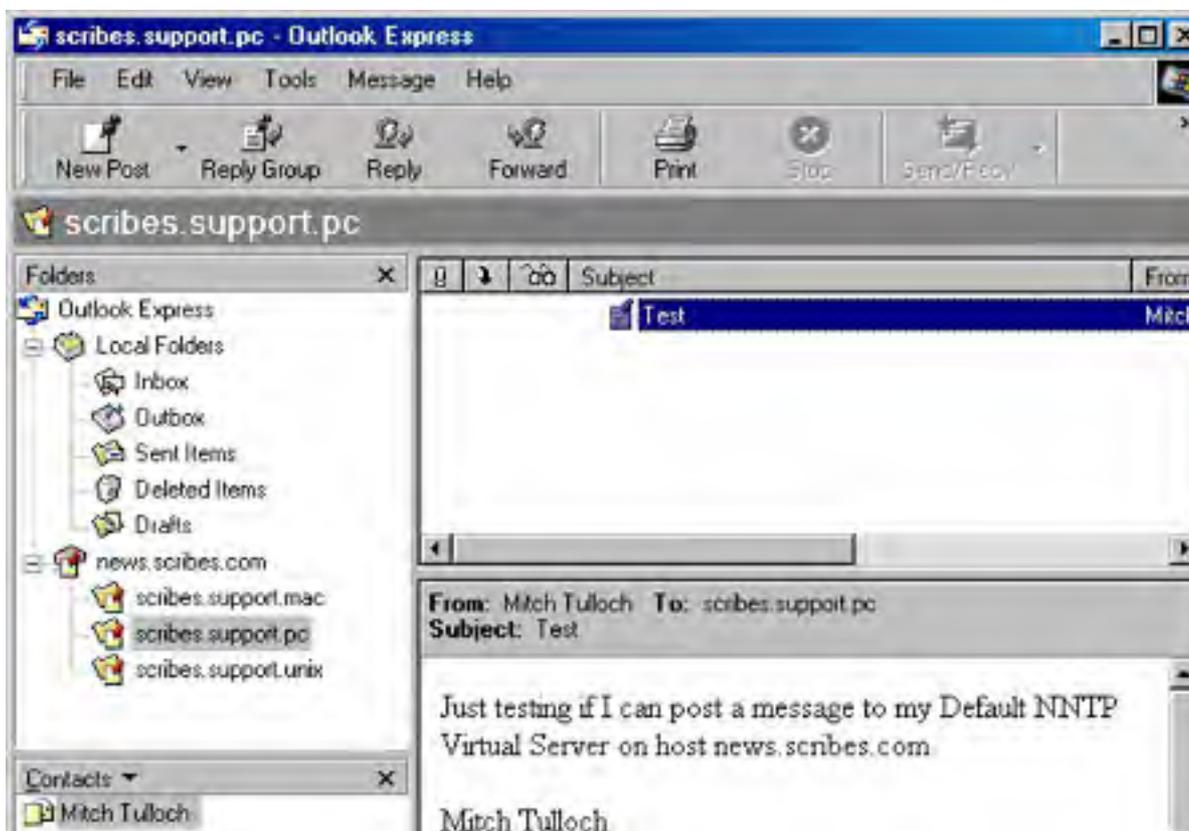

The Access tab allows you to specify which authentication methods can be used when users try to connect to the virtual server. Do this by clicking Authentication under Access Control, which opens the Authentication Methods dialog box. These methods are similar to those for Web sites as discussed earlier in this chapter, although the way this dialog box presents them is slightly different.

Connection Control is the same as IP Address And Domain Name Restrictions for Web and FTP sites, which were discussed earlier. Secure Communication is also similar. Click Certificate to start the somewhat misnamed Web Server Certificate Wizard described earlier in this chapter.

## Connecting to the Default NNTP Virtual Server

After you've configured your NNTP virtual server properties, you can test the virtual server by trying to access your newsgroups using an NNTP client like Outlook Express. Follow these steps:

1. Start Outlook Express and cancel out of the wizard that tries to help you configure an SMTP mail account (if this wizard appears).
2. Choose Accounts from the Tools menu to open the Internet Accounts dialog box.
3. Click Add and choose News to create a new NNTP account. Specify your name, e-mail address, and the fully qualified DNS name of the news server (or its IP address if you prefer). If the NNTP virtual server doesn't have anonymous access enabled, select the My News Server Requires Me To Log On check box and specify your credentials accordingly.
4. Click Next and then click Finish.
5. Close the Internet Accounts dialog box. You'll be prompted to download newsgroups from the news account you just added. Click Yes.
6. The Newsgroup Subscriptions dialog box appears, showing you all the newsgroups available on the NNTP virtual server you connected to and allowing you to subscribe to groups of your choice. Double-click a group to subscribe to it.
7. Click OK to return to the main Outlook Express window.
8. To test the newsgroups, simply browse through them on your virtual server, post messages, read messages, and so on (Figure 29-25).

**Figure 29-25.** Testing the new newsgroups by posting to them using Outlook Express.

## Displaying NNTP Sessions

After you make some test postings, switch to the IIS console on your IIS server and select the Current Sessions node under the Default NNTP Virtual Server node in the console tree. This displays information regarding the users who are currently logged on to the virtual server. You can select any user, click Action, and choose either to terminate that user's connection or terminate all connections to the NNTP virtual server.

## Rebuilding an NNTP Virtual Server

You can perform one important maintenance task on an NNTP virtual server: rebuilding the indexes and hash tables that the virtual server employs to keep track of the articles that have been posted to it. Circumstances that warrant rebuilding the server include manually deleting files from the NNTP directories where newsgroup content is stored, experiencing a disk failure and losing some newsgroup content, or having trouble accessing articles.

To rebuild the Default NNTP Virtual Server, for example, follow these steps:

1. To stop the Default NNTP Virtual Server, select the Virtual Server in the console tree and then click the Stop button on the console toolbar (or click the Action button or right-click the Virtual Server node and then choose Stop from the shortcut menu).
2. With the Default NNTP Virtual Server node still selected, click Action, point to All Tasks, and choose Rebuild Server from the drop-down menu.
3. Select a standard or thorough rebuild (thorough is slower), and click Start.

## Managing SMTP Virtual Servers

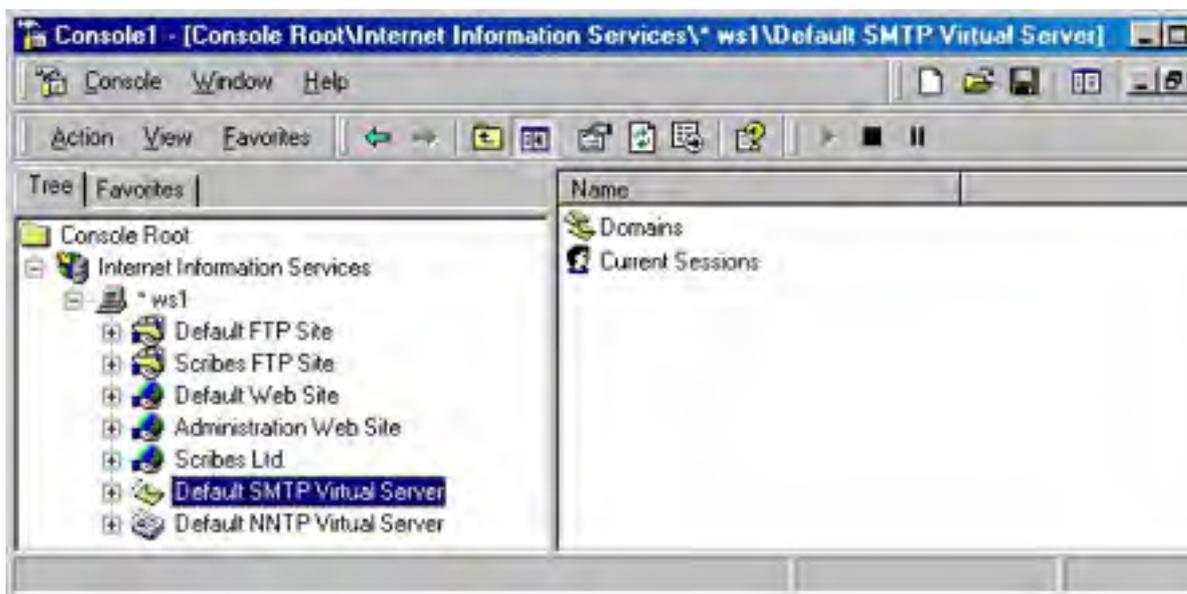

The fourth and last core service that is included as part of IIS on Windows 2000 Server is the Simple Mail Transfer Protocol Service (SMTP Service). SMTP is the application-layer protocol that underlies the worldwide system of SMTP hosts (mail servers) on the Internet. If it's not already installed on IIS, use Add/Remove Programs in Control Panel to do so.

### What SMTP Service Does

You can administer SMTP Service on IIS 5 either by using the IIS snap-in for the MMC or a Web browser using SMTP Service Manager (HTML). Like other core IIS facilities, it is fully integrated with Windows 2000 event and performance monitoring. IIS includes SMTP Service primarily for use by mail-enabled Web applications. A simple example is an HTML form that a user fills out and submits, after which the form handler (the script or program that takes the information entered by the client and actually does something with it) composes an e-mail message and sends it using SMTP Service.

Note that SMTP Service included with IIS isn't intended to replace a company mail server—IIS has no facility for creating individual user mailboxes. SMTP Service is intended mainly for mail forwarding by mail-enabled Web applications, although it can both send and receive mail and relay mail from other SMTP hosts. If you need a full-featured mail server for your company, try Exchange Server 5.5 and implement the Internet Mail Service on it to give it SMTP capability.

When you install SMTP Service on IIS, it automatically creates a Default SMTP Virtual Server, as shown in Figure 29-26. You can host multiple SMTP virtual servers on a single machine, but this is rarely needed because the Default SMTP Virtual Server can be configured to forward mail for multiple SMTP domains. Like other IIS core services, SMTP Service is managed by a combination of Properties dialog boxes and wizards.

**Figure 29-26.** The Default SMTP Virtual Server shown in the IIS console window.

### SMTP Directories

Important to the operation of an SMTP virtual server are a series of directories that are used for processing mail. For the Default SMTP Virtual Server, these directories are all located within the \Inetpub\Mailroot directory on the server. Some of the more important directories include the following:

- **Drop** If SMTP Service receives incoming messages that are addressed to recipients belonging to SMTP domains managed by the SMTP virtual server, they are dropped here. Web applications can then be written to collect incoming mail delivered to this directory and process it accordingly.
- **Pickup** If SMTP Service picks up outgoing messages, they are placed in the Pickup folder

and delivered to their destination SMTP host once a connection is made with that host (or with an intermediate host that can relay mail).

- **Queue** If a message that a Web application places in the Pickup folder can't be delivered immediately (for example, if the remote SMTP host is temporarily down), it is moved to the Queue folder to await further delivery attempts.
- **Badmail** If message delivery repeatedly fails, outgoing mail is classed as undeliverable, and if it can't be returned to the sender, it winds up here.

## Configuring the Default SMTP Virtual Server

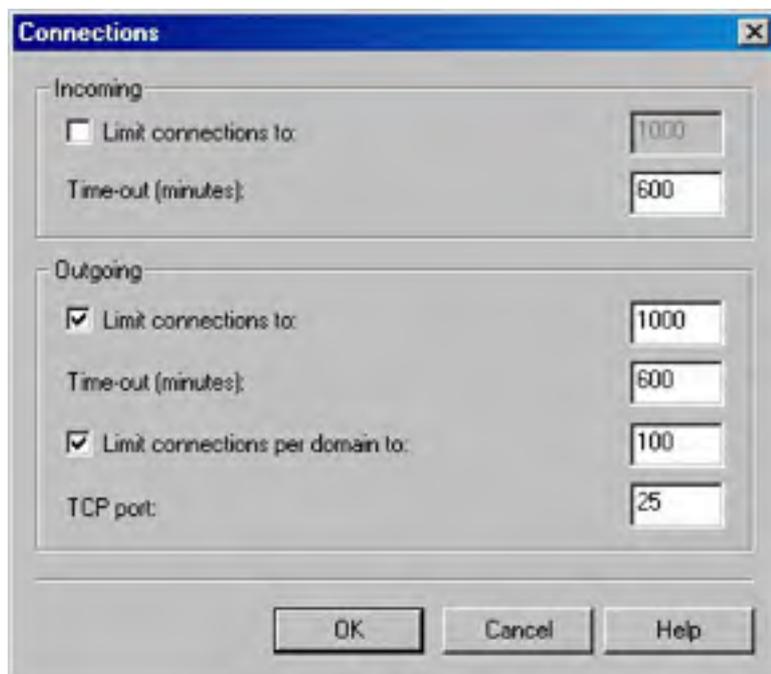

To configure an SMTP virtual server, use the various tabs in its Properties dialog box. For this example, we'll use the Default SMTP Virtual Server for simplicity. Configuring an SMTP virtual server is similar to configuring Web and FTP sites and NNTP virtual servers (all discussed previously).

### The General Tab

The virtual server identity is configured in the General tab of the Properties dialog box for the virtual server. IIS logging is implemented the same as for the other IIS core services. Note, however, that logging is disabled by default.

**Identification** An SMTP virtual server has a two-part identity similar to that of an NNTP virtual server. The two parameters that uniquely specify an SMTP virtual server are IP address and TCP port number. (The default TCP port number is 25.) By clicking Advanced in this tab, you can assign multiple identities (IP address and TCP port number) to your server, but each identity must differ by at least one of these parameters. The usual procedure is to leave the TCP port set to 25 and use one IP address for the virtual server, with a mapping from this address to a fully qualified DNS name in a DNS server or Hosts file.

**Connections** Clicking Connection in the Connection section of the General tab opens the Connections dialog box (Figure 29-27). Here you configure connection limits separately for incoming and outgoing messages. You can either specify the number of connections allowed numerically or set them as unlimited by clearing the check boxes. You can also set a timeout value for outgoing connection attempts. You can also limit connections on a per-domain basis if multiple SMTP domains are configured for the virtual server. Note that you can specify the outgoing TCP port here, whereas you specify the incoming TCP port as part of the virtual server's identity settings. (See the previous section.)

**Figure 29-27.** Configuring connection settings for the Default SMTP Virtual Server.

**IIS Logging** IIS logging is implemented the same way as it is for the other IIS core services. Note, however, that logging is disabled by default.

## The Access Tab

In the Access tab, you can choose the type of access and control you want.

**Anonymous Access and Authentication Control** SMTP Service supports anonymous access, basic authentication, and Windows Security Package (Windows integrated security) for inbound connection attempts. Basic authentication security uses a user name and password, whereas Windows Security Package includes the Windows 2000 domain name as well. Clicking Authentication in the Access tab opens the Authentication dialog box, where you configure these settings. Note that by default an SMTP virtual server is configured to try to authenticate inbound connection attempts using all three authentication methods, if necessary.

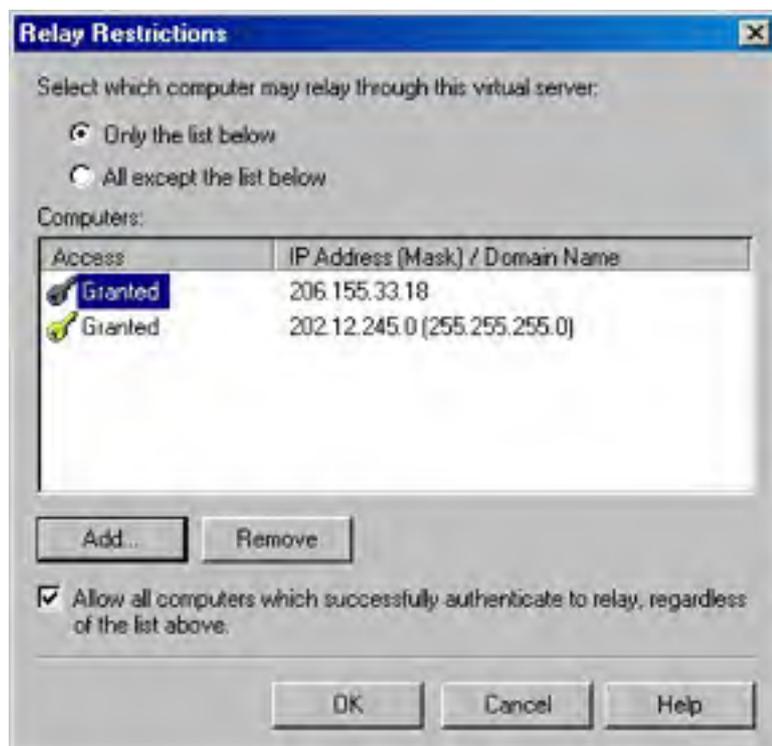

The Transport Layer Security (TLS) option is essentially a variant of SSL encryption, and you can enable it here for inbound connection attempts. You must first obtain a server certificate from a CA and install it on the SMTP virtual server before TLS can be properly enabled. (See the next section.) For more information on IIS authentication methods, see the earlier coverage of Web sites, FTP sites, and NNTP virtual servers, all in this chapter.

The settings configured here specify how your SMTP virtual server authenticates remote SMTP hosts that are trying to connect to it to deliver mail—that is, for inbound connection attempts. To specify authentication methods for outbound connection attempts, select Outbound Security in the Delivery tab.

**Secure Communications** As expected, if you click Certificate, the Web Server Certificate Wizard (still a misnomer) starts. Click Communication to require that access take place on a secure channel, once the certificate has been installed on the virtual server. If you choose Require Select Channel, you must also enable TLS in the Authentication dialog box. Requesting, obtaining, and installing server certificates is discussed earlier in this chapter.

**Connection Control** IP address and domain name restrictions function in the same way for SMTP Service as they do for the other three IIS core services.

**Relay Restrictions** Click Relay in the Relay Restrictions field in the Access tab to open the Relay Restrictions dialog box (Figure 29-28). This setting is important because allowing untrusted SMTP hosts to relay mail through your SMTP virtual server is an invitation for sending spam. You should generally deny relay privileges to all hosts and grant them to only known hosts that you trust or those that can properly authenticate with your server.

**Figure 29-28.** Configuring relay restrictions for the Default SMTP Virtual Server.

## The Messages Tab

You can use the Messages tab to limit messages in three ways:

- Limit the maximum message and session sizes in kilobytes for this virtual server. (Session size refers to all the messages delivered by a single SMTP connection.)
- Limit the maximum number of outbound messages that can be sent in one connection. If more messages need to be sent, additional connections will be opened between the hosts.
- Limit the maximum number of recipients for a message.

In addition, you can change the directory where nondelivery reports (NDRs) are sent and also send copies of NDRs to an e-mail address that you specify.

Make sure the maximum session size is greater than the maximum message size. Don't choose a maximum session size that's too low, or a remote SMTP host might continually resubmit a message for delivery. On the other hand, if you regularly send a lot of messages to a few domains, set the maximum number of outbound messages per connection low enough so that SMTP Service opens multiple connections to the remote host, resulting in faster and more efficient transfer of messages.

## The Delivery Tab

The Delivery tab allows you to specify the following different settings related to mail delivery:

- **Outbound** Allows you to specify how your virtual server responds when it tries to connect to a remote SMTP host to deliver mail but can't connect. For outbound mail, you can specify a series of retry intervals, a delay notification value, and an expiration timeout value.
- **Local** For local delivery, you can specify only delay notification and expiration timeout values.
- **Outbound Security** Allows you to specify the authentication method (No Authentication, Basic Authentication, or Windows Security Package, any of which can run with or without TLS) when attempting an outbound connection with a remote SMTP host. If you specify either form of authenticated access, you need to specify credentials as well. Note that you can configure only one outbound authentication method for an SMTP virtual server, and anonymous access is selected by default because this is most commonly used on the Internet.
- **Advanced** Clicking this button opens the Advanced Delivery dialog box, in which you can configure the following settings:
  - **Maximum Hop Count** Allows you to specify the maximum number of hops between SMTP hosts that is allowed before the message is determined to be undeliverable. The value you specify here is included in the header fields of each message sent. Be sure to specify a value here to prevent messages from endlessly looping when they can't be delivered directly to the remote host.
  - **Masquerade Domain** Allows you to specify the DNS domain name, which replaces the local domain name in the Mail From header field of each message sent. This feature is optional.
  - **Fully Qualified Domain Name** Allows you to specify the full DNS name of the SMTP virtual server. The value displayed here is the one found in the Network Identification tab of the Control Panel's System Properties dialog box, but you can change this if your server has multiple roles and DNS names.
  - **Smart Host** Allows you to route all outgoing messages to a specific SMTP host instead of trying to connect to the host responsible for the recipient's DNS domain. You can enter either a fully qualified domain name or an IP address. (Place square brackets around the IP address if you use one.) This feature is optional.
  - **Attempt Direct Delivery Before Sending To Smart Host** This option can be enabled only when a smart host has been specified. Its use is self-explanatory.

- **Perform Reverse DNS Lookup On Incoming Messages** Should be left disabled because it causes a significant hit on server performance.

## The LDAP Routing Tab

If you want your SMTP virtual server to be able to access an LDAP-compliant directory service to obtain information like the addresses of senders and recipients, you can enable this feature and specify the name, schema type, binding type, account, password, and naming context for connecting to the directory server. If you enable LDAP Routing, the default entries in the fields allow the SMTP virtual server to connect to and use Windows 2000 Active Directory. Supported directory services include the following:

- Microsoft Exchange Server directory
- Microsoft Windows 2000 Active Directory
- Microsoft Site Server 3 Membership Directory
- Microsoft Commercial Internet System 2 LDAP service
- Custom directory service, such as an Internet service like Four11 or Bigfoot

## The Security Tab

SMTP operators have limited administration privileges for the virtual server, similar to the way operators function in Web sites, FTP sites, and NNTP virtual servers.

## SMTP Domains

Each SMTP virtual server that is created manages at least one SMTP domain. This domain is specified automatically as the default local domain, and you can view it by selecting the Domains node under the SMTP virtual server node in the console tree. This is the DNS domain that is being serviced by the virtual server, and any incoming messages addressed to recipients within this domain are either dropped in the Drop folder or returned to the sender with an NDR.

You can have only one default local domain on the virtual server, and this domain is stamped on the message headers of all outgoing messages. However, you can create additional alias domains so that your virtual server can manage more than one SMTP domain. Alias domains use the same settings as the default domain and deliver incoming messages to the same Drop folder.

You can also create remote domains and specify delivery requirements for each one differently, which is useful if some remote SMTP hosts that you need to connect to use TLS but others don't. Global TLS configuration isn't enough in this case. In addition, for remote domains you can specify a predefined delivery route and even use wildcards to include subdomains. Use remote domains for connecting to remote SMTP hosts to which you frequently need to send mail.

Like NNTP Service, an SMTP virtual server node has a Current Sessions node under it in the console tree that you can use to view current connections to the server and terminate any or all of those connections.

## The New Domain Wizard

Use the New Domain Wizard to create either alias domains or remote domains. We'll only look at how to create alias domains here. (See the online documentation for information about creating remote domains.) To create an alias domain for the Default SMTP Virtual Server, follow these steps:

1. Select the virtual server node in the console tree, click the Action button, point to New, and choose Domain from the drop-down menu. This starts the New SMTP Domain Wizard.
2. Select the Alias domain type button, which creates an alias domain for the default local domain. Click Next.
3. Specify the DNS name for the new alias domain, netsolvers.com. Click Finish.

4. View the domains for the Default SMTP Virtual Server by selecting the Domains node in the console tree. Any incoming messages that are addressed to recipients in the netsolvers.com domain are dropped in the Drop folder and stamped with the default domain name, scribes.com.

By opening the Properties dialog box for the default local domain, you can change the location of the folder where mail is dropped from Mailroot\Drop to some other local folder on your server. Alias domains always use the same Drop folder as the default local domain, however.

## Remote Administration

Our final topic for this chapter is using a standard Web browser like Microsoft Internet Explorer for remote administration of IIS sites, servers, and services. Until now we've used only the IIS console for IIS administration. However, IIS requires a remote procedure call (RPC)-based connection and is thus intended primarily for administration on the internal network of a company. By using ISM (HTML), however, administrators can manage most (but not all) aspects of IIS from remote locations, even over a nonsecure connection on the Internet and through a proxy server or firewall (if configured properly). This section looks briefly at ISM (HTML) and how to use it.

Using a Web browser to administer IIS is considerably less secure than using either the IIS console or Terminal Services over an RPC-based connection, so it's best to disable the Web browser capability. If you want to perform remote administration over the Internet, consider establishing a VPN connection to your network and then using the IIS console or Terminal Services.

## The Administration Web Site

ISM (HTML) is an optional component of IIS that is installed by default when you install Windows 2000 Server. (It's *disabled* by default when using the IIS Lockdown tool to secure IIS, as discussed in [Chapter 28](#).) Once this component is installed, a new Web site appears in the console tree of the IIS console window. This new Web site is called the Administration Web Site and is basically an ASP application that allows administrators to manage IIS using any Web browser that supports JavaScript.

## Enabling Remote Administration

To be able to use ISM (HTML), administrators need only to be able to connect to the Administration Web Site. To make this possible, you need to perform this procedure first:

1. Open the Properties dialog box for the Administration Web Site in the IIS console.
2. In the Web Site tab, find the TCP port number assigned to this site and write it down. (A random port number between 2000 and 9999 is assigned to the site during installation of the component, and you need to know this number to be able to connect to the site using a Web browser.)
3. Click the Directory Security tab and open the IP Address And Domain Name Restrictions dialog box. By default, only the local host computer (127.0.0.1) is allowed access to the Administration Web Site; all other IP addresses are denied.
4. Add to the Granted list the IP address of any machines from which you want to be able to remotely administer the server. (Remote clients need to have static IP addresses.)
5. Apply the changes by closing the Properties dialog box for the Administration Web Site. You're ready to go.

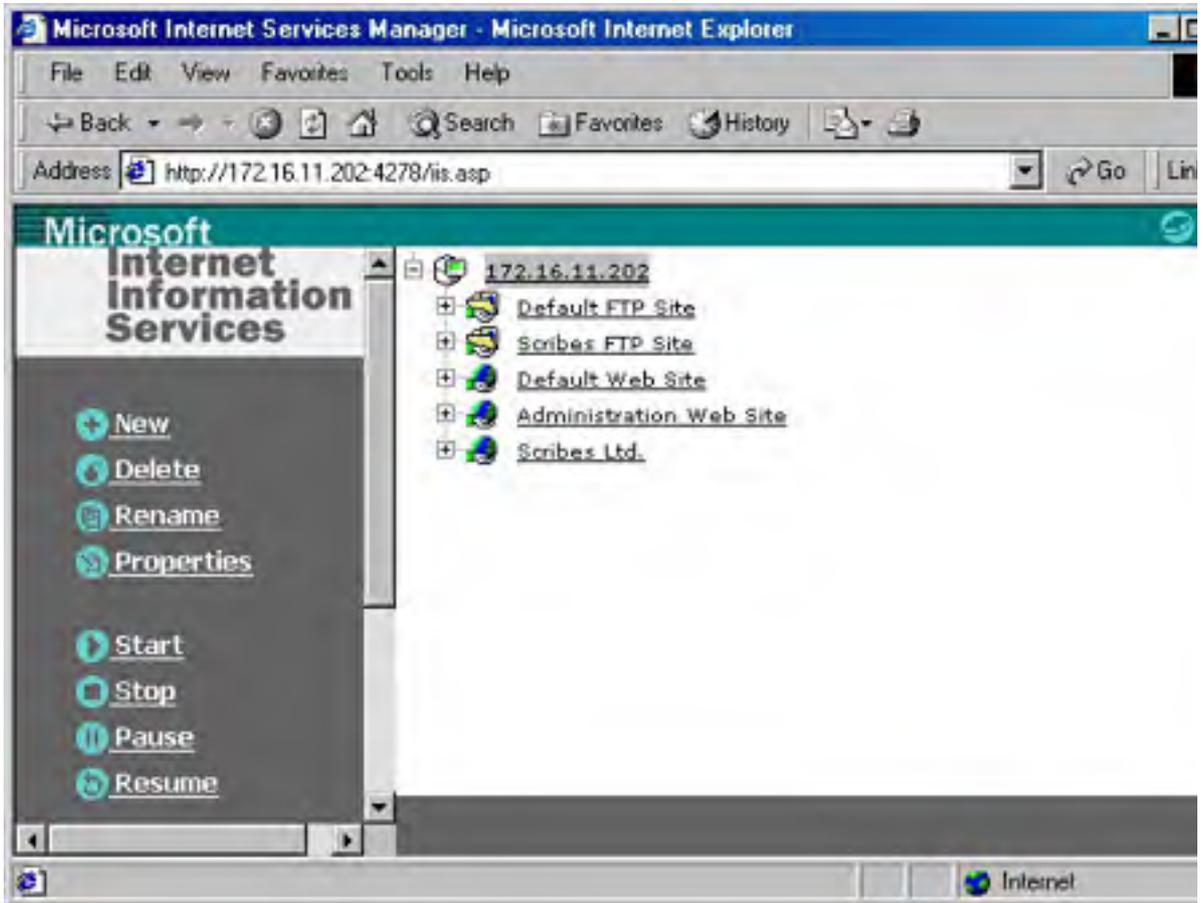

You won't be able to remotely administer IIS using the Administration Web Site if you let the IIS Lockdown tool remove the Administration Web Site. Use the IIS console or Terminal Services instead of the Administration Web Site when security is important.

## Testing Remote Administration

To test your configuration of the Administration Web Site, start Internet Explorer on the machine whose IP address you have granted access and open the URL `http://Server_Name:Admin_Port`, where *Server\_Name* is the IP address or DNS name of the IIS server, and *Admin\_Port* is the TCP port number you noted for remote administration.

A dialog box appears requesting your credentials (user name, password, and Windows 2000 domain), after which you are informed that you are using a nonsecure connection for performing remote administration. (You can configure SSL on the Administration Web Site just as on any other Web site if you prefer more security.)

At this point (if you've done everything correctly), ISM (HTML) should be functional and you should be connected to the Administration Web Site with your browser (Figure 29-29). You can perform most administration tasks using ISM (HTML), but not all. For example, you can't configure certificate mapping using ISM (HTML) because to do so requires coordination with other Windows 2000 services that aren't accessible from a Web browser.

**Figure 29-29.** The opening page of ISM (HTML) as seen in Internet Explorer 5.

## **Summary**

This chapter demonstrated the common administration tasks of configuring the settings of the four IIS core services: WWW, FTP, NNTP, and SMTP. You can configure these services at up to four different levels: server, site, directory, and file. And you configure them using a combination of Properties dialog boxes and wizards. The next chapter addresses Microsoft Internet Explorer and its role in the enterprise.

# Chapter 30

## Internet Explorer Administration

Microsoft Internet Explorer 5 consists of a suite of Internet tools that includes the Microsoft Internet Explorer 5 Web browser, Microsoft Outlook Express mail and news client, Microsoft NetMeeting and Microsoft Chat collaboration tools, and a variety of other components and supporting files. Using tools like the Microsoft Connection Manager Components (included with Windows 2000 Server) and the Microsoft Internet Explorer Administration Kit (available separately from Microsoft), corporate network administrators can easily deploy and manage Internet Explorer 5 and its components onto 32-bit, 16-bit, and UNIX platform client desktops.

This chapter focuses on the deployment and administration of Internet Explorer 5 and client connections for users of the following operating systems: Microsoft Windows NT 4, Windows 98, Windows 95, Windows 3.x, Windows NT 3.51, and UNIX. The Internet Explorer 5.01 Administration Kit shouldn't be used to deploy Internet Explorer to Windows 2000 systems (they already have Internet Explorer 5.01) or Windows XP systems (they already have Internet Explorer 6). To customize Internet Explorer for Windows 2000 and Windows XP Professional users, use Group Policy, as described in [Chapter 9](#). To update Windows 2000 and Windows XP Professional users to a newer version of Internet Explorer, use Group Policy's Software Installation and Maintenance feature, as discussed in [Chapter 25](#).

Service Pack 3 for Windows 2000 Server updates Internet Explorer 5 to Internet Explorer 5.01. In this chapter, references to Internet Explorer 5 include 5.01. To download later versions of Internet Explorer, visit <http://www.microsoft.com/windows/ie>. To download newer versions of the Internet Explorer Administration Kit, visit <http://www.microsoft.com/windows/ieak>. For information about using Internet Explorer 5 from a user's perspective, consult one of the books from Microsoft Press, such as *Microsoft Internet Explorer 5 Step by Step* by ActiveEducation (1999).

## Internet Explorer Administration Kit

Let's begin by considering how you can deploy and install Internet Explorer 5 and associated components in your enterprise. (Managing client connections is covered later in this chapter.) The installation of Internet Explorer 5 isn't an issue if your desktop machines all have Microsoft Windows 2000 Professional installed on them, because Internet Explorer 5 is included with the Windows 2000 Professional operating system, but configuring, managing, and updating these machines is an important aspect of network administration in a Microsoft Windows-based network.

Fortunately, Microsoft provides a set of tools—called the Internet Explorer Administration Kit (IEAK)—that makes it easy to deploy, install, customize, and manage Internet Explorer 5 on the desktop. The IEAK contains tools that can be used to customize the configuration of Internet Explorer 5 to match your organization's needs. For example, administrators can specify a home page, a Favorites list, a Links bar, and so on. This customization can be done prior to installing Internet Explorer 5 on desktop machines, and the Setup program that installs it can itself be configured to require minimal user intervention during installation.

In addition, administrators can prevent users from modifying specified configuration settings such as security and connection settings. This reduces the support costs of maintaining and troubleshooting Internet Explorer 5 deployments and facilitates adherence to corporate standards and policies with regard to Internet access. The tools and programs that make up the IEAK include the following:

- **Internet Explorer Customization Wizard** This wizard provides administrators with an easy way of configuring and building customized installation packages for Internet Explorer 5 and its associated components. Administrators can use the wizard to create special packages for mobile users with limited hard disk space on their machines; create packages that can be installed from network shares, CD-ROMs, or over the Internet; create packages with different security settings for different groups of users; and so on.
- **IEAK Profile Manager** This tool can be used by administrators to manage users' settings automatically after Internet Explorer 5 has been installed on their machines.
- **IEAK Toolkit** This is a miscellaneous collection of programs and files that helps administrators configure and manage various aspects of Internet Explorer 5 and its associated components. The Toolkit contents are located in the Toolkit folder of the IEAK program folder.

The IEAK is designed to be used by corporate network administrators, Internet service providers, and Internet content providers. This chapter focuses on its use within the enterprise network.

Another component of the IEAK is the Connection Manager Administration Kit (CMAK). This kit provides administrators with an easy way of configuring and building customized Microsoft Connection Manager dialers that can be installed on users' machines to configure their Internet connection. Windows 2000 Server includes a newer version of this component than the one included with IEAK 5; it can be used to create customized Connection Manager service profiles for client machines running Windows 2000 Professional. The version of CMAC included with the IEAK can create service profiles only for earlier versions of Microsoft Windows. The CMAC for Windows 2000 is discussed later in this chapter.

### Obtaining the IEAK

The IEAK is included in the *Microsoft Internet Explorer 5 Resource Kit*, available from Microsoft Press. You can also download the IEAK for Internet Explorer 5.01 from Microsoft's IEAK Web site at <http://www.microsoft.com/windows/ieak>.

However you obtain the IEAK, you need to go to Microsoft's IEAK Web site afterward and register your copy to obtain the necessary customization code to run it. This involves creating a personal profile for yourself and choosing a licensing agreement. (You must specify whether you will be using the IEAK to distribute Internet Explorer 5 to either corporate intranet users or external Internet users.) Once you've completed the profile and accepted the agreement, the customization code is e-mailed to you immediately.

### Installing the IEAK

Installing the IEAK is straightforward and is done from the main menu of the Microsoft Internet Explorer Administration Kit 5 CD (or the CD that accompanies the *Microsoft Internet Explorer 5 Resource Kit*). By default, the application is installed in the folder C:\Program Files\Ieak.

## Planning Your Internet Explorer 5 Deployment

The IEAK gives administrators a great deal of control over most aspects of Internet Explorer 5 and its associated components, including the ability to lock down program settings to prevent users from changing them. Before actually creating the installation packages, you need to carefully plan how you want to customize them. In doing so, ask yourself questions like these:

- Which version of Internet Explorer (5.01, 5.5, 6, or later) should you deploy to which users? (Windows 2000 users already have 5.01 and Windows XP users already have 6).
- Which groups of users need their own specially tailored Internet Explorer 5 installation packages?
- What platforms (32-bit Windows, 16-bit Windows, UNIX) will you need to create packages for?
- What Internet Explorer 5 components will each group of users need?
- What settings need to be preconfigured for users?
- Which settings should users be able to modify and which should be controlled by administrators?
- What media (CD-ROM, floppy disks, network share, Web directory) will be used for storing your installation packages?
- What third-party software do you want to include in the installation packages?
- What additional desktop and user settings do you want to configure?

If you use the Automatic Version Synchronization feature of the Internet Explorer Administration Kit, you'll be able to easily deploy Internet Explorer 5.01 with the latest service pack already applied. Windows 2000 users can obtain the latest Internet Explorer service pack from Windows Update. Windows 2000 service packs also update Internet Explorer to the latest service pack level; for example, installing Windows 2000 Service Pack 3 automatically updates Internet Explorer 5 to 5.01.

In addition, you need to think about these questions:

- What machine will you use for building installation packages? This machine must be running a 32-bit Windows operating system, have Internet Explorer 5 installed, and have sufficient hard disk space to store the packages you create.
- Have you created any custom bitmaps, Favorites lists, digital certificates, or other items required for creating installation packages? You can import Internet Explorer 5 settings from a machine that is already appropriately configured.
- What connection profile will you use? Have you already established one, or will you need to create a new one as part of the process of creating an installation package?

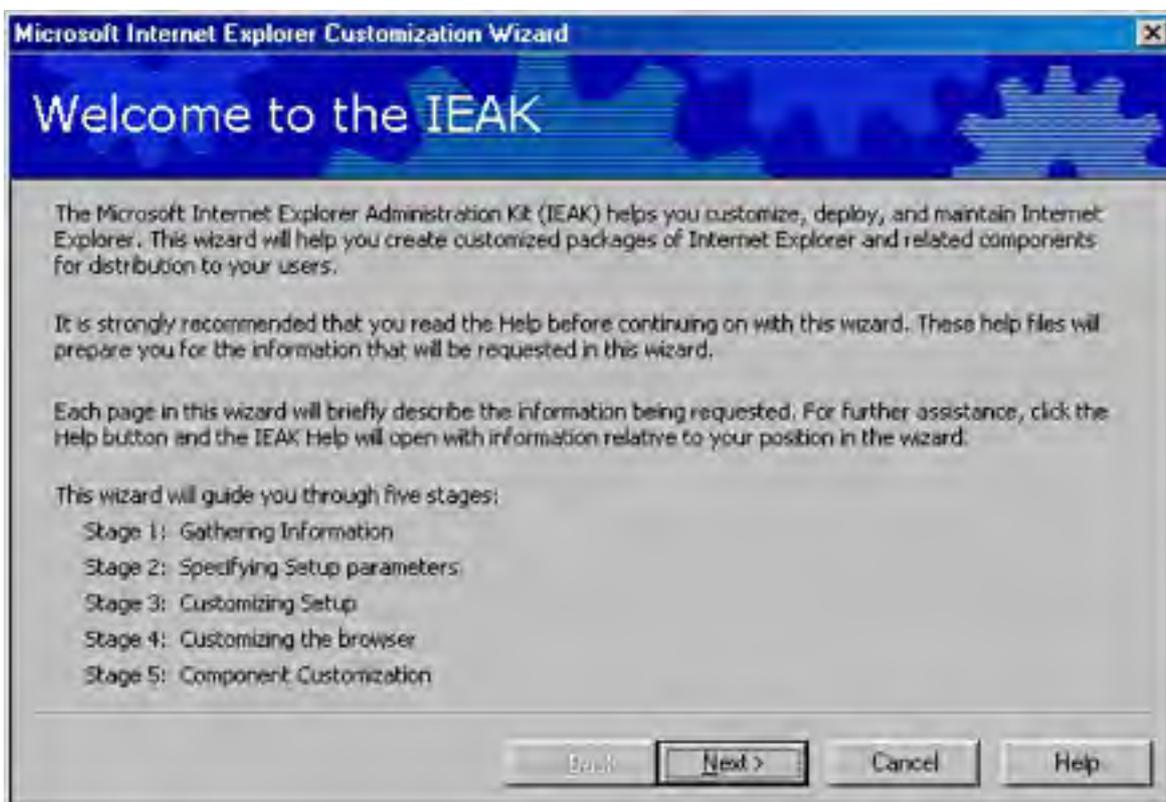

## Creating an Installation Package

The Microsoft Internet Explorer Customization Wizard is used to create custom Windows Update Setup packages for installing Internet Explorer 5 and its associated components. These packages can then be distributed to users on CD-ROMs or floppy disks, as e-mail attachments, or as downloads available from a shared folder on the network or from a Web page. The wizard also lets you create different packages for different groups of users. Packages can be created either from scratch or with settings imported from an existing Internet settings (.INS) file (also called an IEAK profile) on a machine that is already configured. An IEAK installation package contains the following:

- The Internet Explorer 5 Setup file (Ie5Setup.exe) and its associated.INF file
- Various program files

- The branding cabinet file (Branding.cab) containing .INS, .INF, and other customization files
- The component information cabinet file (Iecif.cab) containing additional components and their customization files

To run the Customization Wizard on the build computer on which the IEAK is installed, click Start, point to Programs, point to Microsoft IEAK, and choose Internet Explorer Customization Wizard. This opens the initial screen of the wizard (Figure 30-1).

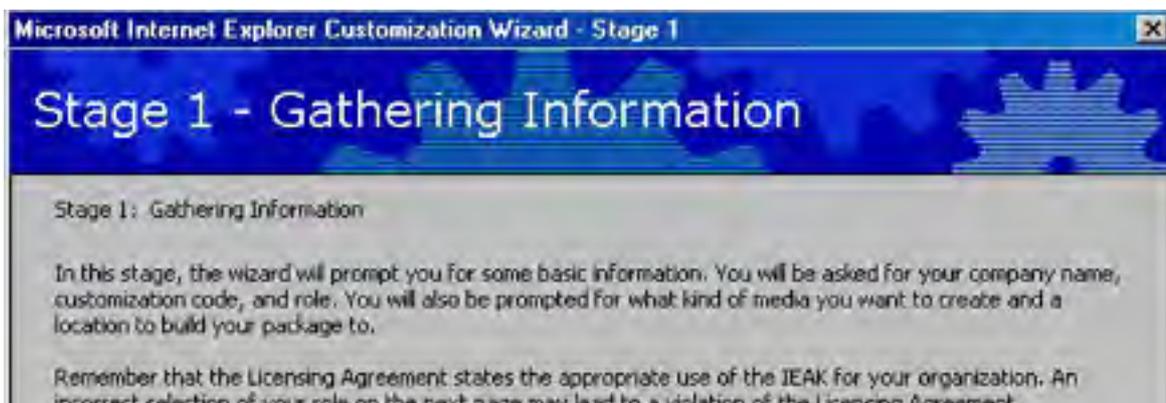

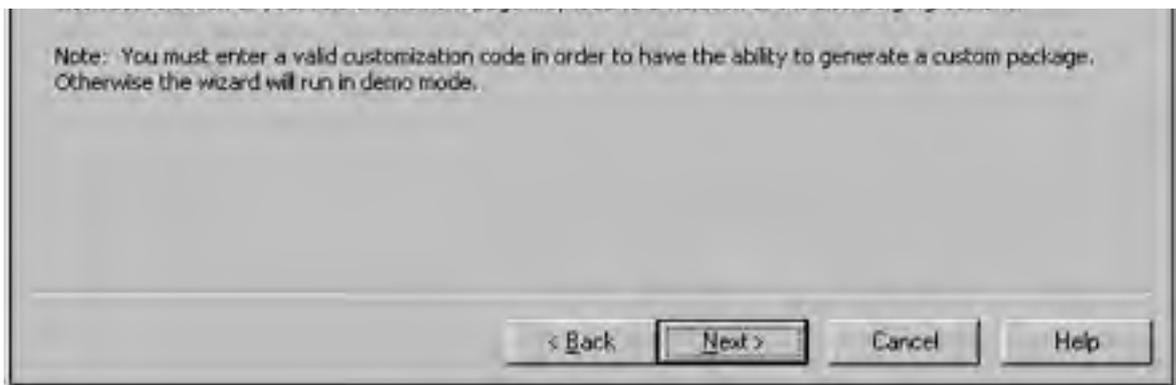

**Figure 30-1.** The opening screen of the Microsoft Internet Explorer Customization Wizard.

The Customization Wizard runs in five stages, using a series of step-by-step screens. The screens that are presented during each stage depend to an extent on the various choices you make along the way, so we can present here only a general outline of the steps that might be involved in a typical customization session. For a more detailed explanation of how to use the IEAK, see either the online Help file for the product or the *Microsoft Internet Explorer 5 Resource Kit*.

### **Stage 1: Gathering Information**

Stage 1 of the Customization Wizard, the first screen of which is shown in Figure 30-2, prompts the user for basic information such as the company name, customization code, role, target media, and so on. You must provide a valid customization code or the wizard runs only in demo mode.

**Figure 30-2.** The screen that introduces Stage 1 of the Microsoft Internet Explorer Customization Wizard.

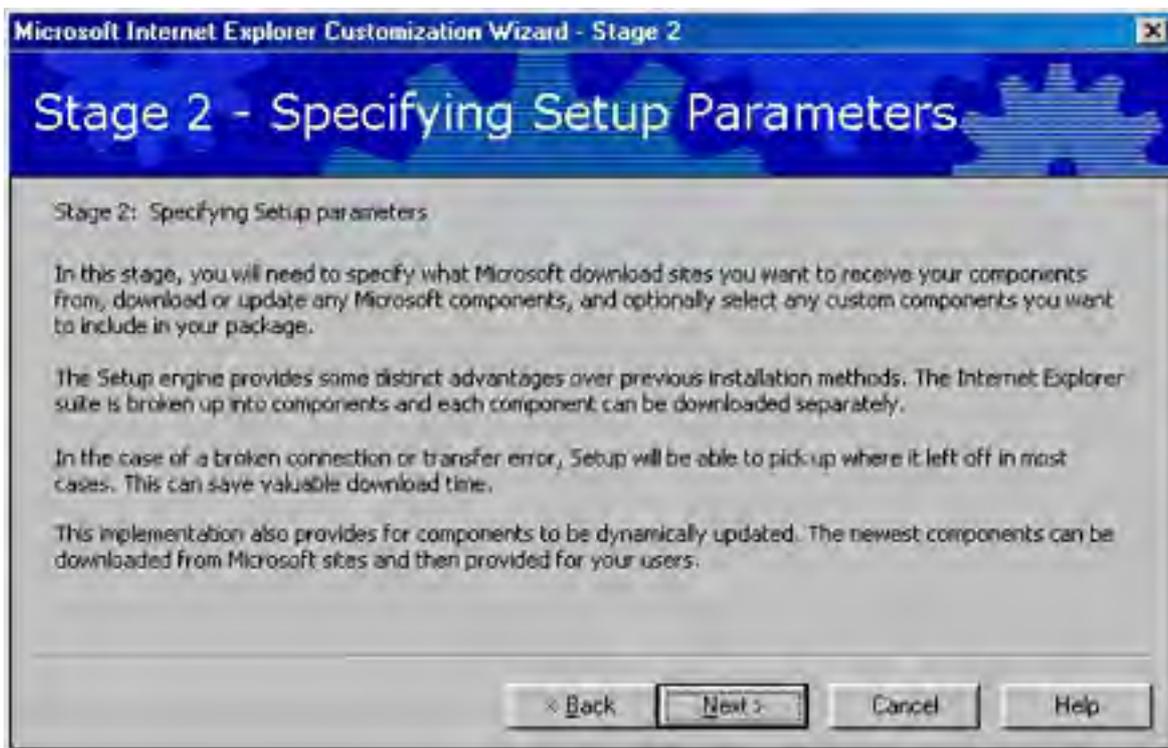

The wizard leads you through the following screens:

1. **Company Name And Customization Code** You must obtain a valid customization code or the IEAK runs only in demo mode. Specify also which title best describes your role in the company: corporate administrator, service provider, or content provider. You must be licensed for your particular role.
2. **Platform Options** Specify the platform for which you want to build the customized Internet Explorer 5 deployment package. Choices include 32-bit Windows (Windows 9x, Windows NT 4), 16-bit Windows (Windows 3.11, Windows for Workgroups, Windows NT 3.51), and UNIX. Note that different platforms support different features.
3. **File Locations** Specify a folder on the build server in which the finished package will be stored. By default, this folder is called C:\Builds \mmdyyyyy, where *mm* is the current month, *dd* is the current date, and *yyyy* is the current year.
4. **Advanced Options** By default, Automatic Version Synchronization (AVS) is turned on. This feature provides version information for the various Internet Explorer 5 components you have available so that you can determine whether you have the most recent version of these components. To use AVS, you must be connected to the Internet. If you downloaded the IEAK from the Internet, you must run AVS at least once when you create the first package. You also specify here the folder in which AVS will store its downloaded Internet Explorer 5 components. You can optionally specify an existing .INS file (an IEAK profile) to use as a starting point for a custom package. Settings in the .INS file are imported into the wizard and used as defaults, but you can modify them as desired.
5. **Language Selection** Specify the localized language to which your customized package will be directed. A package can be customized for only a single language, so if you need pages for several different languages you must run the wizard several times.
6. **Media Selection** Specify the target medium for the package. This can be any of the following (not all options are available under all licensing schemes):
  - Download From A Web Site On The Internet (Or On An Intranet). For example, users could click a link to start the installation.
  - CD-ROM Distribution (Uses Autorun).
  - Flat. Select this option (which refers to a flat file system) if you want users to download the package from a shared folder on the network. The installation files are all written to the same folder.
  - Multiple Floppy Disks. Service providers can distribute their complete package on a set of distribution floppies, but CD-ROM is generally preferable.
  - Single Floppy Disk. Service providers can distribute a single floppy disk that will connect users to a distribution Web site so that they can download the rest of their package.
  - Single-Disk Branding. This produces a single floppy disk that can be used to brand an already existing Internet Explorer 5 installation with a corporate logo bitmap, Favorites list, and so on.
7. **Feature Selection** Use this screen of the wizard to specify which features of Internet

Explorer 5 and its components you want to customize in succeeding stages of the wizard. (This walkthrough assumes that all options are selected.)

## Stage 2: Specifying Setup Parameters

Stage 2 of the wizard, the first screen of which is shown in Figure 30-3, lets you specify which Microsoft download sites you want to receive the Internet Explorer 5 components from and, optionally, to specify any custom software components. The Setup engine is designed to be able to resume after a broken connection and continue downloading at the point at which it was interrupted, which saves time when performing long downloads over unreliable Internet connections.

**Figure 30-3.** The screen that introduces Stage 2 of the Microsoft Internet Explorer Customization Wizard.

This stage of the wizard takes you through the following screens:

1. **Download Locations** If you left AVS enabled in the previous stage, you need to specify which Microsoft site you will use for downloading the latest versions of Internet Explorer 5 components. Choose a location that is close to your geographical region.
2. **Automatic Version Synchronization** Shows the status of each of the Internet Explorer 5 components you currently have available for installation. The first time you run the wizard, all components are displayed with a yellow exclamation point icon, which indicates that you have an older version of this component. After you run AVS, some of the components show up with a green check mark icon, indicating that you have the most recent version of the component, whereas new components available on the Microsoft site you are connected to show up with a red X icon, indicating that you have not yet downloaded those components. You can select a specific component that you want to update and click Synchronize to download it from the Microsoft site, or you can just click Synchronize All.
3. **Add Custom Components** Allows you to package up to 10 third-party components in an Internet Explorer 5 package. You can include scripts and self-extracting executable programs that you want to distribute to users. You can compress custom components into .CAB files for distribution as well. Applications that will be distributed with Internet Explorer 5 over the Internet should be digitally signed to verify their authenticity to users downloading them.

## Stage 3: Customizing Setup

Stage 3 of the wizard, the first screen of which is shown in Figure 30-4, lets you customize the Setup title bar, bitmap, custom component install title, installation options, user install sites, and other information.

**Figure 30-4.** The screen that introduces Stage 3 of the Microsoft Internet Explorer Customization Wizard.

This stage of the wizard takes you through several screens:

1. **CD-ROM Autorun Customization** If you specified CD-ROM as the distribution medium, you can specify an Autorun splash screen and a Readme file.
2. **Customize Setup** Lets you customize how the Windows Update Setup program will appear to users installing the package. You can specify the title bar and bitmap graphic for the Setup screen, as well as other information.
3. **Silent Install** If you have selected the corporate (intranet) licensing option, you can specify the degree to which users interact with the computer during the installation. The three choices are as follows:
  - **Interactive Install** Users are prompted to make decisions and enter information during the installation.
  - **Hands-Free Install** Users are not prompted during the install, but message screens inform users of the progress of the installation and any errors that occur are displayed.
  - **Completely Silent Install** Users do not even know that the installation is taking place, as no prompts, messages, or errors are displayed.
4. **Installation Options** Specify which components are included in the installation and provide up to 10 setup options for users to select or deselect components. You can create custom installation options or use the standard ones, which are Minimal, Typical, and Full.
5. **Component Download Sites** Specify up to 10 different Web or FTP sites from which users can download the package. These can be either corporate intranet or public Internet sites, depending on your licensing scheme. (This option assumes that you indicated that users will perform their installation from a Web site in Stage 2 of the wizard.) For silent installations you can specify only one site.
6. **Component Download** Customize the URL that is pointed to by the Windows Update option of the Tools menu in Internet Explorer 5.

7. **Installation Directory** Specify the folder on users' machines where the package will be installed (or leave this decision to users).
8. **Corporate Install Options** If you selected a corporate installation during Stage 1 of the wizard, this screen provides a number of options. You can disable the Custom Installation option so that users cannot choose which components to install, disable the saving of uninstall information that allows users to revert to their previous version of Internet Explorer, and specify whether Internet Explorer will be the users' default browser (or leave the choice up to them).
9. **Advanced Installation Options** Allows you to further customize installation by indicating which components will be displayed in the Customize Component Options screen during setup.
10. **Components On Media** Specify whether components not selected for installation should nevertheless still be installed on the medium to make them available for automatic install later if desired.
11. **Connection Manager Customization** The CMAK, which is included with the IEAK, is designed to allow administrators to customize and manage Internet connections for users. You can either start the CMAK Wizard at this point to customize a connection or use an existing custom connection profile created earlier with the CMAK. The CMAK is discussed later in this chapter.
12. **Windows Desktop Update** This option is for corporate administrators only; it allows you to specify whether to include the Windows Desktop Update in the package. You do not need to include this component for users who are currently running Microsoft Windows 98 or later.
13. **Digital Signatures** Specify whether to digitally sign the package. By using the Certificates snap-in for Windows 2000 Server, you can generate digital certificates and public/private key pairs, acting as your own certificate authority (CA).

#### Stage 4: Customizing the Browser

Stage 4 of the wizard, the first screen of which is shown in Figure 30-5, asks you to provide information concerning browser customization by specifying a browser title, default home page, search bar URL, online support page, preset list of favorites and links, and other information.

**Figure 30-5.** The screen that introduces Stage 4 of the Microsoft Internet Explorer Customization Wizard.

This stage of the wizard takes you through the following screens:

1. **Browser Title** Specify the text that will appear in the title bar of Internet Explorer 5 once the package is installed. For example, if you specify the title bar text as *Scribes.com*, that text will be displayed in the title bar of users' copies of Internet Explorer 5 as "Microsoft Internet Explorer provided by Scribes.com." You can specify a toolbar background bitmap image here as well.
2. **Browser Toolbar Buttons** Specify additional custom toolbar buttons that you want to appear on users' browser screens once installed. You can add these additional buttons to existing ones or delete the existing ones first and then add your own buttons. Developers can create new buttons for the toolbar and attach them to scripts and executables. (See MSDN Online for details.)
3. **Animated Logo** If you don't like the rotating Internet Explorer logo in the top right corner of the browser window, you can replace it with your own animated corporate logo. Specify the path to the bitmap here.
4. **Static Logo** Here you can specify a static logo to replace the Internet Explorer logo.
5. **Important URLs** Specify the home page, search bar, and online support page URLs for your customized browser.
6. **Favorites And Links** This is one of the most useful IEAK options. In this screen you can preconfigure the Favorites folder and Links bar on your customized browser. You can specify individual URLs one by one here, or you can import them from the \Windows\Favorites folder (or some other folder) of any machine that is accessible on the network. Note that, unfortunately, you can import a maximum of only 255 URLs in this way. You can also test each URL prior to creating the package.
7. **Channels** Specify which custom channels or channel categories you want to include in the package. You need a Channel Definition Format (.CDF) file for each channel. Corporate administrators might want to delete all existing channels for the package if this feature is not used internally on the network.
8. **Welcome Page** Specify a custom welcome page that is displayed when Internet Explorer 5 is started for the first time, use the default Internet Explorer 5 welcome page, or go directly to the user's home page. Custom welcome pages are specified by entering their URLs.
9. **User-Agent String** This advanced feature allows you to append a custom string to the user-agent string for Internet Explorer. User-agent strings are part of HTTP and can be used for tracking site visits and other things.
10. **Connection Settings** Allows you to import connection settings for the package and modify those settings. You can also delete existing settings if any are present.
11. **Automatic Configuration** Specify a pointer to a configured file on a server that can be used to globally change configuration settings on all stations where you have deployed the package, instead of having to modify these settings on each user's computer. This useful feature reduces the administrative overhead and support costs of managing Internet Explorer on users' desktops. Changes to users' configurations are performed using the IEAK Profile Manager, which is discussed later in this chapter.

Most settings are specified using an IEAK profile (an .INS file), but special advanced proxy settings can be specified using JavaScript files in .JS, .JVS, or .PAC format. Select the Enable Automatic Configuration option, specify the URL to the .INS file and script files, and specify a time interval in minutes to indicate how often the browser will check for a newer version of the configuration files. If you select the Automatically Detect Configuration Settings option and are using DNS and DHCP on the network, Internet Explorer is automatically customized the first time users start it on their machines. This allows administrators to create Internet Explorer 5 packages that are not fully customized and then have users' copies of Internet Explorer 5 further customized when the users first start the program on their desktops.

12. **Proxy Settings** Proxy servers are used with firewalls to protect corporate networks over their Internet connections. They can also be used to cache frequently requested Web content and help balance network traffic. Specify your proxy settings for individual Internet protocols like HTTP, Secure HTTP, FTP, Gopher, and Socks Proxy.
13. **Security** Lets you import CAs and customize Microsoft Authenticode security to allow

Internet Explorer 5 security settings to function properly. An additional screen called Security Settings lets you customize different security settings for each zone and customize content ratings.

14. **Sign-Up Screens** These screens appear only when the service provider licensing option is specified; they allow service providers to specify how their users will sign up for their services and connect to their Internet sites. We won't discuss these options further, because this chapter focuses on corporate deployment of Internet Explorer 5.

## Stage 5: Customizing Components

Stage 5 of the wizard, the first screen of which is shown in Figure 30-6, lets you customize additional options for the components you have included in the installation package. You do this by using the System Policies And Restrictions screen, a two-pane view in which the left pane displays a tree view of the various groups and categories of restrictions you can configure, and the right pane shows the options you can configure for the restriction you have selected. The IEAK includes support for importing your own system policy template (.ADM) files for customizing what is displayed here.

**Figure 30-6.** The screen that introduces Stage 5 of the Microsoft Internet Explorer Customization Wizard.

This stage of the wizard takes you through the following screens:

1. **Programs** Lets you import current default program settings to specify which Windows program is used for which Internet service. You can specify the programs to use for each of the following:
  - HTML Web page editor (no default)
  - SMTP e-mail client (Outlook Express is the default.)
  - NNTP news client (Outlook Express is the default.)
  - Internet call client (Microsoft NetMeeting is the default.)
  - Calendar client (no default)
  - Contact list (Windows address book is the default.)
2. **Outlook Express Accounts** Specify the Internet hosts (servers) to which Outlook

Express will connect for mail and news services. You can supply a host for each of the following:

- Incoming mail (POP3/IMAP4) server
- Outgoing mail (SMTP) server
- Internet news (NNTP) server

You can also specify that the applications must log on to any of these servers using Secure Password Authentication, which requires a Security Service Provider Interface (SSPI) provider such as Microsoft NT LAN Manager (NTLM), which is Windows 2000's authentication protocol for Windows NT 4 servers and clients. You can lock down these settings so that users can't change them or modify their Internet accounts.

3. **Outlook Express customization screens** Specify a custom welcome message that will appear when users first start the program on their desktops. You can also specify Outlook Express as the default mail and news client, indicate newsgroups that will automatically be subscribed to, turn on junk mail filtering, choose which view elements of the program will be enabled by default, specify the signature that will be appended to messages, indicate whether plain text or HTML will be used for sending messages, and other options.
4. **Address Book Directory Service** Specify additional options for directory services to be used by the Windows address book. Any LDAP-compliant directory service can be specified here, such as Four11 or Bigfoot on the Internet or Windows 2000 Active Directory on a corporate network.
5. **System Policies And Restrictions** This screen is a powerful tool that allows administrators to configure and lock down various desktop, shell, and security options for all users in their organization. You can also import policy files to customize the settings you can configure here.

## Deploying IEAK Packages

When you've completed the wizard, click Finish to generate and compress the custom installation package files and create the customized version of Internet Explorer 5. The final result will be stored in the appropriate subfolder of the \Builds folder on the build computer. You can then do the following:

- Digitally sign the package (for 32-bit Windows platforms only).
- Prepare your distribution Web site or virtual directory (or network share or some other medium) and create a link to the Ie5setup.exe file that users download and use to install Internet Explorer 5. See [Chapter 28](#) for information on creating Web sites and virtual directories.
- Copy the language version folder and its contents to the appropriate virtual directory on the Web site. For example, if your package is an English language version, you need to copy the contents of the \Builds\mmdyyyy\Download\Win32\En folder on the build machine (assuming a 32-bit package was created) to the appropriate virtual directory on the Web server.
- Copy the Ie5sites.dat file, which points to the download sites you specified during the wizard. This file is typically found in the IEAK profile folder for that package on the build machine—for example, \Builds \mmdyyyy\Ins\Win32\En.
- Notify your users of the Web page (or other medium) they need to visit so that they can install the package by clicking a specified link to the Ie5setup.exe file.
- If you want to later manage users' Internet Explorer 5 configurations automatically, using the IEAK Profile Manager, you need to copy the IEAK profile (the .INS file) for your build to the URL you specified during the wizard.

## IEAK Profile Manager

The IEAK Profile Manager is a tool for modifying and maintaining the IEAK profile associated with a particular package. The profile specifies the configuration settings for the package, and the Profile Manager lets you modify any aspect of that profile. Furthermore, if you didn't enable automatic configuration when you created the package with the Internet Explorer Customization Wizard, you can enable it later using the Profile Manager.

The Profile Manager works by allowing you to open a selected .INS file (an IEAK profile), make changes to it, and save the result. The Profile Manager also maintains the companion files to the .INS file, which are stored in the same folder as the .INS file for that package. Two basic types of settings can be configured using the Profile Manager:

- **Wizard settings** Administrators can modify any settings that were specified during Stages 2 through 5 of the Internet Explorer Customization Wizard.
- **Policies and restrictions** These settings refer to users' desktop, shell, and security settings (system policy settings), which were specified in the System Policies And Restrictions screen of the Internet Explorer Customization Wizard (step 5 under "Stage 5: Customizing Components" earlier in this chapter.

## Using Profile Manager

To start the IEAK Profile Manager on the build computer, click Start, point to Programs, point to Microsoft IEAK, and choose IEAK Profile Manager. This opens the IEAK Profile Manager main window. You can either import an existing .INS file or create a new one. Figure 30-7 shows a file that has been imported from a package located on the build computer.

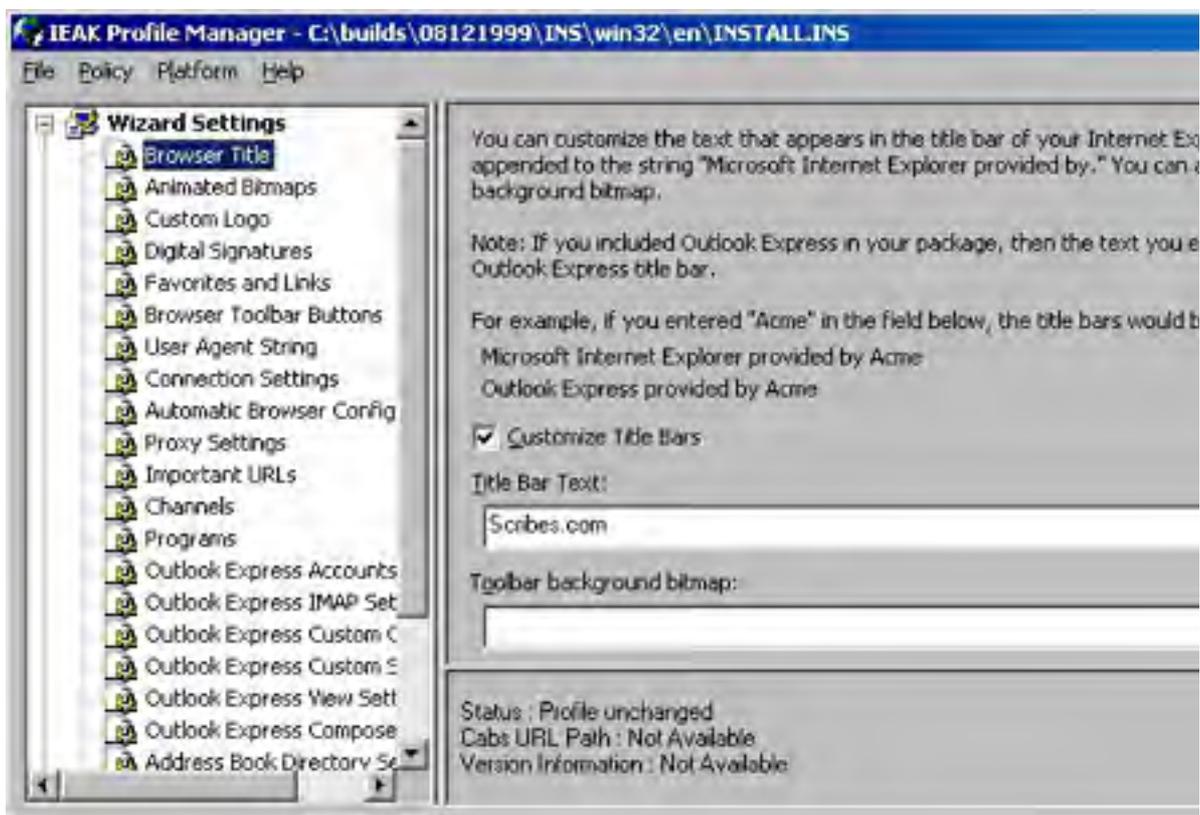

Figure 30-7. The IEAK Profile Manager.

The IEAK Profile Manager window cannot be resized and should be displayed on screens with a resolution of 800 by 600 or higher.

Using the Profile Manager is straightforward: Simply select the type of wizard or policy settings you want to modify in the left pane of the window and make the appropriate modifications in the right pane. Save the results when finished (or use Save As to keep the existing .INS file while creating a new one with the new settings). Be sure to test the new configuration on a test machine before deploying it on the production site, where users' machines can be updated using autoconfiguration.

## Connection Manager Administration Kit

The CMAK included with Windows 2000 Server (and the earlier version included with IEAK 5) is used to customize Connection Manager service profiles for the installation packages you create. Using the CMAK, you can create and manage custom Connection Manager service profiles that enable Internet Explorer 5 users to connect to your Internet or intranet services. Microsoft Connection Manager is the client dialer and connection software tool that uses the service profiles created with the CMAK. In other words, the service provider or corporate network administrator creates a service profile, packages it with Connection Manager, and deploys it onto users' client desktop machines—enabling users to connect to the corporate intranet or to the service provider's Internet Web site and access its services.

In particular, the CMAK can be used to do the following:

- Create and manage dial-up and virtual private network (VPN) Connection Manager service profiles for connecting to ISPs and corporate networks
- Configure custom programs to run automatically when a user connects to your service
- Import existing connection settings and modify them
- Configure system policies and restrictions for connections
- Enable users to use the Internet Connection Wizard on their machines to sign up for your service

Like the IEAK, the CMAK is implemented as a wizard that takes you through a series of steps to create a new Connection Manager service profile. Preliminary planning is important here, just as it is for the IEAK; you need to ensure that you have any branded graphics, access numbers, scripts, or other items ready before running the wizard. The online CMAK Guide states that creating a new Connection Manager service profile involves six different phases. We cover these phases only briefly here and only in regard to corporate deployments of installation packages.

### More Info

For more information on using the CMAK, refer to the online CMAK Guide or see the *Microsoft Internet Explorer 5 Resource Kit* (Microsoft Press, 1999).

For a corporate deployment of Internet Explorer 5, the six phases of the process look like this:

- **Phase 1: Planning** Create telephone book and region files for your service providers and decide what type of connection you want and how you want it to be customized. The online CMAK Guide includes a planning worksheet that is very helpful for this task.
- **Phase 2: Developing custom elements** Create any custom graphics or other items needed for your profile.
- **Phase 3: Running the CMAK Wizard** The wizard creates a new service profile for the connection; this wizard is discussed later.
- **Phase 4: Preparing for delivery** You can deliver the connection to users either as part of an IEAK installation package or as a separate package.
- **Phase 5: Testing** Test deliverables before letting users download them.
- **Phase 6: Providing support** Develop a strategy for supporting your users after the service profile has been delivered.

## Installing CMAK

As mentioned earlier in this chapter, the version of CMAK included with the IEAK does not support the Windows 2000 platform but only legacy Microsoft Windows platforms. If you plan to deploy Connection Manager connections to client machines running Windows 2000 Professional, you need to use the version of CMAK included with Windows 2000 Server. To install the CMAK and Phone Book Services (PBS) on Windows 2000 Server, open Add/Remove Programs in Control Panel and select Add/Remove Windows Components. Then select Management And Monitoring Tools, click Details, and select Connection Manager Components.

## Using the CMAK Wizard

Once installed, the CMAK Wizard (Figure 30-8) can be started either from within the IEAK Wizard (see step 11 in "Stage 3: Customizing Setup" earlier in this chapter) or directly from the Start menu by selecting Connection Manager Administration Kit from the Administrative Tools folder on the Programs menu of Windows 2000 Server.

**Figure 30-8.** The first screen of the Connection Manager Administration Kit Wizard.

To create a new Connection Manager service profile for a typical corporate networking scenario, start the CMAK Wizard and follow these steps:

1. **Service Profile Source** Specify whether you want to create a new service profile or edit an existing one.
2. **Service And File Names** Specify a name for the service (for example, Scribes Connection Services) and a filename to be used for the service profile folder and files.
3. **Merged Service Profile** Lets you merge the settings of a number of existing service profiles into the one you are creating or editing.
4. **Support Information** Lets you specify a line of support information for the profile. For example, you could enter *Call 1800SCRIBES for customer support* or something similar.
5. **Realm Name** Lets you specify a realm if one is needed. The realm is automatically appended to the user name during connection establishment, using a separator character that you specify. Microsoft Internet Authentication Service Commercial Edition, available in Microsoft Commercial Internet System, supports the use of realm names for remote authentication purposes.
6. **Dial-Up Networking Entries** Specify the dial-up networking entries associated with the

- telephone numbers in the address book. You can either specify DNS and WINS addresses or let the server assign these IP addresses to the client during connection establishment.
7. **VPN Support** Allows you to enable a virtual private networking connection for this service profile. If you enable this feature, you can either specify DNS and WINS addresses or let the server assign these IP addresses to the client during connection establishment.
  8. **Connection Actions** Specify actions that will occur before connection establishment, after connection establishment, or before connection termination. In succeeding screens of the wizard, you specify the actual programs or scripts to be run and any parameters needed by them. For example, after connection establishment you might want to automatically download any telephone book updates.
  9. **Auto Applications** Specify additional programs or scripts that will run during a communications session. For example, you might want to open the e-mail client program automatically when a connection is established.
  10. **Logon Bitmap** Specify the bitmap to be displayed in the Logon dialog box. For example, you might use your corporate logo here.
  11. **Phone Book Bitmap** Specify the bitmap to be displayed in the Phone Book dialog box.
  12. **Phone Book** Specify whether you want to include a telephone book in this service profile.
  13. **Phone Book Updates** Specify how clients will receive updates to their telephone books, typically by connecting to a Connection Point Services server that is specified by a URL. If you do not include a telephone book in the service profile, you must specify one here that can be downloaded later by clients.
  14. **Icons** Specify icons to be used to represent Connection Manager on the client machines. Use a corporate logo icon if desired.
  15. **Status Area Icon Menu** Lets you customize the shortcut menu that appears when users right-click the status area icon.
  16. **Help File** Specify a Help file to be used by your users. You can either use the default one or specify a custom one that you have created.
  17. **Connection Manager Software** Your users must have Connection Manager 1.2 installed on their machines to use the service profile you are creating. If they don't have it, you can indicate here that the Connection Manager software itself is to be included with the service profile. Users can then download the package, install Connection Manager, and have it configured by the profile you have created for them.
  18. **License Agreement** Specify a text file containing the license agreement you want users to accept (if desired).
  19. **Additional Files** Specify other programs and files to be included in the service profile you are creating that are not specified elsewhere in the wizard.

## Real World

### Connection Point Services

The Connection Point Services (CPS) component of Windows 2000 provides support for creating, maintaining, and updating telephone books. CPS consists of two components:

- **Phone Book Services (PBS)** This extension to Internet Information Services (IIS) 5 enables users to connect to a server and download updates to the Connection Manager profiles on their client machines. Queries from Connection Manager are handled by the WWW Publishing Service on IIS 5.
- **Phone Book Administrator (PBA)** This tool lets you create and edit multiple telephone books, specify service types for points of presence (POPs), and publish new telephone book information to the PBS, using the FTP service on IIS 5.

## Deploying CMAK Packages

When you are done with the CMAK Wizard, click Finish to build the customized Connection Manager service profile. Makecab.exe runs within a command-prompt window to generate and compress the connection package. A final screen displays the location of the self-installing executable service profile, which by default is located in C:\Program Files\Cmak\Profiles\Service\_Directory\Service\_Profile, where *Service\_Directory* and *Service\_File* are the directory and file, respectively, specified in step 2 of the CMAK Wizard.

If you started the CMAK Wizard from within the IEAK Wizard, you can then continue with the IEAK Wizard, and the Connection Manager service profile will be packaged together with the Internet Explorer 5 installation package you are creating. If you started the CMAK Wizard from the Administrative Tools folder, you can copy the service profile package files to a Web site or network share and deploy the package as you would an Internet Explorer 5 package, or you can select it later from the IEAK Wizard when creating an Internet Explorer 5 package. If users on the Internet will download the service profile package separately, it should be signed with Microsoft Authenticode technology.

To install the new connection, users simply click on the link of the appropriate Web page, where they can choose either to download the self-extracting file and run it later or to open it from its remote location, which installs it immediately on their machines. At the end of installation, users can optionally add a shortcut to their desktops for the new connection. The connection also appears in the Network And Dial-Up Connections folder, accessed from Control Panel. Figure 309 shows the dialog box for a new connection, which is opened by double-clicking the connection shortcut.

**Figure 30-9.** A new Connection Manager connection created using the CMAK Wizard.

## **Summary**

This chapter has looked at how corporate network administrators can deploy and manage Internet Explorer 5 and Connection Manager connections using tools like the Internet Explorer Administration Kit and the Connection Manager Administration Kit. Deploying and managing Internet tools and client connections is an important task for today's network administrator, and Windows 2000 makes this task easy.

Once you have deployed Internet Explorer, you can choose to utilize a server to act as a proxy between your internal network and the Internet. The next chapter covers the installation and configuration of Microsoft Internet Security and Acceleration Server.

# Chapter 31

## **Internet Security and Acceleration Server**

Microsoft Internet Security and Acceleration Server (ISA Server) is Microsoft's most powerful and secure solution for sharing an Internet connection on a network. As such, it replaces Microsoft Proxy Server 2.0 and exceeds the capabilities of other Microsoft solutions such as Routing and Remote Access (RRAS) and Internet Connection Sharing (ICS).

This chapter introduces you to important concepts related to ISA Server, covers some planning considerations, and then shows you how to set up and manage ISA Server on the network.

### **More Info**

For detailed information about deploying and managing ISA Server, see the MCSE Training Kit: Microsoft Internet Security and Acceleration Server 2000 (Microsoft Press).

## Concepts

The main goals of ISA Server are to insulate the network from hackers, improve Internet performance for clients on the network, and control client access to the Internet.

ISA Server maintains control of connectivity and isolates the internal network by having two (or more) completely separate physical connections—one to the Internet and one to the internal network. Each network is connected to a different network card, and all packets must pass through the ISA Server software to get from one connection to the other.

The mechanisms that ISA Server uses to achieve these aims are fairly straightforward. The following three basic techniques are used:

- Network address translation
- Packet filtering
- Caching

The following sections discuss each of these techniques, as well as the different methods available to support clients, how ISA Server works in a large enterprise environment, and how to plan your ISA Server deployment.

There are two versions of ISA Server: the Standard Edition and the Enterprise Edition. The only difference is that the Enterprise Edition allows you to create and centrally manage arrays, which consist of one or more ISA servers linked together under a single Enterprise policy.

### Real World

#### Methods of Sharing Internet Connections

There are two basic methods of providing Internet connectivity to clients on the network; using stand-alone devices such as a router or firewall device, and software-based solutions running on a PC.

Microsoft offers a number of software-based solutions: Internet Connection Sharing (a simple method of sharing an Internet connection on a workgroup, built into Microsoft Windows XP, Windows 2000 Professional, Windows Me, and Windows 98 SE), Routing and Remote Access (a somewhat more sophisticated solution that comes integrated into Windows 2000 Server), and ISA Server, which replaces Proxy Server 2.0.

Although Routing and Remote Access is capable of sharing an Internet connection with multiple clients and providing limited security to the internal network using NAT, ISA Server provides better security and user control, in addition to accelerating Internet access for users.

Firewall devices such as those manufactured by SonicWall (<http://www.sonicwall.com>) can also provide powerful network security, although they are typically expensive and lack the acceleration and user access control features provided by ISA Server.

## Network Address Translation

Network address translation (NAT) hides your actual IP address from machines beyond the device doing the translation. Only the device doing NAT needs to have a valid Internet IP address; all clients and servers on the internal network can be given free private addresses from the address ranges reserved for private networks (see sidebar).

To provide NAT, you can use a stand-alone router or firewall device, a proxy server or firewall software package such as ISA Server, or the built-in NAT functionality of Windows 2000 (provided by either the Routing and Remote Access service or the Internet Connection Sharing service).

Although NAT is the backbone of any Internet connection sharing technique, the security it provides is inadequate for networks where security is a priority (even home and small office users are increasingly requiring additional security methods). This is why ISA Server supplements NAT with additional security measures, most notably packet filtering.

## Real World

### IP Addresses for Internal Networks

Back when folks were deciding how to parcel out IP addresses (and long before anyone figured out how to perform NAT), the need for addresses that could be used for test networks was recognized. A special set of IP addresses called *private network addresses* was defined in RFC 1918 for test or other networks not physically connected to the Internet.

These private network addresses allow a much larger address space than would be possible with officially assigned addresses while protecting the integrity of the Internet. If a machine with one of these addresses were to connect to the Internet, it wouldn't cause a conflict with another machine because routers automatically filter out these addresses.

The following addresses are designated for private networks that won't be directly connected to the Internet. They can, of course, be connected to the Internet through ISA Server or another method that performs NAT.

```
10.0.0.0 through 10.255.255.255 (a single Class A network)
172.16.0.0 through 172.31.255.255 (16 contiguous Class B networks)
192.168.0.0 through 192.168.255.255 (256 contiguous Class C networks)
```

ISA Server automatically includes these addresses in its local address table (LAT) when you initially install the program.

Another by-product of using ISA Server for address translation is that all the machines on a network *appear* to have the same single address to the outside world—the external address of the ISA server itself. This allows an entire organization to connect to the Internet with as little as a single public IP address, and even that one address doesn't need to be a fixed IP address—ISA Server can handle a DHCP-supplied public IP address.

## Packet Filtering

Because every packet that passes to or from the Internet must first pass through the ISA server, ISA Server is in a perfect position to act as a gatekeeper. Besides performing simple NAT, ISA Server can inspect each packet to see which protocol is being used and whether it's a permitted connection. This is called packet filtering, and it greatly increases the security of ISA Server.

When packet filtering is enabled, you can also restrict access to specific external sites or enable only certain external sites to be seen. In addition, third-party ISA Server plug-ins can add controls and functionality.

## Caching

Every organization has certain sites that almost everyone uses regularly. Because even dynamic sites have much information that doesn't change often (like HTML documents, graphics files, and so on), ISA Server can cache information from these frequently accessed sites so that when users connect to the site, much of the information is actually delivered by the ISA server, not the remote site. Caching significantly improves the apparent speed of the connection to the Internet and leaves more Internet bandwidth available.

ISA Server can use off hours when few users are connected to the Internet to check frequently accessed sites to make sure that the information it has stored for that site is current. This monitoring, called active caching, helps to balance and smooth out demand, providing improved throughput during busier times because fewer pages and images need to be downloaded.

ISA Server also performs fancy tricks like splitting audio or video streams and sharing them with multiple users on the network, and performing reverse caching, which accelerates the perceived performance of the Web servers to Internet clients.

## Client Types

Clients can connect to the ISA server using the Firewall client, the SecureNAT client, or the Web Proxy client.

For Windows clients, install the Firewall client software. This lets you manage clients by user group. For Macintosh and UNIX clients and network devices, set up their TCP/IP properties to use the ISA Server as the default gateway. (This is what a SecureNAT client is, a client that uses ISA Server as a gateway.) Set up all systems to use the Web proxy service for Web browsing. This is done automatically when installing the Firewall client software, but needs to be done manually for SecureNAT clients.

Table 31-1 describes each method.

**Table 31-1.** ISA Server client modes

Feature	Firewall Client	SecureNAT Client	Web Proxy Client
Operating system support	Windows clients	All TCP/IP systems	All HTTP 1.1-compliant Web browsers
Software configuration	Firewall client software	TCP/IP default gateway	Web browser proxy configuration

Windows version 3.1 and Windows NT version 3.51 and earlier aren't supported as Firewall clients. These systems must be configured as SecureNAT or Web Proxy clients, or both.

## ISA Server Policies and Policy Elements

Setting an ISA Server rule requires two separate steps: creating the policy elements that define to what protocol, client group, time of day, address, or other element the policy will apply, and then creating the actual policy that will be applied to one or more policy elements. You might define a schedule policy element that is "Weekends"—that is all day Saturday and Sunday. Then you might create a policy that prohibits the use of the FTP protocol. When you combine those two, you have a rule that doesn't allow anyone to download files onto their computer on the weekend.

So when you create or modify a policy element such as a Client Address Set, Protocol Definition, or Schedule, you aren't actually creating any rules; you're just changing the options to which the rules apply. Policies are the rules you actually create, and you apply them to policy elements.

## ISA Server Deployment

The next sections discuss how to select hardware based on the number of clients on the network; using multiple ISA servers in an array for enhanced performance and fault tolerance; setting up multiple ISA servers in series to create two levels of protection from the Internet, as well as migrating from Proxy Server 2.0.

### Choosing Appropriate Hardware

The number of clients you plan to service determines what kind of hardware on which to deploy ISA Server. Besides all the usual requirements and recommendations for Windows 2000 (see [Chapter 5](#)), use Table 31-2 to help determine the appropriate hardware for your ISA servers.

**Table 31-2.** ISA Server hardware requirements

Number of Users	Minimum Processor	RAM	Disk Space for Caching
1-500	Pentium II 300 MHz	256 MB	2-4 GB on an NTFS partition
500-1000	Pentium III 550	256 MB	10 GB on an NTFS partition
1000-2000	2 Pentium III 550s	256 MB per server	10 GB per server on an NTFS partition

Alternatively, you could deploy servers with faster processors, such as a 1 GHz or faster system. A 1.4 GHz system should be able to handle roughly 2000 clients; however, you should test this on the network before deploying a number of servers.

#### More Info

For information about performance monitoring and reporting in ISA Server, see the section entitled [Monitoring ISA Server](#) later in this chapter, or see the online Help system.

### Arrays and the Enterprise

If your firewall and caching needs exceed the capabilities of a single ISA server, you can link multiple ISA servers together in an array to provide fault tolerance and better performance, provided you own copies of the ISA Server Enterprise Edition.

ISA Server arrays are powerful and easy to use. The number of clients you can handle scales linearly with the number of ISA servers you deploy in an array: add a second system of the same specifications and you double the number of clients you can handle. Arrays require no additional setup work on the clients and are centrally administered as if they were a single server.

Array members communicate with each other to ensure that the Web cache is split between members of the array with no overlap (and therefore no wasted space or bandwidth consumed). Clients are automatically routed to the array member that contains the desired Web page in its cache.

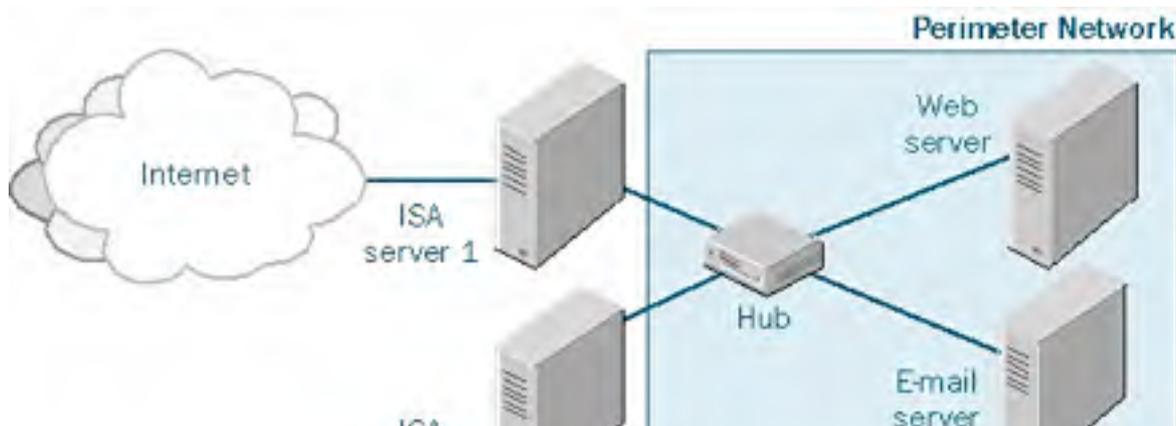

To deploy an array, the ISA servers must be members of the same Active Directory domain (Windows NT domains won't work), and you must install the ISA Server schema to Active Directory, as described in the section entitled [Installation](#) later in this chapter.

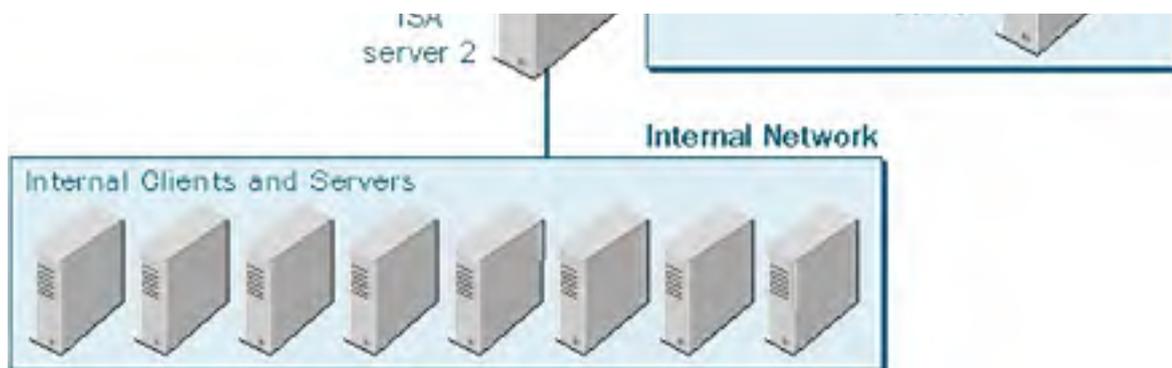

Installing the ISA Server schema into Active Directory allows you to set policies that apply to all ISA Server arrays in the enterprise. For this reason, many administrators choose to create all ISA servers as arrays, even if they only contain one server. This allows you to control their settings using enterprise policies.

Don't install ISA Server on a domain controller, even if you're going to set up an array. ISA doesn't need to be physically on a domain controller to interact with Active Directory and placing a domain controller outside the firewall is an enormous security risk.

### Perimeter Networks and Cascading ISA Servers

To make a number of servers available from the Internet, such as Web servers, media servers, and mail servers, you can implement a so-called perimeter network, also known as a DMZ (demilitarized zone) network. Perimeter networks allow the setting of two levels of security so Internet clients can access the Internet servers behind a firewall but can't get to the internal network, which is located behind a second firewall with a tighter security policy. A back-to-back perimeter network is shown in Figure 31-1.

**Figure 31-1.** A back-to-back perimeter network.

To implement a back-to-back perimeter network, follow these steps:

1. Set up the LAT (local address table) on the ISA server connected to the Internet to include the addresses of all servers in the perimeter network. Also include the address of the second ISA server (make sure to specify the address associated with the network card connected to the perimeter network, *not* the network card connected to the internal network).
2. Set up the LAT on the second ISA server (the one connected to the internal network) to include the addresses of all computers on the internal network. Do not include the addresses of any computers on the perimeter network or the first ISA server.
3. Create publishing rules on the first ISA server (the one connected to the Internet) for the desired servers on the perimeter network, such as your Web server and e-mail server. This process is covered later in this chapter.

You can implement a perimeter network with a single ISA server by installing three network cards in the desired server. This saves the cost of an extra ISA Server computer and software license. If you do implement a perimeter network with a single ISA server, make sure that all addresses in the perimeter segment are valid Internet addresses (talk to your ISP about this). Also, make sure only to include addresses from the internal network segment in the LAT. Consult the Help system on perimeter networks for more information.

## Migrating from Proxy Server 2.0

Although Microsoft ISA Server isn't simply Proxy Server 3.0, you can still perform an upgrade from Proxy Server to ISA Server. Most Proxy Server settings are migrated to ISA Server, and existing Proxy clients continue to function.

However, there are some prerequisites and actions you need to take to upgrade to ISA Server, as described in the following list:

- The Proxy Server computer you upgrade must be running Proxy Server 2.0 on Windows 2000 Service Pack 1 or later.
- If Proxy Server is still running on Windows NT 4, stop all Proxy Server services, upgrade the server to Windows 2000, and then install ISA Server (ignore the warning that ISA Server isn't compatible with these operating systems).
- If your network uses the IPX/SPX protocol for internal clients you need to install TCP/IP and configure all clients to use it because ISA Server doesn't support IPX.
- If you're migrating a Proxy Server array to a stand-alone ISA Server, most of the settings are migrated. If you're migrating to an ISA Server array, the enterprise policies you create affect how Proxy Server's settings are transferred.
- To migrate a Proxy Server array, first remove all members from the array. During ISA Server setup, create a new array, and migrate each Proxy Server array member to this new array.

**More Info**

For more information about migrating from Proxy Server 2.0, including how tasks are performed differently on ISA Server, see the ISA Server online Help system.

## Installation

Installing ISA Server involves several tasks. First, you need to prepare the server for the installation. Then, if you're going to set up an ISA Server array or administer servers using enterprise policies, you need to install the ISA Server schema to Active Directory. After doing this, install ISA Server and use ISA Server's Getting Started Wizard to run the initial configuration.

The following sections walk you through these tasks.

## Preinstallation

Before you install ISA Server, use the following steps to prepare the server:

1. If you're setting up an ISA Server array (discussed earlier), make sure there is a Windows 2000 domain available to join, because the ISA Server array schema must be stored in Active Directory. If the network is still using Windows NT 4 domains, create a new Windows 2000 domain and set up a one-way trust between the domains.

All ISA servers in an array must belong to the same domain and site.

2. Verify that the network adapter connected to the internal network is properly set up. This adapter should use a static IP address and should *not* have a default gateway specified. The internal network will probably consist of addresses from the private address ranges (discussed earlier in this chapter).

Windows can only store a default gateway for one network interface, the external interface. Therefore, if the internal network is routed, you can create static routes to ensure full connectivity. Creating static routes using the ROUTE command is covered in the Windows Help system as well as the *Microsoft Windows 2000 Resource Kit*.

3. Verify that the network adapter, modem, or ISDN adapter connected to the Internet or external network is properly set up. This connection can use a dynamically assigned IP address or a static IP address. Either way, the address needs to be a valid Internet address obtained from your ISP.
4. Remove File and Printer Sharing for Microsoft Networks and Client for Microsoft Networks from the external interface. You should also disable NetBIOS Over TCP/IP.
5. Test connectivity by connecting to other clients or servers on the internal network, as well as the external network (most likely the Internet). Alternatively, use the Ping command to test the ability to reach hosts on the internal and external network.
6. To enable the ISA server to access the Web (for example, to use Windows Update), set up the Web browser to use the ISA server's internal network address as the proxy server address, as described in the section entitled [Configuring Web Proxy](#) later in this chapter.
7. Update Windows 2000 with the latest service pack and relevant security updates.

### Real World

#### Creating a Secure Configuration

To maximize security, follow these rules:

- Don't install additional applications or services on the ISA Server computer.
- Don't install ISA on a domain controller unless it belongs to its own domain and forest with a one-way trust to the rest of your company.
- Stop any unnecessary services on the server.
- Apply the *hisecweb* security template to the server to increase the security settings of Windows (see [Chapter 28](#) for more information).

- Install the latest Windows and ISA Server service packs and security patches.

## Enterprise Initialization

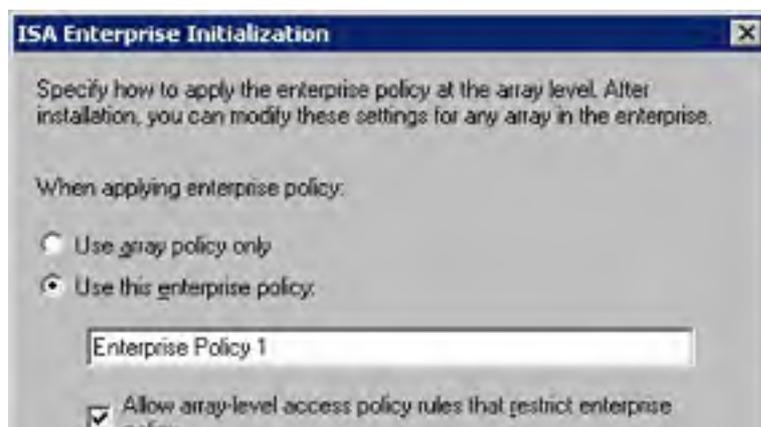

Before you can set up an ISA Server array, you need to install the ISA Server schema into Active Directory. You can also install the ISA Server schema to Active Directory so that you can apply enterprise-wide policies to your ISA servers, or turn a stand-alone server into an array at some point in the future (you don't have to create arrays immediately).

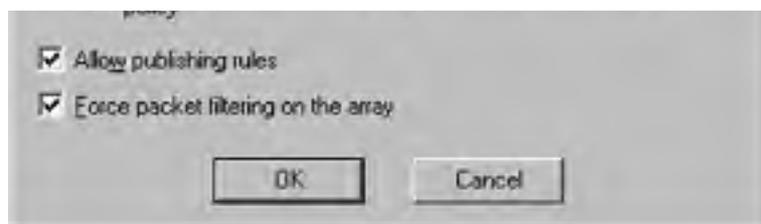

To install the ISA Server schema to Active Directory, thereby preparing the network for ISA Server arrays or enterprise policies, use the following procedure:

1. Insert the ISA Server CD in the CD-ROM drive or run ISAautorun.exe from a network location.
2. Click Run ISA Server Enterprise Installation in the Microsoft ISA Server Setup window. Click Yes to install the ISA Server schema to Active Directory.

Installing the ISA Server schema to Active Directory is irreversible. Even if you uninstall ISA Server on all computers, the schema still exists in Active Directory. However, installing the ISA Server schema only has a minimal effect on Active Directory, typically only a couple megabytes of storage space is consumed in the Global Catalog and several megabytes of extra replication traffic is generated. Because there isn't any way around this, and the impact is small, you should consider this point, and then forget about it.

3. In the dialog box shown in Figure 31-2, specify how to apply policies to the enterprise and name the new enterprise policy (if you choose to create one):
  - **Use Array Policy Only** This setting prevents you from applying policies at the enterprise level, dictating that you must configure each ISA Server array individually.
  - **Use This Enterprise Policy** If you select this option and don't select the Allow Array-Level Access Policy Rules check box, all policies must be applied at the enterprise level. This means that all arrays in the enterprise will have the same policy settings, whether you like it or not.
  - **Enterprise and Array Policies combined** Set up ISA Server to permit both enterprise and array policies. This allows you to set policies at the enterprise level, but also individually set more restrictive policies at the array level (although you can only further restrict policies at the array level, not make them more permissive). To do so, select the Use This Enterprise Policy option and then select the Allow Array-Level Access Policy Rules check box.
  - **Allow Publishing Rules** Select this check box so that arrays are allowed to publish (make available to the Internet) Web servers and other servers.
  - **Force Packet Filtering On The Array** Select this check box to force all arrays to use packet filtering. If you clear this check box, you can enable or disable packet filtering on an array-by-array basis.

**Figure 31-2.** Choosing how ISA Server should handle enterprise and array policies.

4. Click OK to install the ISA Server schema. Active Directory processes the updates. When it's finished, click OK.

You should wait until there is adequate time for Active Directory to replicate the changes before you set up any arrays.

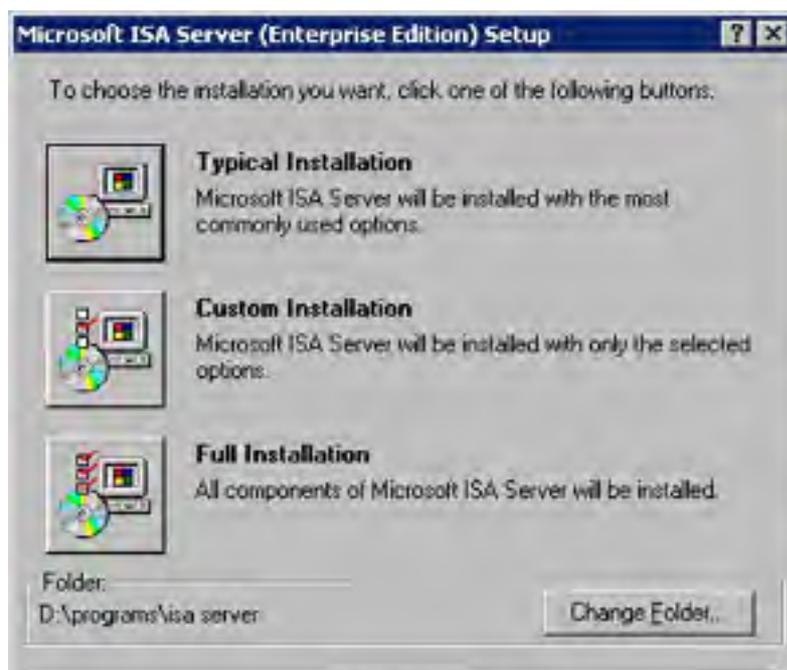

## ISA Server Installation

To install ISA Server, follow these steps:

1. Disconnect the ISA server from the Internet. This eliminates the possibility of any security breaches while installing ISA Server.
2. Insert the ISA Server CD in the CD-ROM drive or run ISAautorun.exe from a network location.

If you need to deploy a number of ISA servers, consider performing unattended setups. For information about how to install ISA Server unattended through a command prompt, search on unattended in the ISA Server Help system.

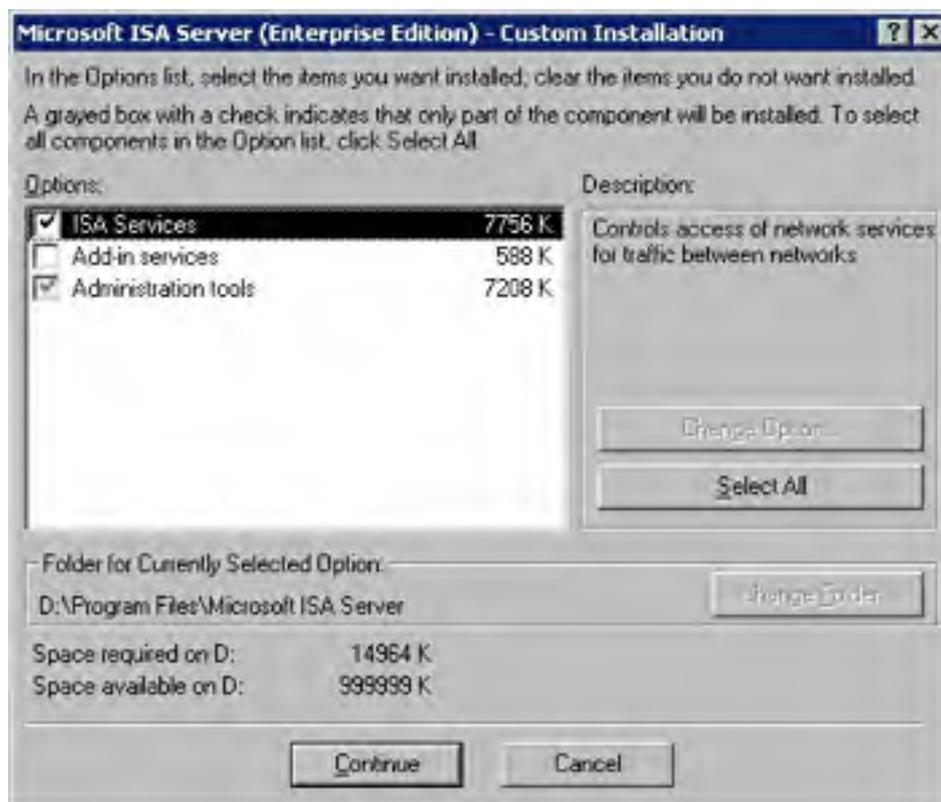

3. Click Install ISA Server in the Microsoft ISA Server Setup window. Click Continue to begin installation.
4. Enter the 10-digit CD key from the back of the ISA Server CD-ROM case and then click OK. Your product ID will be displayed. Click OK again to continue.
5. Read the standard Microsoft license agreement screen, and then click I Agree to continue.
6. Click Change Folder at the bottom of the screen shown in Figure 31-3 to optionally change the installation location. Roughly 20 MB of disk space is used at this location (the ISA Server cache can be stored elsewhere).

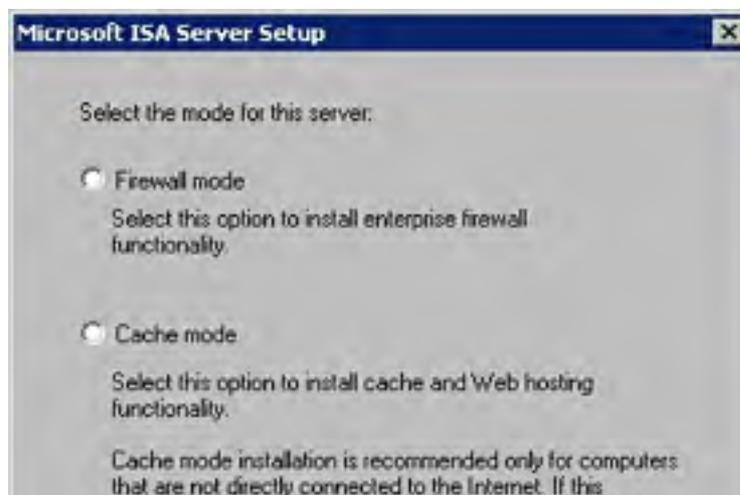

**Figure 31-3.** Choosing an installation type.

7. Click the button associated with the type of installation you want to perform. Choose Typical to install the most commonly used options, Custom to specify exactly what options to install, as shown in Figure 31-4, or Full to install all options.

**Figure 31-4.** The Custom Installation dialog box.

8. Choose whether to install ISA Server as a stand-alone server or as an array member (if you initialized the enterprise first, as described in the previous section). If you choose to make the server an array member, enter a name for the array or choose an existing array.
9. Choose whether to use the existing enterprise policy with the array (if creating or adding members to an array), or use custom enterprise settings, and then click Continue.
10. Choose which mode of ISA Server to use, as shown in Figure 31-5: Firewall mode for security purposes only, Cache Mode for Internet acceleration purposes only, or Integrated Mode to provide both security and acceleration services (this is the recommended mode for most networks).

**Figure 31-5.** Choosing which mode of ISA Server to use.

You can enable or disable ISA Server's firewall and caching services any time after installing by selecting Microsoft ISA Server in Add/Remove Programs in Control Panel, clicking Change, and then choosing Reinstall. Select a new mode and away you go. Make sure to back up the ISA Server configuration first.

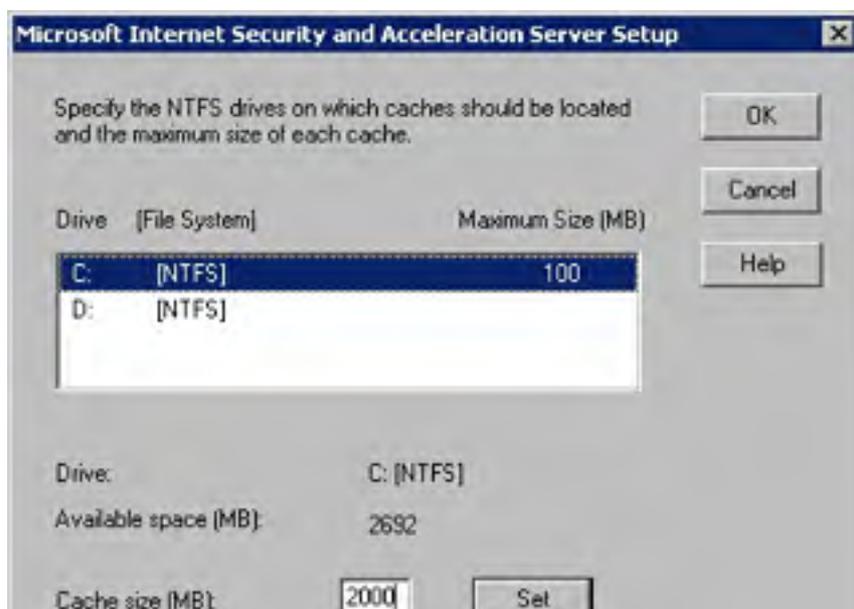

Installing ISA Server in Cache Mode will not allow SecureNAT clients to access the Internet. SecureNAT clients are only supported in Firewall Mode and Integrated Mode.

11. Setup stops Internet Information Services (IIS), if installed. Click OK to continue.

To host Web sites from behind an ISA Server firewall, you need to "publish" the Web server using ISA Server, permitting Internet clients to access the published servers. This is discussed in the section entitled [Publishing Internal Servers to the Internet](#) later in this chapter.

12. Set the size and location of the local Web cache as shown in Figure 31-6. Hard disk space is inexpensive, so set aside a large chunk of disk space for the cache; 10 GB is a good amount for many organizations, but see Table 31-2 earlier in this chapter for more recommendations.

You can place the cache on any NTFS drive, but for the best performance, you should place it on the fastest hard drive or spread it across several physical disks (spreading across partitions on the same physical disk offers no performance improvements).

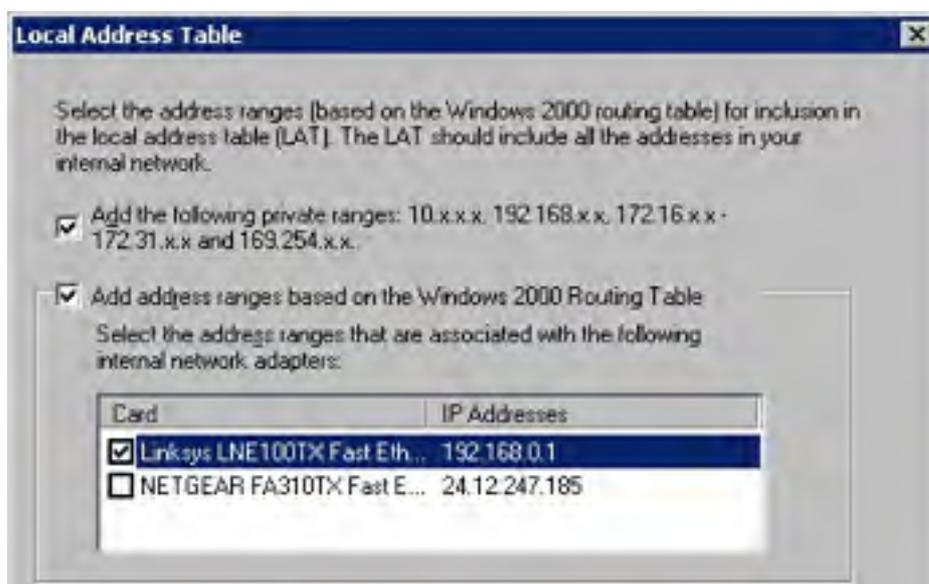

**Figure 31-6.** Specifying on which drives to store the Web cache.

13. The Server Setup Construct LAT dialog box appears, as shown in Figure 31-7. Here you can build the local address table (LAT). This table identifies which addresses are on your local network, and thus accessible through the network adapter connected to the internal company network. Addresses not located in the LAT are accessed using the network adapter connected to the external network (the Internet).

**Figure 31-7.** The Server Setup Construct LAT dialog box.

14. In the Edit box, type the range of addresses on the local network. You don't need to add any RFC 1918 privatized addresses—they'll be added automatically when you click Construct Table. Click Add after entering each range of addresses.
15. When you've added all the internal IP addresses, click Construct Table to open the Local Address Table dialog box shown in Figure 31-8.

**Figure 31-8.** *The Local Address Table dialog box.*

16. To add the private IP addresses automatically, select the Add The Following Private Ranges check box. To allow Windows to use the internal IP routing table, specify the network card(s) connected to the internal network (do *not* select the adapter connected to the Internet or external network). When you've made your selections, click OK.
17. A setup message appears, warning you that the automatically constructed LAT might include external addresses. Click OK again to return to the Server Setup Construct LAT dialog box in Figure 31-7.
18. Now you'll see the automatically configured LAT as ISA Server is about to construct it. Edit it to remove any external addresses from the table or any other errors you encounter. If any local addresses aren't showing, add them. When the table is correct, click OK.
19. Click OK to finish setup and start the ISA Server Getting Started Wizard, discussed in the next section.
20. Reconnect the ISA server to the Internet.

Until you run the ISA Server Getting Started Wizard, discussed in the section entitled [Initial Configuration](#) later in this chapter, no Internet connectivity exists for the network; internal clients can't access Internet Web sites, and Internet users can't access any Web servers you have on the internal network.

## Initial Configuration

ISA Server's default settings prohibit all Internet access, so to enable ISA Server, you need to change some settings. (Microsoft did this so that total security is ensured until you consciously allow access to the network.)

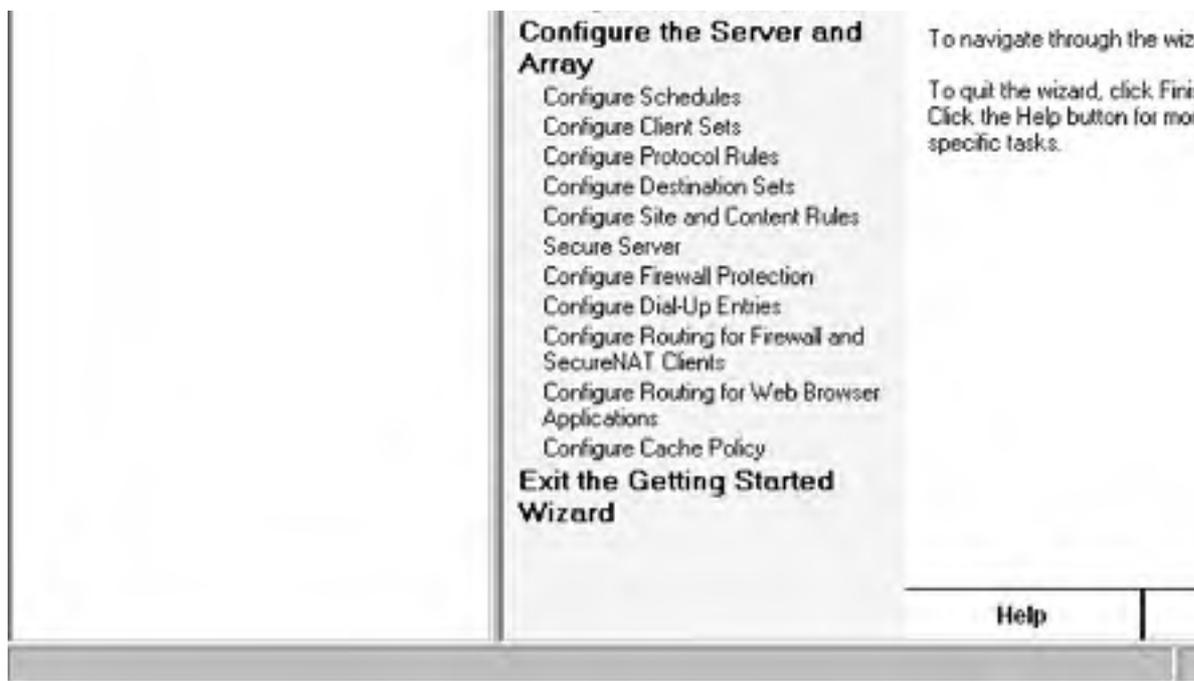

ISA Server provides the Getting Started Wizard to walk you through this initial setup. Table 31-3 describes the default settings of a freshly installed ISA server. For more complete control over the various aspects of ISA Server, use the console tree to locate the appropriate element, as described in the section entitled [Administering ISA Server](#) later in this chapter. The Getting Started Wizard provides an abbreviated list of options for each task.

**Table 31-3.** ISA Server postinstallation default settings

Feature	Default Setting
User permissions	Members of the Administrators group on the local computer can configure policies on stand-alone servers. Only members of the Domain Admins and Enterprise Admins groups can configure array and enterprise policies.
Enterprise Policy Settings	The default enterprise array policy is used for new arrays. Stand-alone servers don't use enterprise policies.
Access control	All clients are allowed access to all content on all sites, using the default site and content rule named Allow Rule. Setup fails to create this rule sometimes, so you should double-check this setting.
Packet filtering	Enabled, unless in cache-only mode.
Publishing	No internal servers (such as Web servers) are accessible from the Internet.
Protocol rules	No protocols are allowed through the firewall, effectively blocking all Internet access.
Routing	All requests from Web Proxy clients are retrieved directly from the Internet.
Caching	HTTP and FTP requests are cached, but active caching (prefetching content) is disabled.
Alerts	All alerts are enabled except All port scan attack, Dropped packets, Protocol violation, and User Datagram Protocol (UDP) bomb attack.

To open this wizard, launch the ISA Management console by clicking Start, pointing to Programs, then to Microsoft ISA Server, and choosing ISA Management. The following sections cover the various parts of the wizard. Click Next in the Getting Started screen to begin the wizard, shown in Figure 31-9, or click a heading to jump directly to that part of the wizard.

**Figure 31-9.** The Getting Started Wizard.

If you don't see the Getting Started Wizard or any links on the right side of the ISA Management console, you probably have the Taskpad view turned off. To turn it on, from the View menu, choose Taskpad.

ISA Server can be configured to reduce the likelihood that the Nimda and Code Red viruses will be transmitted into or out of the network. For more information, see <http://www.microsoft.com/isaserver/techinfo/prevent/default.asp> on the ISA Server Web site.

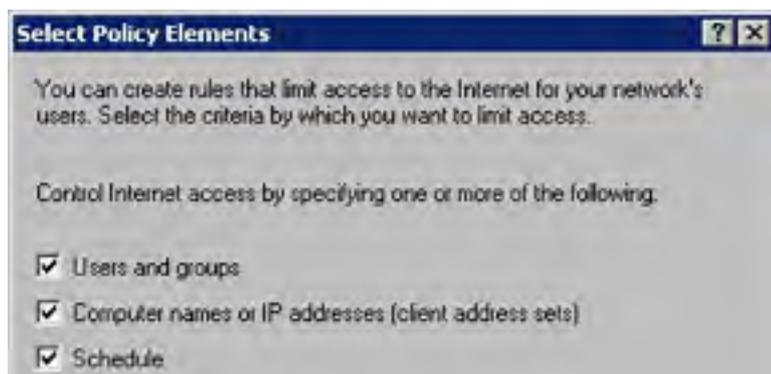

## Configuring Enterprise Policy

If you installed ISA Server as an array member, the Getting Started Wizard displays a number of headings you can use to configure the default policy for arrays in the enterprise.

These headings work identically to those discussed in the following sections; the only difference is that the settings you specify under the Configure Enterprise Policy heading apply to all arrays in the enterprise. The settings you specify under the Configure The Server And Array heading apply only to the server or array you're administering.

## Selecting Policy Elements

Click the Select Policy Elements link to display the Select Policy Elements dialog box shown in Figure 31-10. Use this dialog box to choose how to apply policies: by users and groups, by computer names or IP addresses, by schedule, or by destination IP address or domain name.

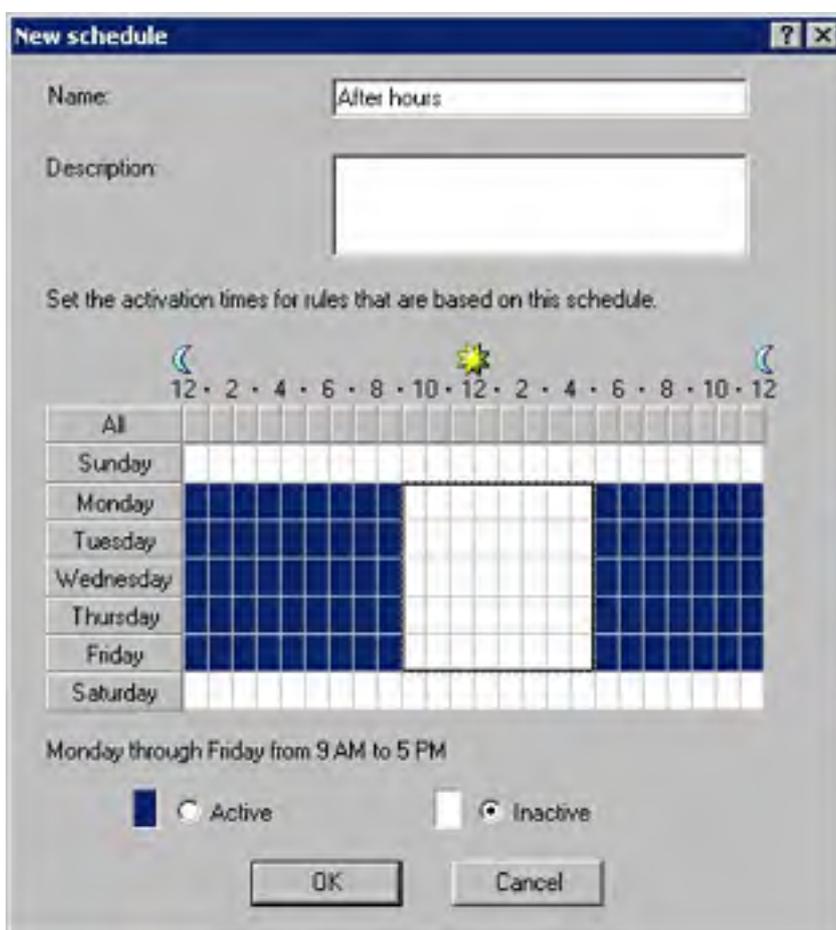

**Figure 31-10.** *Selecting policy elements to configure.*

## Configuring Schedules

Click the Configure Schedules link to set up or modify schedules (a type of policy element) that you can use when creating access rules. ISA Server automatically sets up a Work Hours schedule (9-5 Monday through Friday) and a Weekends schedule (all day Saturday and Sunday).

Double-click a schedule to modify it, or click the Create A Schedule link to create a new schedule, as shown in Figure 31-11. Click and drag the outline of a time block, and then select Active or Inactive to specify whether the schedule applies to the selected time period or not. Enter a name and optionally a description for the schedule and then click OK.

**Figure 31-11.** *Creating a new schedule.*

## Configuring Client Sets

Click Next or Configure Client Sets to create policy elements that define groups of internal network clients to which you can then apply rules. Click the Create Client Set link to open the Client Set dialog box, shown in Figure 31-12.

Create a new client set by clicking Add and entering the starting and ending IP addresses for the group of internal network clients. When you're finished adding IP address sets, enter a name and optionally a description for the group of clients, and then click OK.

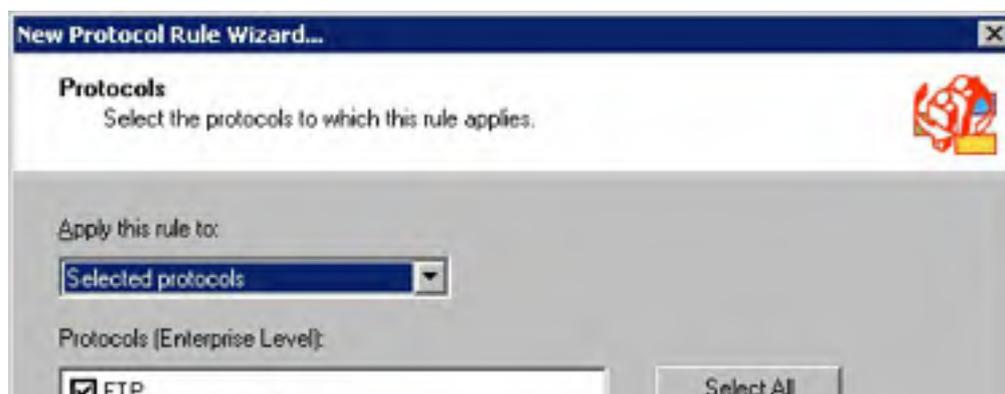

Figure 31-12. Creating a client set.

## Configuring Protocol Rules

To enable clients access to the external network (which is most likely the Internet), you need to specify which protocols clients can use to access the external network. To do so, click Next or the Configure Protocol Rules link, and then use the following steps to create a protocol rule, a type of policy:

1. Click the Create A Protocol Rule For Internet Access link to enable internal clients to use the HTTP, HTTPS, FTP, and Gopher protocols, or click the Create A Protocol Rule link to enable other protocols. This opens the New Protocol Rule Wizard.
2. Enter a name for the new protocol rule in the first screen of the New Protocol Rule Wizard and then click Next.
3. In the Protocols screen shown in Figure 31-13, choose All IP Traffic in the Apply This Rule To list box to allow clients to use any IP protocol to access the Internet, or choose Selected Protocols or All IP Traffic Except Selected Protocols to limit access by protocol. Select the protocols and then click Next. Clear the Show Only Selected Protocols check box to display all protocols for which ISA Server has protocol definitions.

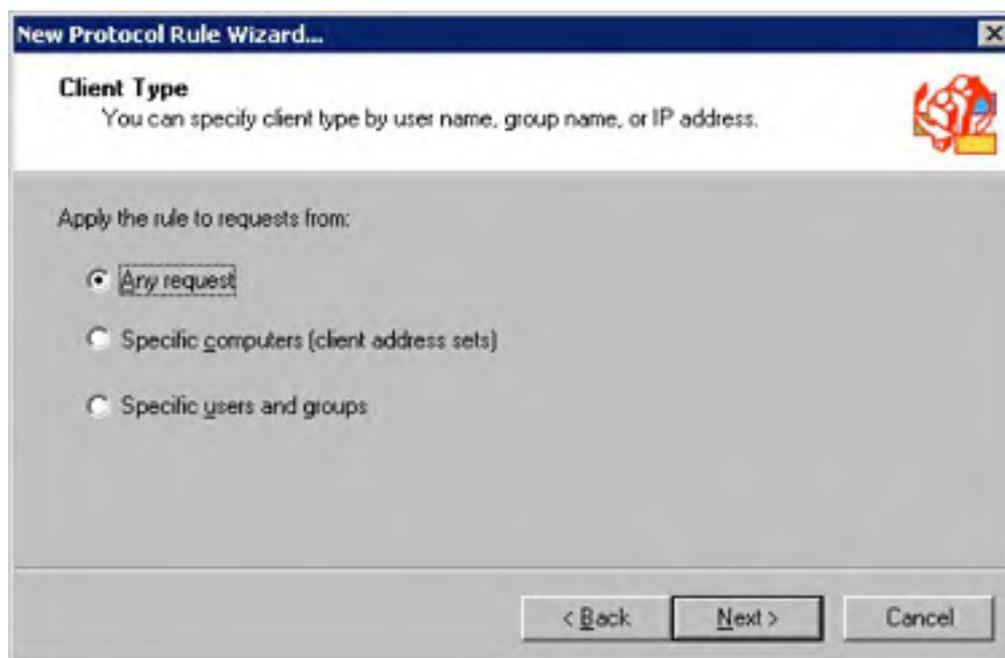

**Figure 31-13.** Selecting protocols to allow clients to use.

A good way to configure ISA Server is to initially allow all protocols, and then create rules to deny those protocols that you know users don't need. This reduces the need to open ports later for different services such as Microsoft NetMeeting, Windows Media, and instant messaging clients.

4. To permit the use of these protocols only during certain time periods, select a schedule from the Use This Schedule drop-down list box and then click Next.
5. In the Client Type screen shown in Figure 31-14, choose whether to apply the protocol rule to all requests, only requests from certain computers (client address sets), or certain user groups. Choose the appropriate option and then click Next.

**Figure 31-14.** Specifying to which clients the rule applies.

6. If you chose to apply the rule to client address sets, click Add in the next screen to select client address sets to which to apply the protocol rule. Click OK and then click Next when you're finished.
7. If you chose to apply the rule to certain Windows user groups, click Add in the Users And Groups screen and then use the standard Select Users And Groups dialog box to specify the appropriate Windows user groups. Click OK and then click Next when you're finished.

Applying a protocol rule to certain users or groups excludes non-Windows clients from the protocol rule. If you don't then create a protocol rule that either applies to all requests or to client address sets containing the non-Windows clients on the network, these clients won't be able to access the Internet or external network.

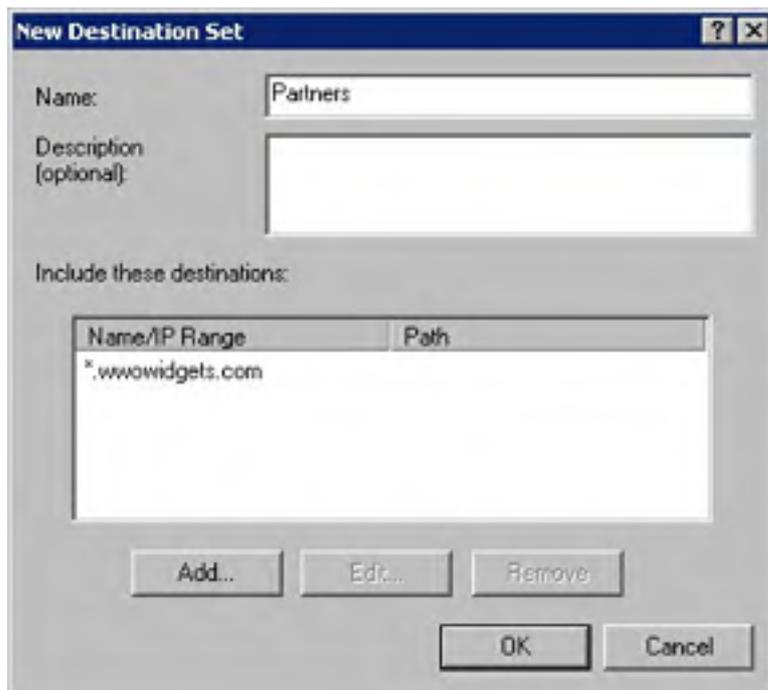

8. Review the summary of the settings you specified, and then click Finish to create the protocol rule.

## Configuring Destination Sets

You can use destination sets to group computers on the Internet together. You can optionally apply rules to these destination sets to control such things as site and content rules, bandwidth rules, Web publishing rules, and routing rules.

To create destination sets, click the Configuring Destination Sets link, and then use the following steps:

1. Click the Create Destination Set link to open the New Destination Set dialog box, shown in Figure 31-15.

**Figure 31-15.** Creating a new destination set.

2. Enter a name for the destination set, and then click Add to display the Add/Edit Destination dialog box, shown in Figure 31-16.

**Figure 31-16.** Adding destinations to a destination set.

3. To add computers or domains by their DNS name, select the Destination option and enter the host name in the box provided, or click Browse to search Active Directory. To specify all computers in a domain, enter an asterisk, followed by the desired domain name, for example, \*.wwwowidgets.com.
4. To specify a range of IP addresses, select the IP Addresses option and enter the beginning and ending IP addresses in the boxes provided.
5. To specify a particular path, enter the path in the Path box. To include all files in a folder, enter the path followed by an asterisk, for example /Inetpub/wwwroot/\*.
6. Click OK when you're finished, add any additional destinations to the destination set, and then click OK to close the destination set.

## Configuring Site and Content Rules

You can use site and content rules to limit which Web sites and content the network clients can access. By default, ISA Server allows access to all content and sites once you've created a protocol rule permitting clients to actually reach the sites.

Our testing indicates that there are some instances when the default Allow Rule isn't created, thereby preventing all Internet access even when the proper protocol rules are in place. Check the enterprise policy and array and stand-alone server configuration if in doubt.

To create additional rules limiting access by destination set, schedule, or client set, use the following procedure:

1. Click the Configure Site And Content Rules link in the Getting Started Wizard.
2. Enter a name for the rule in the first screen of the wizard and then click Next.
3. Choose whether the rule should allow access or deny access to content. If the rule is denying access, optionally select the check box shown in Figure 31-17 to redirect requests to another Web page, such as a page stating your company's Web surfing policy. Click Next to continue.

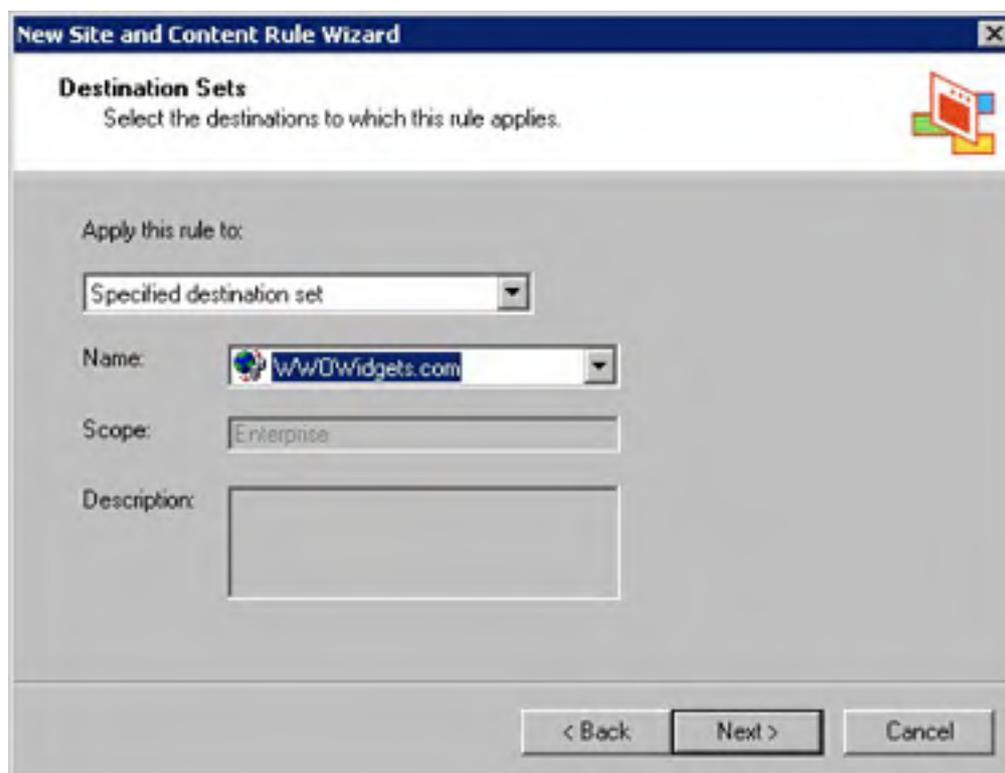

**Figure 31-17.** *Creating a site and content rule.*

Be careful not to create conflicting or overlapping rules. In the event of overlapping rules, the more restrictive rule is used.

4. In the next screen, choose the destinations to which to apply this rule. To use a destination set you created earlier, choose Specified Destination Set or All Destinations Except Selected Set from the drop-down list box, and then choose the appropriate set from the Name drop-down list box that appears, as shown in Figure 31-18. Click Next to continue.

**Figure 31-18.** *Specifying which destinations to include in the rule.*

5. In the Schedule screen, select a schedule to use for the rule and then click Next.
6. In the Client Type screen, choose which clients to process in this rule. Choose Any Request to apply the rule to all clients, Specific Computers to apply the rule to a client address set you created earlier, or Specific Users And Groups to apply the rule to particular user groups. Click Next to continue.
7. Review the summary of the settings you chose, and then click Finish to create the site and content rule.

## Securing Your Server

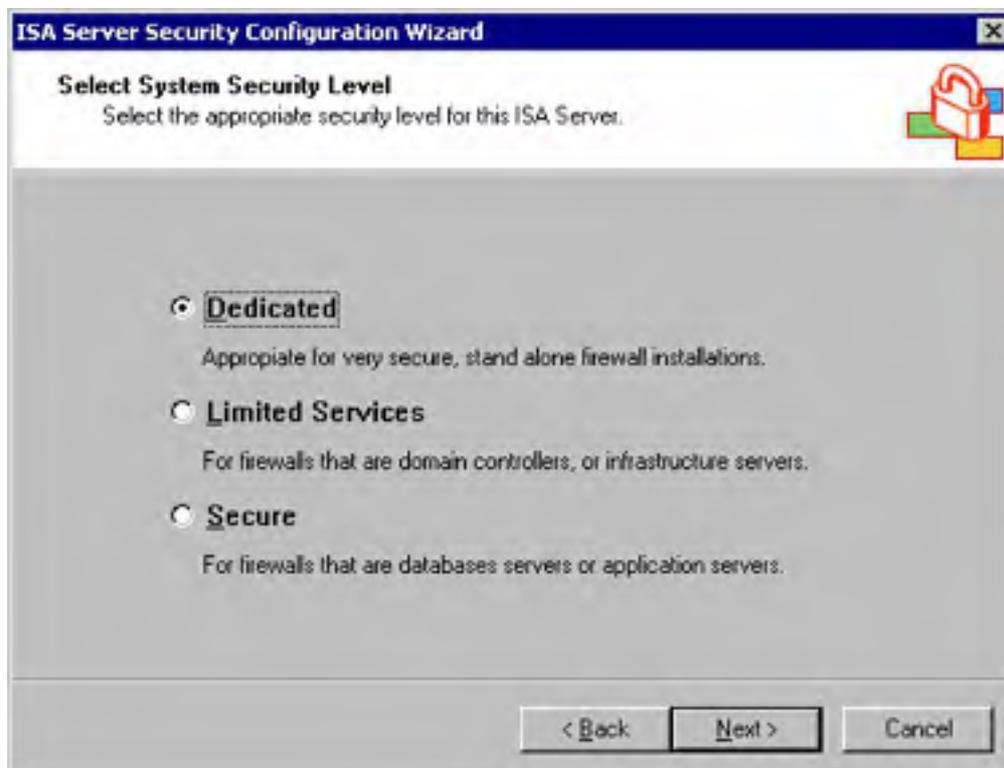

The default security settings for Windows are not appropriate for an ISA server that will be exposed to potential attacks on the Internet. For this reason, Microsoft provides the ISA Server Security Configuration Wizard to walk you through locking down Windows. To use this wizard, follow these steps:

1. Click the Secure Server link in the Getting Started Wizard.
2. Click the Secure Your ISA Server Computer link to begin the ISA Server Security Configuration Wizard.
3. Click Next in the first screen, choose the appropriate security level as shown in Figure 31-19, and then click Next:
  - **Dedicated** This is the highest security option. This option prevents any

functionality other than ISA Server's firewall service (this means no caching as well). To provide caching with your ISA server, don't use this setting.

- **Limited Services** This is the medium security option (best for most networks). This option is appropriate for servers that are firewall and caching servers or domain controllers.
- **Secure** This is the least secure setting. This option is appropriate for servers that also act as database, Web, or mail servers.

**Figure 31-19.** Securing an ISA server.

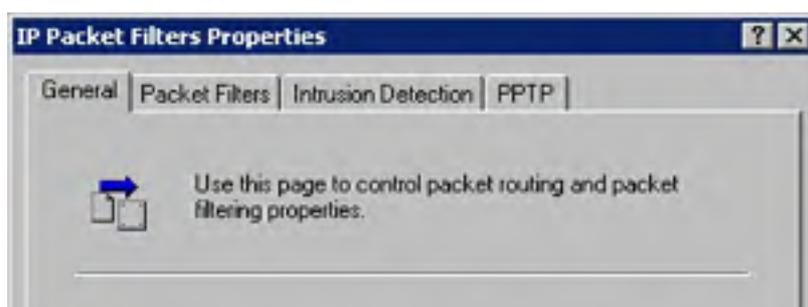

4. Review your choice and click Finish to implement the security changes.

Security level changes you make using the ISA Server Security Configuration Wizard are difficult to undo, and they might impact applications that require low security levels to run. This isn't a reason not to lock down your server, but it is a reason to test the functionality of other server applications after running the wizard.

## Configuring Firewall Protection

A key security component of ISA Server is its packet filtering capabilities. To modify packet filtering settings, use the following procedure:

1. Click the Configure Firewall Protection link in the Getting Started Wizard.
2. Click the Configure Packet Filtering And Intrusion Detection link to open the IP Packet Filters Properties dialog box, shown in Figure 31-20.

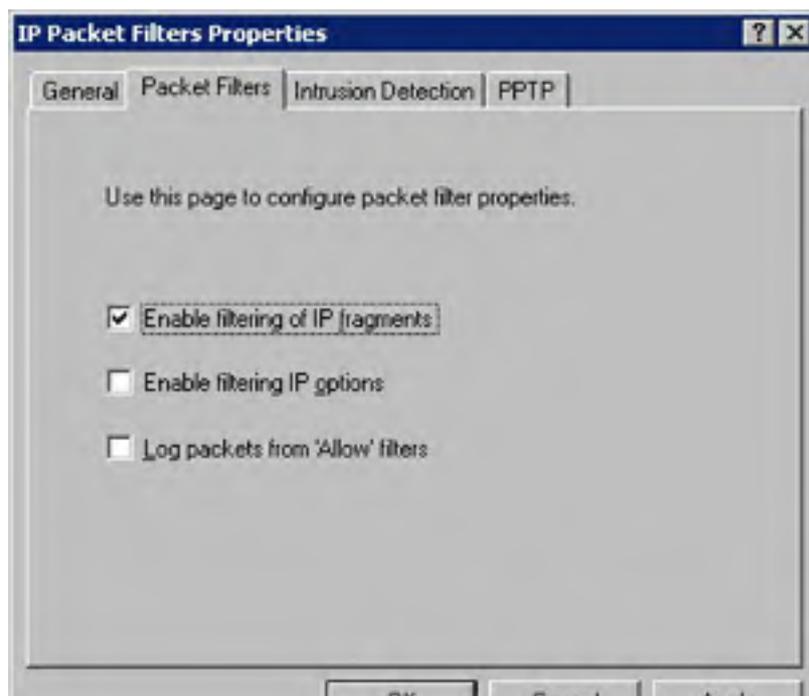

**Figure 31-20.** Configuring packet routing and packet filtering properties.

3. To toggle packet filtering on or off (it's on by default), use the Enable Packet Filtering check box. Individual packet filters are configured from the IP Packet Filters folder in the ISA Management Console tree, as discussed later.
4. Select the Enable Intrusion Detection check box to enable ISA Server to generate an alert when an attempt is made to hack into your network or bring down the server.
5. Select the Enable IP Routing check box to enable ISA Server to route non TCP-UDP-based packets from the internal network to the external network (most likely the Internet).

If you don't enable IP routing, internal clients won't be able to use the Ping, Tracert, or Pathping utilities. Additionally, outbound PPTP connections are disabled as well. Note, though, that the Ping tool only functions with SecureNAT clients; Firewall clients need to disable the Firewall client software to use Ping.

6. Click the Packet Filters tab to enable or disable filtering of fragmented IP packets or packets with IP options, as shown in Figure 31-21. You can also enable the logging of packets that are allowed to pass through the ISA server here.

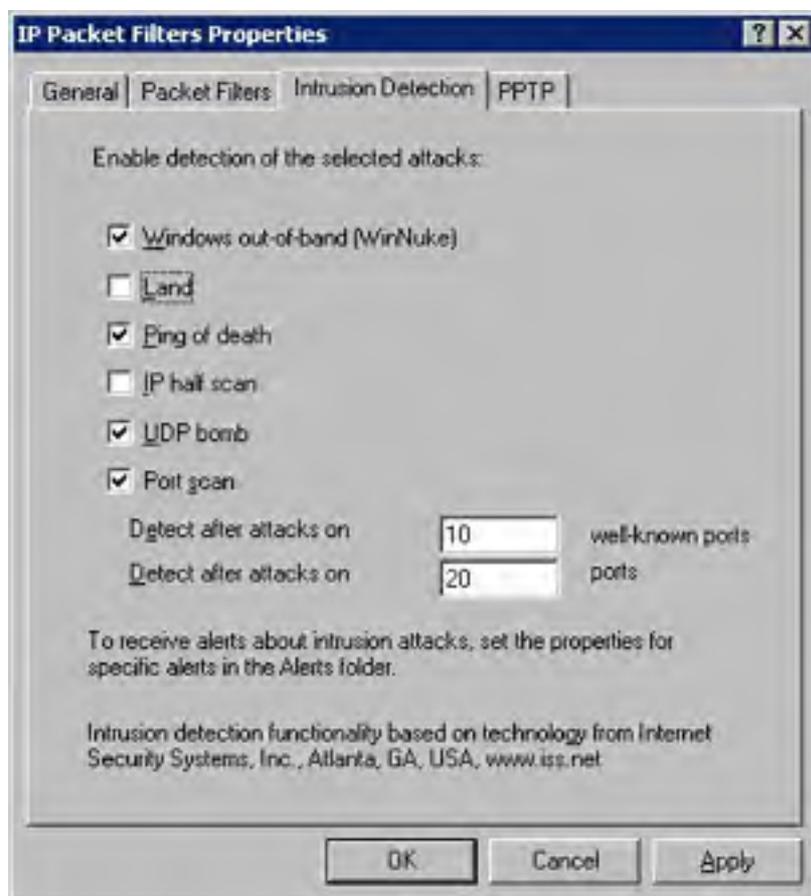

Don't enable filtering of fragmented IP packets if you use streaming audio or video across the ISA server.

**Figure 31-21.** Configuring packet filtering.

7. Click the Intrusion Detection tab to enable the logging of frequently used attacks such as the ping of death or port scanning, as shown in Figure 31-22 (the Intrusion Detection check box must be selected in the General tab to enable any of these options).

**Figure 31-22.** Enabling intrusion detection.

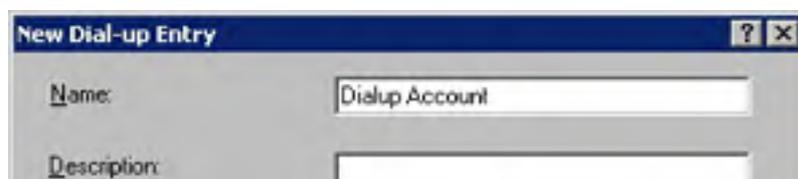

8. To enable virtual private networking with the PPTP protocol to work with ISA Server, click the PPTP tab and select the PPTP Through ISA Firewall check box.
9. Click OK when you're finished configuring the packet filtering options.

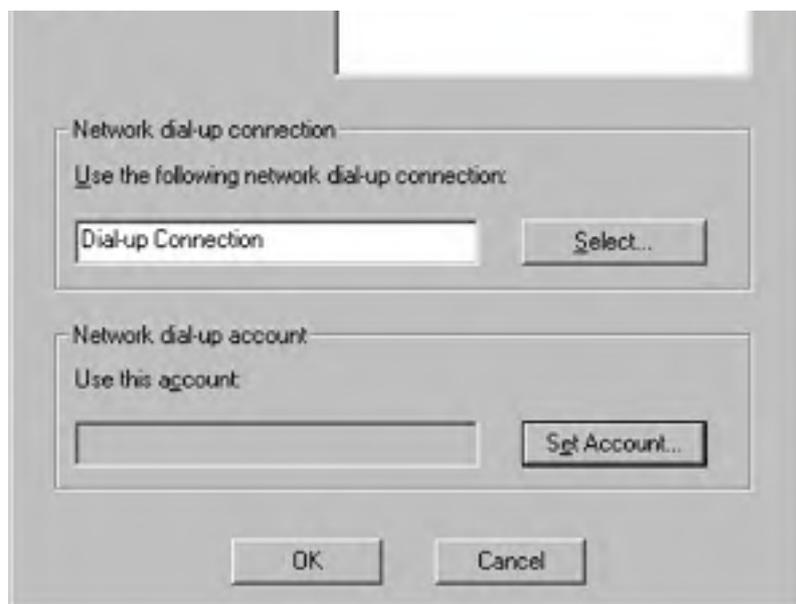

## Configuring Dial-Up Entries

ISA Server provides the ability to use dial-up connections to provide Internet access to clients.

To set up ISA Server to use a dial-up connection as the primary network connection, use the following steps:

1. Click the Configure Dial-Up Entries link in the Getting Started Wizard.
2. Click the Create A Dial-Up Entry link. Click Yes when asked to make the dial-up entry the default.
3. Enter a name for the dial-up entry, and then click Select to choose the dial-up account to use, as shown in Figure 31-23. Note that you must create the dial-up entry in the Windows 2000 Network And Dial-Up Connections folder before you can use it in ISA Server.

**Figure 31-23.** Configuring a dial-up entry.

4. Click Set Account to enter the user name and password for the dial-up entry. Click OK when finished.

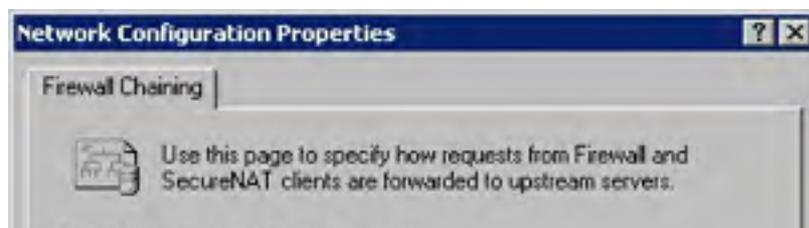

ISA Server automatically establishes a connection as needed, as long as you don't have a default gateway specified on any network card in the ISA server. Also note that ISA Server probably won't hang up a connection once established, so make sure that you want to be connected continuously before using a dial-up link with ISA Server.

## Configuring Routing for Firewall and SecureNAT Clients

The Configure Routing For Firewall And SecureNAT Clients link allows you to specify how requests from Firewall and SecureNAT clients are routed: either directly to the Internet using ISA Server, or using an upstream server such as another ISA server or Microsoft Proxy Server 2.0.

To modify these routing settings, use the following steps:

1. Click the Configure Routing For Firewall And SecureNAT Clients link in the Getting Started Wizard.
2. Click the Configure Firewall Routing link.
3. Use the Network Configuration Properties dialog box shown in Figure 31-24 to specify how to route incoming Firewall and SecureNAT client requests:
  - **Use Primary Connection** This option retrieves content directly from the Internet.
  - **Use Dial-Up Entry** This check box uses the active dial-up entry to retrieve content from the Internet.
  - **Chain To This Computer** This option forwards requests to the computer you specify in the box provided (or choose using the Browse button). Optionally specify the appropriate account to use to connect to the upstream server or specify to use a dial-up connection.
4. Click OK when finished.

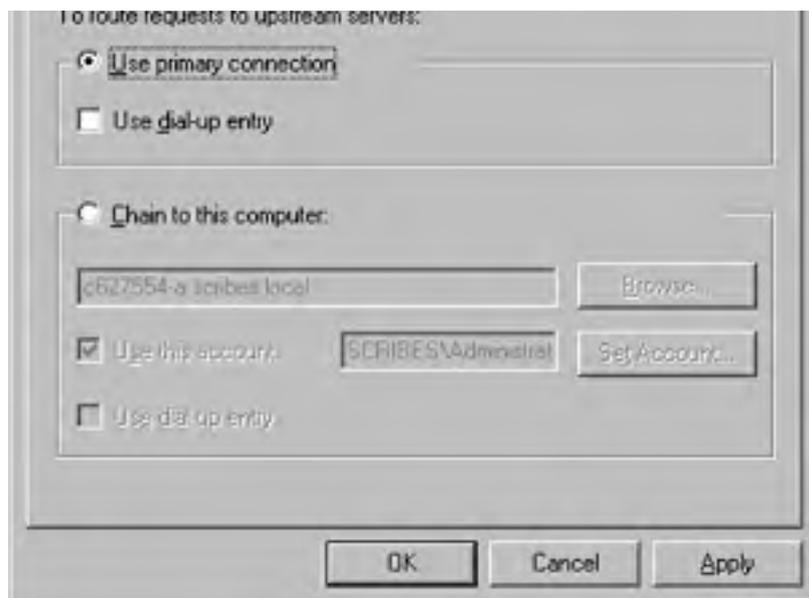

Figure 31-24. Modifying firewall routing properties.

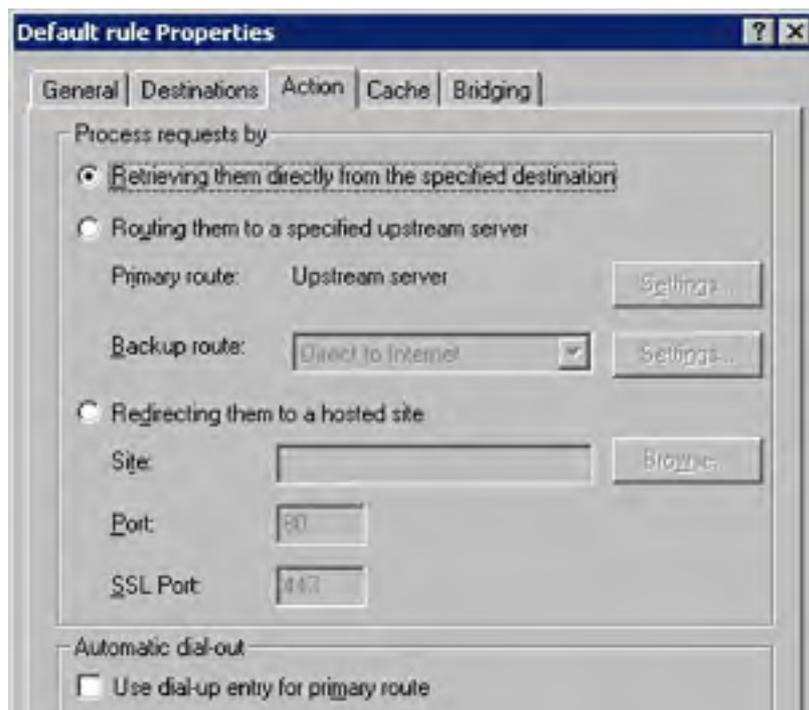

## Configuring Routing for Web Browser Applications

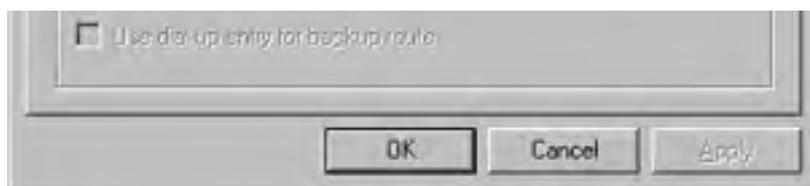

Most companies use the default routing rule for Web Proxy clients (any client using a Web browser configured to use the ISA server as the proxy server). This rule automatically routes requests for Web pages to the Internet if the requested page isn't available from ISA Server's cache.

However, you can also set up ISA Server to route Web Proxy client requests to an upstream server, or create multiple rules to route clients differently based on the destination set of the request.

To configure routing for Web proxy clients, use the following steps:

1. Click the Configure Routing For Web Browser Applications link in the Getting Started Wizard.
2. Click the Configure A Routing Rule For Web Browser Applications link.
3. Specify how Web browser clients should be routed, as shown in Figure 31-25, and then click OK.

**Figure 31-25.** Configuring routing for Web browser applications.

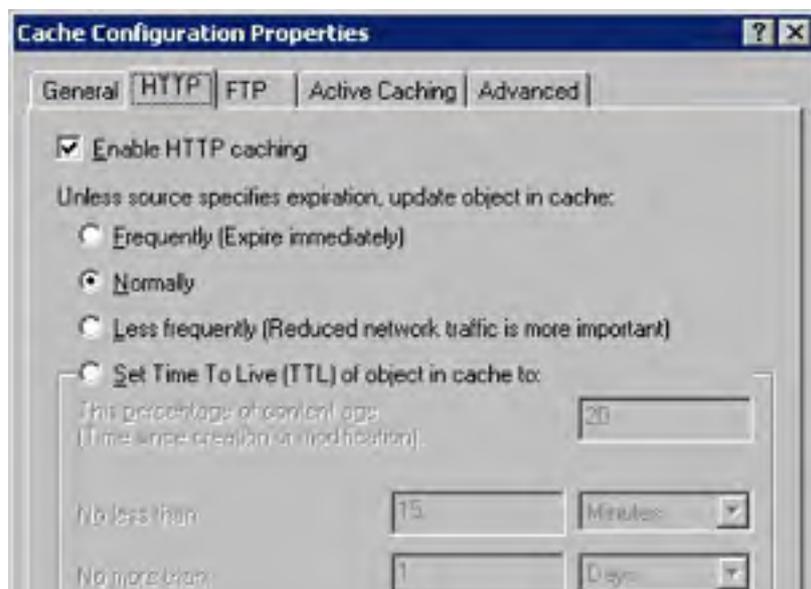

If clients frequently access your company's own Web site, you can create a routing rule that routes requests for your company's external Web site directly to your company's internal Web site or intranet. To do this, first create a destination set containing the desired Web site or Web sites (destinations). Then click the Routing folder in the ISA Management console tree, choose the New Rule command from the Action menu, and use the wizard to create a new routing rule.

## Configuring Cache Policy

Although you configure the size and location of ISA Server's cache during installation, there are some additional configuration steps that you should take to ensure that ISA Server provides optimal performance for your network:

1. Click the Configure Cache Policy link in the Getting Started Wizard.
2. Click the Configure Cache Policy link. This displays the General tab of the Cache Configuration Policy dialog box, which lists the total cache size.
3. Click the HTTP tab to configure how long Web pages are stored in ISA Server's disk cache, as shown in Figure 31-26. Use the options listed next, or clear the Enable HTTP Caching check box to disable the caching of Web pages (not recommended):
  - **Frequently (Expire Immediately)** Refreshes cached Web pages frequently (but not immediately, as indicated by the label).
  - **Normally** Provides a balance between frequently updating cached content and conserving bandwidth by infrequently updating content. Use this setting, which appropriately enough, is the default.
  - **Less Frequently (Reduced Network Traffic Is More Important)** Conserves network bandwidth by updating cached Web pages less frequently. This setting is most appropriate for networks with slow or expensive Internet connections.

Some Web pages have a Time to Live (TTL) setting, which overrides the settings you make here. This permits dynamic Web pages to work properly without presenting users with stale data.

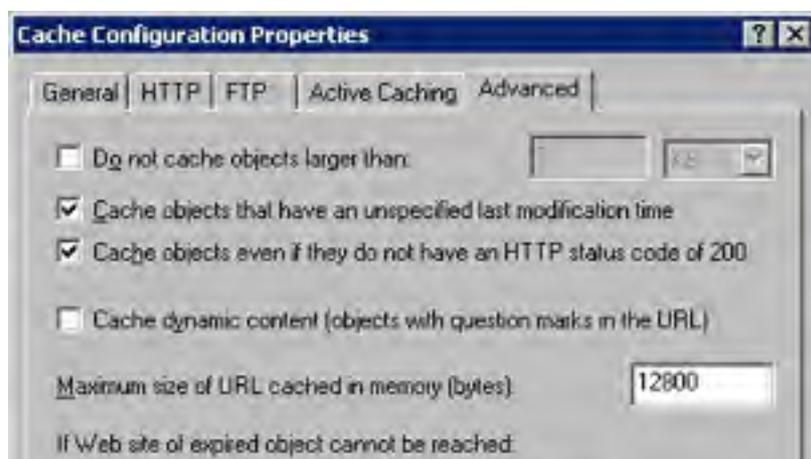

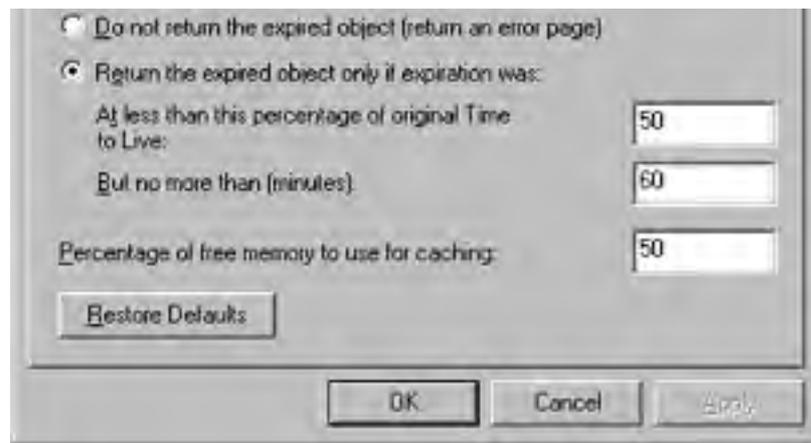

**Figure 31-26.** Configuring caching for Web pages.

4. Click the FTP tab to specify how long to cache FTP objects. The default setting is 1440 minutes (24 hours), but because FTP objects aren't usually updated very frequently, you can increase this so that large objects such as programs and software patches remain cached longer.
5. Click the Active Caching tab to enable active caching, which is highly recommended. Choose an option corresponding to how aggressively ISA Server should perform active caching:
  - **Frequently** Provides the fastest perceived performance for clients, but utilizes the most network bandwidth. If your Internet connection has plenty of unused bandwidth, choose this setting.
  - **Normally** Balances client performance with network usage. This is a good setting for networks with an Internet connection that is under medium levels of load.
  - **Less Frequently** Updates the cache less frequently, which provides less performance boost for clients but also uses less network bandwidth. This setting is appropriate for networks that need to conserve precious Internet bandwidth for applications other than Web browsing.

Active caching permits ISA Server to preemptively go to the Internet and update frequently accessed Web pages. Then when a client requests the Web page, the latest version is already available from the ISA Server cache.

6. Click the Advanced tab to modify other cache policy settings, as shown in Figure 31-27:
  - Click the Do Not Cache Objects Larger Than check box to set an upper limit on the size of cached objects. In general you should avoid using this setting, unless you need to conserve hard disk space on your ISA servers (better to purchase additional hard disks rather than to do this).
  - In the Maximum Size Of URL Cached In Memory box, enter the maximum object size that ISA Server should cache in RAM (larger objects are cached only on the hard drive to conserve RAM usage).
  - In the If Web Site Of Expired Object Cannot Be Reached section, specify what ISA Server should do if a client requests an object that is expired but can't be refreshed because the Web site is inaccessible.
  - In the Percentage Of Free Memory To Use For Caching box, enter the percentage of available RAM to use as a RAM cache. The RAM cache provides even faster client response than possible with the slower hard disk cache.

**Figure 31-27.** *Configuring other cache settings.*

7. Click OK when finished.

#### **More Info**

To change the size of the ISA Server cache or on which drives it is located, see the section entitled [Changing Cache Properties](#) later in this chapter.

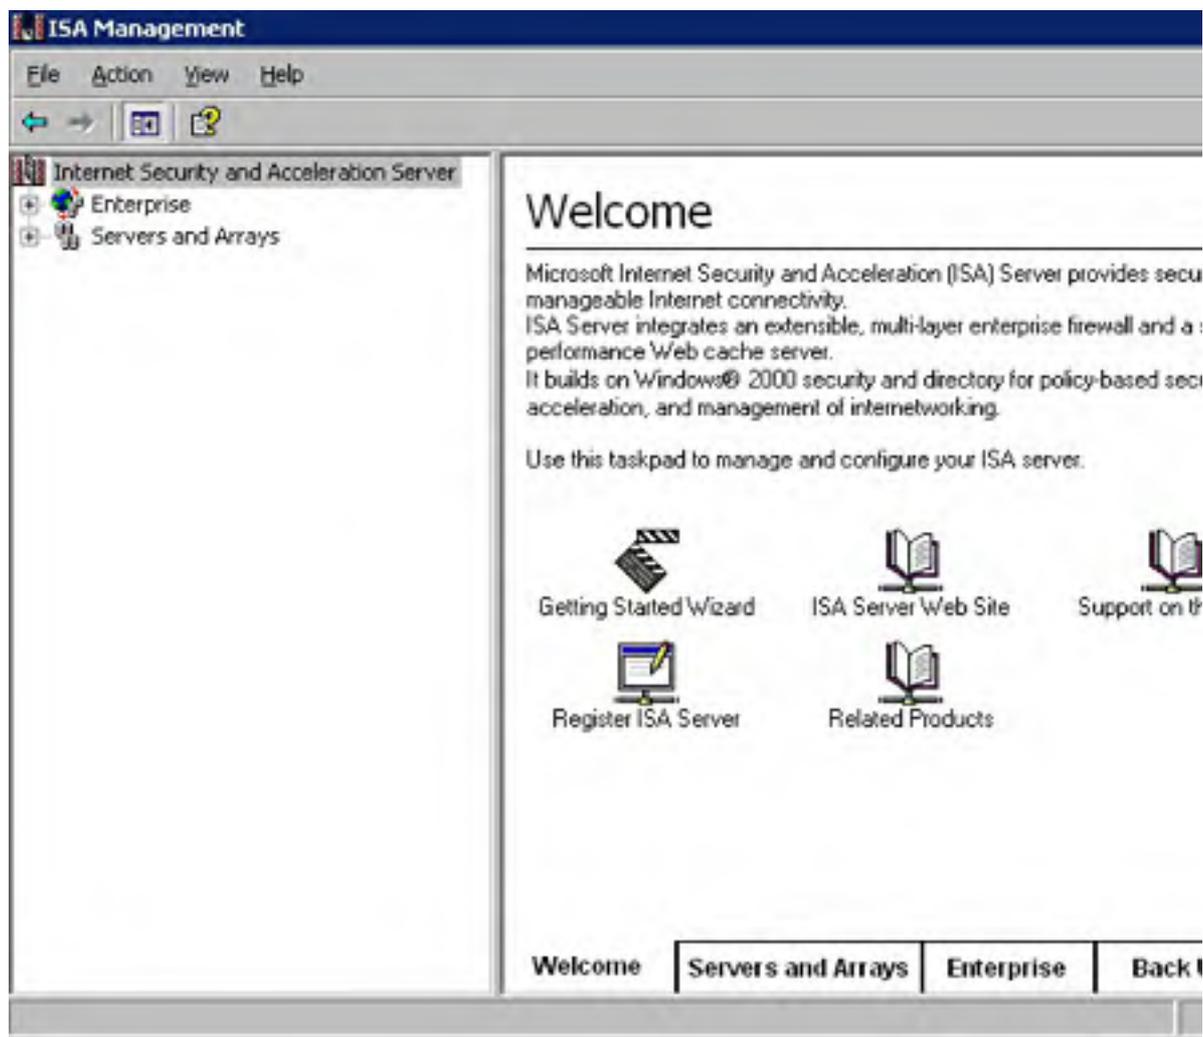

## Administering ISA Server

The only way to administer ISA Server is by using the ISA Management MMC snap-in, but unfortunately there are no command prompt administration tools provided.

However, the ISA Management console is a pretty nifty tool for administering ISA Server. It provides three ways of navigating administrative tasks:

- Using the Getting Started Wizard
- Using the taskpad (Web-like interface on the right side of the console, shown in Figure 31-28)
- Using the console tree to locate the exact part of ISA Server to administer as if you were using Windows Explorer

**Figure 31-28.** The ISA Management window.

We discuss how to accomplish most tasks in the section entitled [Initial Configuration](#) earlier in this chapter, so we won't repeat those instructions here. The same settings are available from the console tree (described next and in the following sections) as from the wizard, so for most tasks, we refer you to the [Initial Configuration](#) section.

All three methods lead you to the same settings, and are somewhat complementary, so how you decide to access settings is up to you. After initial configuration, we usually navigate using the console tree, and then use the taskpad to accomplish the desired task, so this is how we'll instruct you for the rest of the chapter.

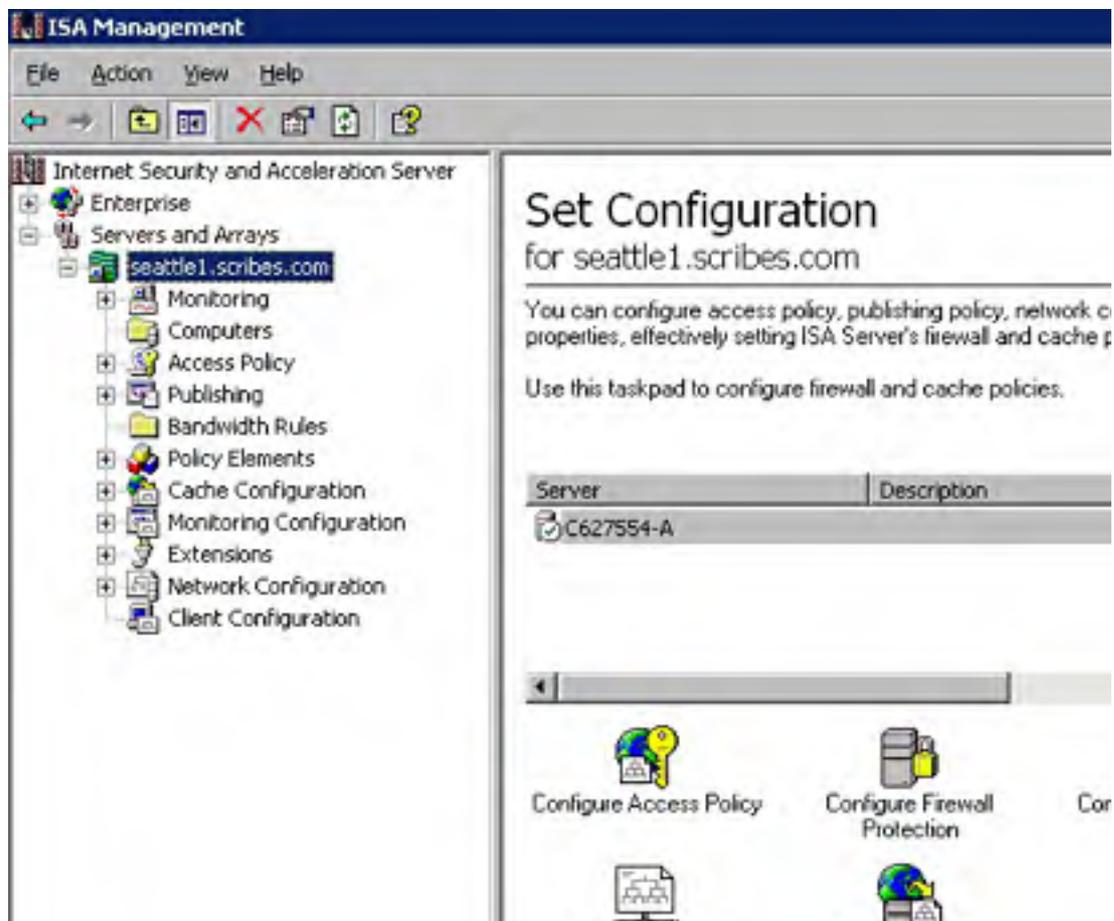

To work with the ISA Management snap-in, use the following procedure:

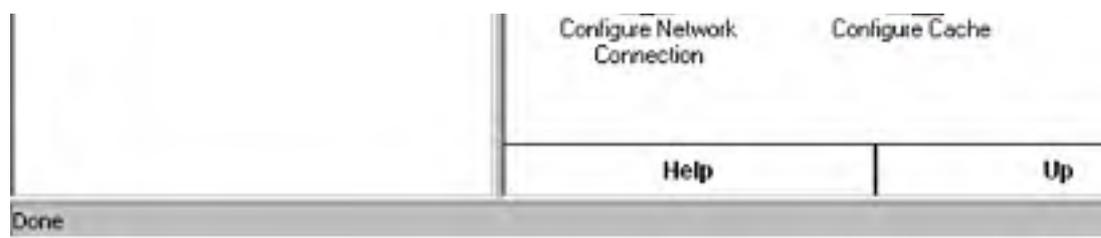

1. Launch the ISA Server snap-in by clicking Start, pointing to Programs, pointing to Microsoft ISA Server, and then choosing ISA Management.
2. If you're not already connected to the desired ISA server, click the Internet Security And Acceleration Server icon at the top of the console tree, choose Connect To from the Action menu, and enter the name of the server to which to connect.

To remotely administer an ISA server, you can either install the ISA Management tools on the desired computer using the ISA Server installation CD, or you can use a Terminal Services connection to remotely control the ISA server (this is discussed in [Chapter 26](#)).

If you don't see the taskpad on the right side of the ISA Management console, you probably have the Taskpad view turned off. To turn it on, choose Taskpad from the View menu.

3. To configure enterprise policies, expand the Enterprise container in the console tree and use the Policies container to create, edit, and delete enterprise policies, or use the Policy Elements container to modify the policy elements available for your policies.
4. To administer a specific server or array, expand the Servers And Arrays container, and then select the desired server or array. A few common tasks are listed in the taskpad, as shown in Figure 31-29. To change additional settings, navigate to the desired setting under the server or array.

**Figure 31-29.** An array displayed in the console tree and taskpad.

You can use the tabs at the bottom of the taskpad to navigate, as well as to display related tasks. When you navigate using the taskpad, the console tree is updated to reflect your new position in the console tree.

## Administering Arrays

As discussed earlier in this chapter, you can group a number of computers running ISA Server Enterprise Edition together into an array. These computers then appear to clients as a single server, and they can also be centrally administered.

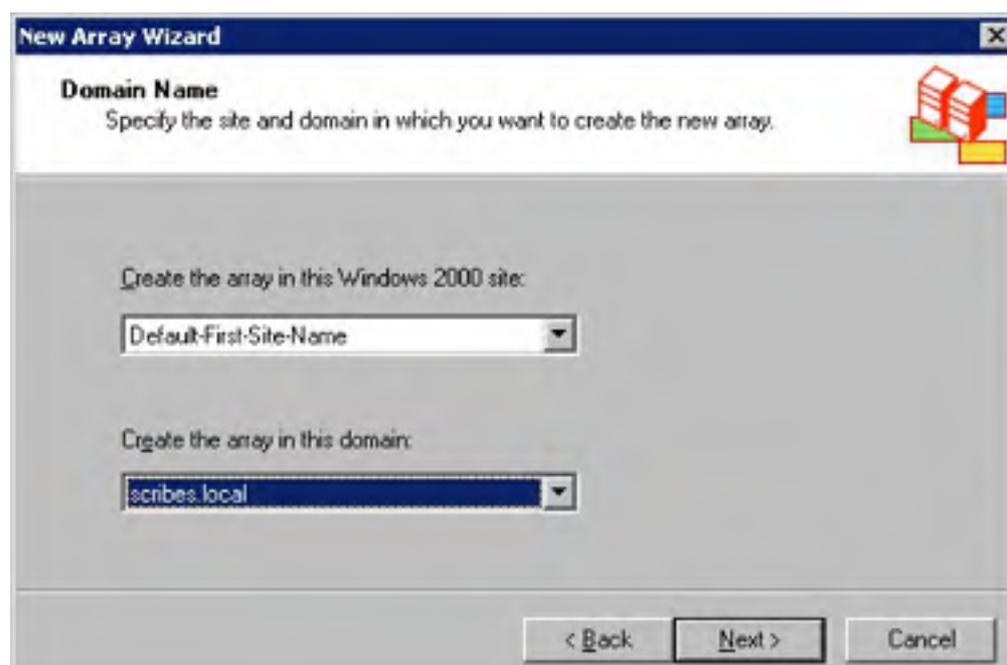

The following sections show you how to create new arrays, as well as add servers to an existing array.

Before you can use arrays on your network you need to install the ISA Server schema into Active Directory. To do so, see the section entitled [Enterprise Initialization](#) earlier in this chapter.

## Creating New Arrays

To create a new array, use the following procedure:

1. On an ISA server that belongs to an array, open the ISA Management MMC snap-in and select Servers And Arrays from the console tree.
2. Choose New-Array from the Action menu.
3. In the first screen of the New Array Wizard, enter a unique name for the array (you should use a fully qualified domain name to ensure uniqueness), and then click Next.
4. Choose which site and domain in which to locate the array, and then click Next, as shown in Figure 31-30.

**Figure 31-30.** Specifying to which array the site and domain should belong.

Unfortunately you can't create a new array using the ISA Management snap-in on a remote machine. To remotely create a new array, use Windows 2000 Terminal Services facilities.

5. In the next screen, choose the Create A New Array option to create a new array, or choose the Copy This Array option and select an existing array to copy settings from, and then click Next (if you chose to copy settings from an existing array, click Finish in the next screen to complete the wizard).
6. In the next screen (shown in Figure 31-31), leave the Use Default Enterprise Policy Settings option selected. Alternatively, select the Do Not Use Enterprise Policy option to use only array policies, or Use Custom Enterprise Policy Settings and then select the desired policy. Click Next to continue.

**Figure 31-31.** Choosing how to apply enterprise policies to the new array.

7. If you chose to use a custom enterprise policy, select Allow Publishing Rules to enable arrays to publish (make available to the Internet) Web servers and other servers. Also choose whether to select Force Packet Filtering, which forces the array to use packet filtering. Click Next to continue.
8. Choose which mode of ISA Server to use: Firewall Mode for security purposes only, Cache Mode for Internet acceleration purposes only, or Integrated Mode, which provides security and acceleration services (the recommended mode). Click Next to continue.
9. Review the array settings and then click Finish.

### Promoting Stand-Alone Servers to Become Arrays

You can easily promote a stand-alone server to become a member of a new ISA Server array. To do so, follow these steps:

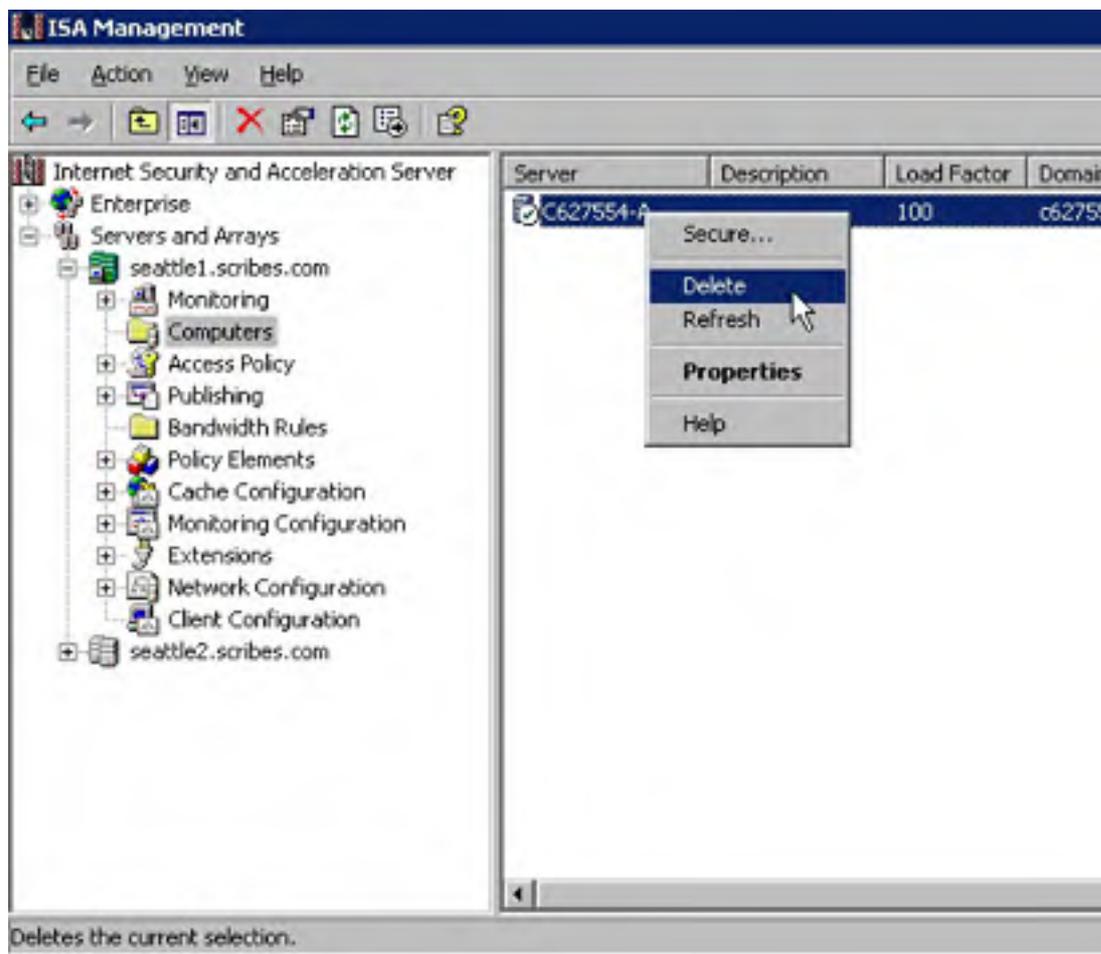

1. Open the ISA Management MMC snap-in, right-click the stand-alone server in the console tree that you want to promote, and then choose Promote from the shortcut menu.
2. Click Yes when asked if you're sure (assuming you are sure).
3. In the next screen, leave the Use Default Enterprise Policy Settings option selected. Alternatively select the Do Not Use Enterprise Policy option to use only array policies, or Use Custom Enterprise Policy Settings to select a specific policy. Click Next or OK to continue the promotion.

4. If you chose to use a custom enterprise policy, select Allow Publishing Rules to enable arrays to publish (make available to the Internet) Web servers and other servers. Also choose whether to force the array to use packet filtering. Click OK to promote the server.

## Removing Servers from an Array

To remove a server from an array, use the following steps:

1. Open the Computer container in the console tree under the desired array's name.
2. Right-click the server to be removed and then choose Delete from the shortcut menu, as shown in Figure 31-32.

**Figure 31-32.** Removing a computer from an array.

3. To completely remove ISA Server from the deleted array member, uninstall the software using Add/Remove Programs in Control Panel.

## Publishing Internal Servers to the Internet

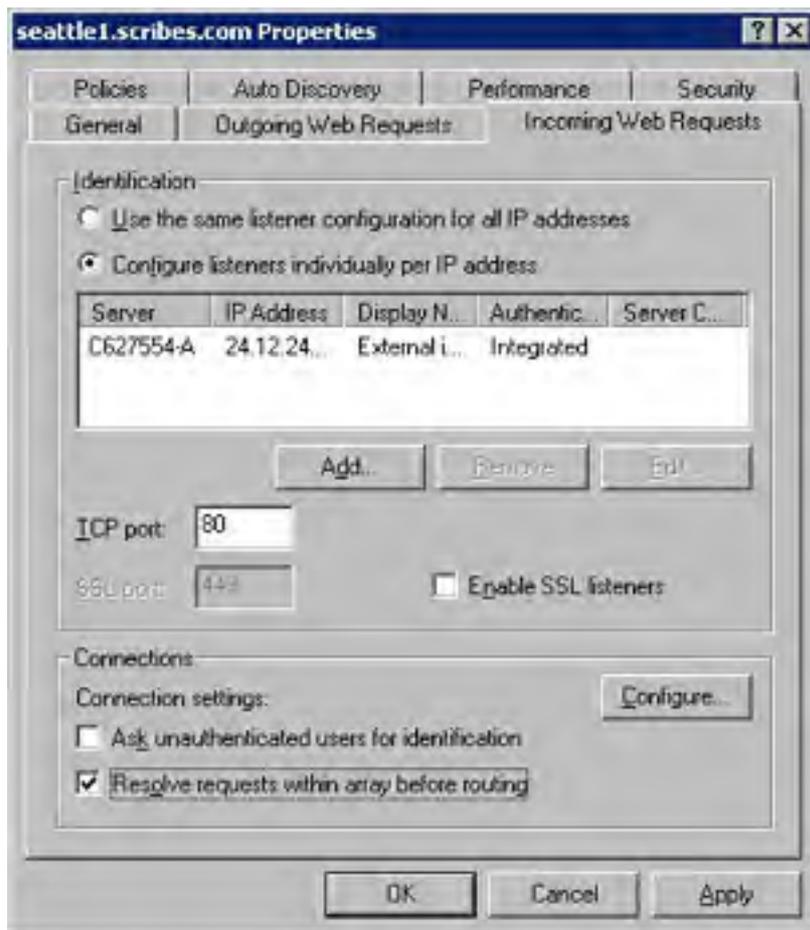

To allow users on the Internet to access servers on your internal network, such as your Web server or e-mail server, you need to "publish" them with ISA Server. When you do this, you create a mapping that transfers external requests through the ISA server to the specific computer and service you specify on your internal network. This maximizes the security of your network while still allowing external clients access to the servers you want to make publicly available.

## Permitting Incoming Requests and Enabling Reverse Caching

Before you can publish servers to the Internet, you need to set up ISA Server to permit incoming requests (by default all incoming requests are denied). To do so, use the following procedure:

1. Open the ISA Management MMC snap-in, right-click the server or array in the console tree on which to allow incoming requests, and then choose Properties from the shortcut menu.

2. Click the Incoming Web Requests tab, shown in Figure 31-33.

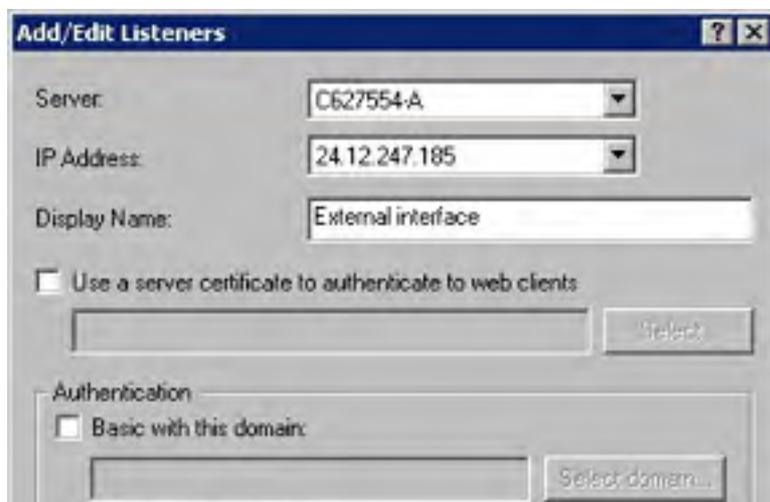

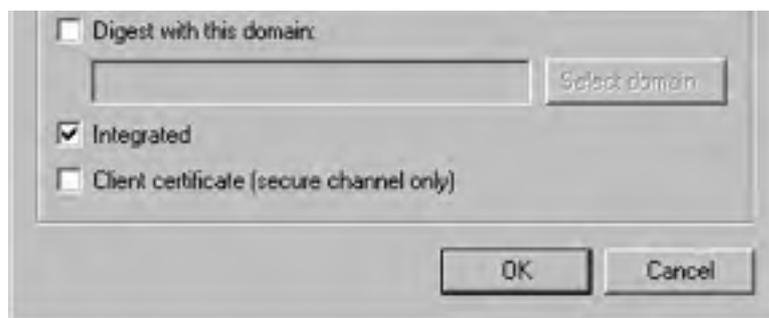

**Figure 31-33.** Permitting incoming requests.

3. To use the same listener configuration on all IP addresses on the server or array, choose the Use The Same Listener Configuration For All IP Addresses option. To configure each IP address individually, leave the Configure Listener Individually Per IP Address option selected.

A listener is just a configuration setting that tells ISA Server to monitor the specified IP address for incoming connections.

4. If you chose to configure each IP address individually, click Add to set up an IP address for incoming connections. Otherwise click Edit to display the same dialog box, which is shown in Figure 31-34.

**Figure 31-34.** Configuring a listener.

5. Select the desired server from the Server list box, and then choose the IP address of the external interface from the IP Address box (if available).
6. Optionally enter a display name for the IP address, and choose whether to use a server certificate to authenticate the server to Web clients (you must to enable SSL access to your internal Web servers). You can also change the Authentication method, although this is not recommended unless you have a good reason for doing so. Click OK when you finish creating or editing the listener.
7. Back in the Incoming Web Requests tab shown in Figure 31-33, optionally enable ISA Server to listen for Secure Socket Layer (SSL) requests by selecting the Enable SSL Listeners check box.

Don't change the default TCP and SSL ports, unless you have a specific reason for doing so and have examined the repercussions of this action.

8. At the bottom of the dialog box, select the Resolve Requests Within Array Before Routing check box to enable reverse caching. Reverse caching allows ISA Server to accelerate the perceived speed of your Web server to external clients by caching frequently requested pages from your Web server. Thus, when an Internet client requests a page, the ISA Server might be able to provide it directly from its cache rather than referring the request to your Web server.
9. Click OK when you're finished. ISA Server asks if you want to save the settings and immediately restart the Web Proxy and Scheduled Download services. Select the Save The Changes And Restart The Service(s) option and click OK to do so; otherwise restart the services at a later time (just realize that no incoming requests will be accepted until you do).

## Creating Internal Destination Sets

When publishing servers to the Internet, limit the computers on your network that external (Internet) clients can access. To do this, create destination sets that contain only those computers on the internal network that you want to make accessible from the Internet. This is the opposite of the way destination sets are normally used—to limit which Internet sites your internal network clients have access to—but is actually a much more important use of destination sets.

To create a destination set for internal servers to publish, use the following procedure:

1. To make the destination set available to all arrays in the enterprise, open the Enterprise-Policy Elements-Destination Sets container in the console tree. To make the destination set available only on a particular server or array, open the Policy Elements-Destination Sets container located under the desired server.
2. Click the Create Destination Set link to open the New Destination Set dialog box.
3. Enter a name for the destination set such as *Internal Web Servers*, and then click Add to

display the Add/Edit Destination dialog box, shown in Figure 31-35.

**Figure 31-35.** Adding destinations to a destination set.

4. Add the computer(s) that you want to allow external clients to access using one of the following methods:
  - To add computers or domains by their DNS name, select the Destination option and enter the host name in the box provided, or click Browse to search Active Directory.
  - To specify a range of IP addresses, select the IP Addresses option and enter the beginning and ending IP addresses in the boxes provided.
  - To optionally specify a particular path in the destination set, enter the path in the Path box. This allows you to provide access only to the publishing directory on a Web server, for example. To include all files in a folder, enter the path followed by an asterisk, for example `/Inetpub/wwwroot/*`.
5. Click OK when you're finished, add any additional destinations to the destination set, and then click OK to close the destination set.

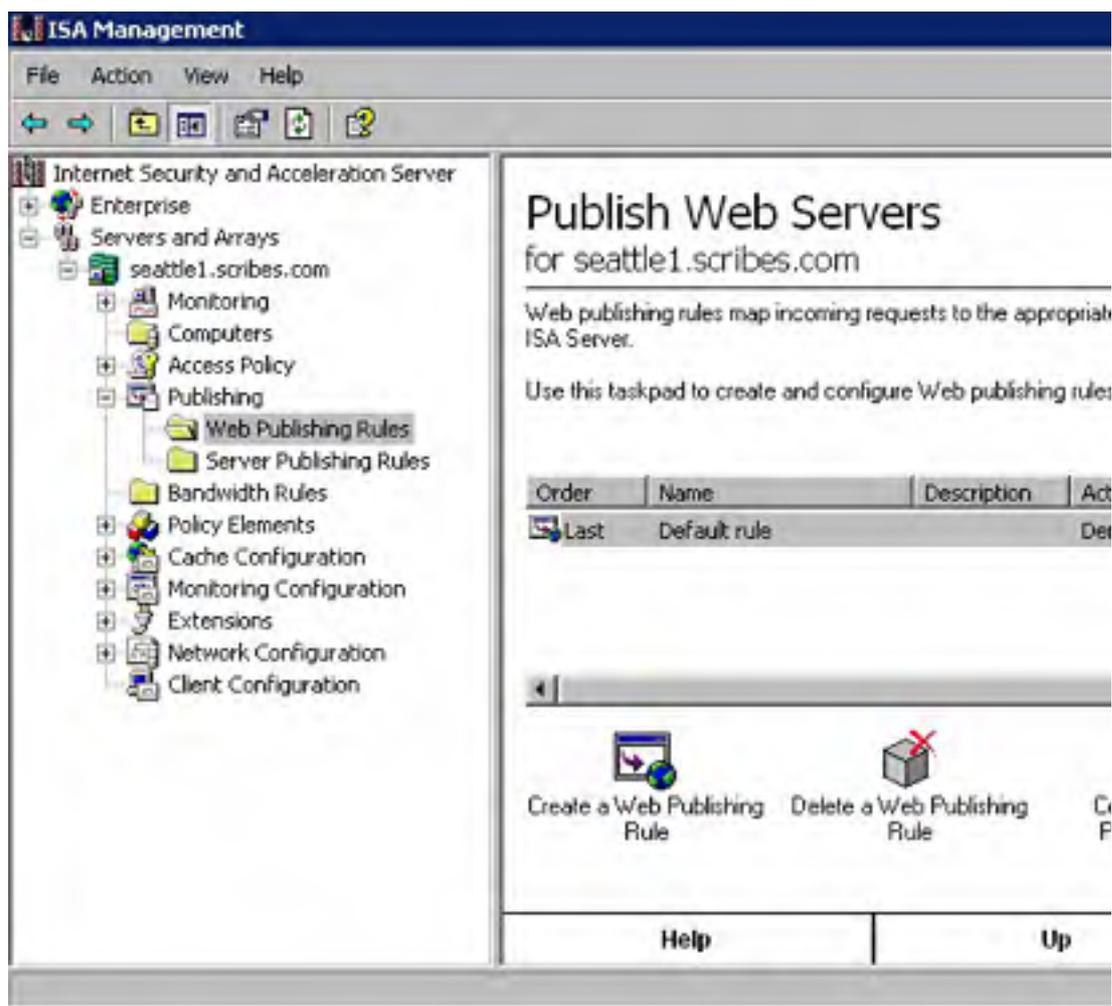

## Publishing Web Servers

To publish a Web server so that external (Internet) users can access it, use the following procedure:

1. In the console tree of the ISA Management MMC snap-in, navigate to the Publishing object under the stand-alone server or array you want to use, and then select the Web Publishing Rules object, as shown in Figure 31-36.

To publish a mail server, see the section entitled [Publishing Mail Servers](#) later in this chapter. To publish another type of server, from the Publishing object in the console tree, click the Publish Servers link and then follow the instructions on screen.

**Figure 31-36.** The Publish Web Servers taskpad.

2. To create a new rule allowing Internet users to access a Web server on the internal network, click the Create A Web Publishing Rule link.
3. In the first screen of the New Web Publishing Rule Wizard, enter a descriptive name for the rule and then click Next.
4. Choose Specified Destination Set from the first list box (shown in Figure 31-37) and then in the Name box, choose the destination set containing only the internal server(s) that you want to allow access to (see the section entitled [Creating Internal Destination Sets](#) earlier in this chapter for more information). Click Next to continue.

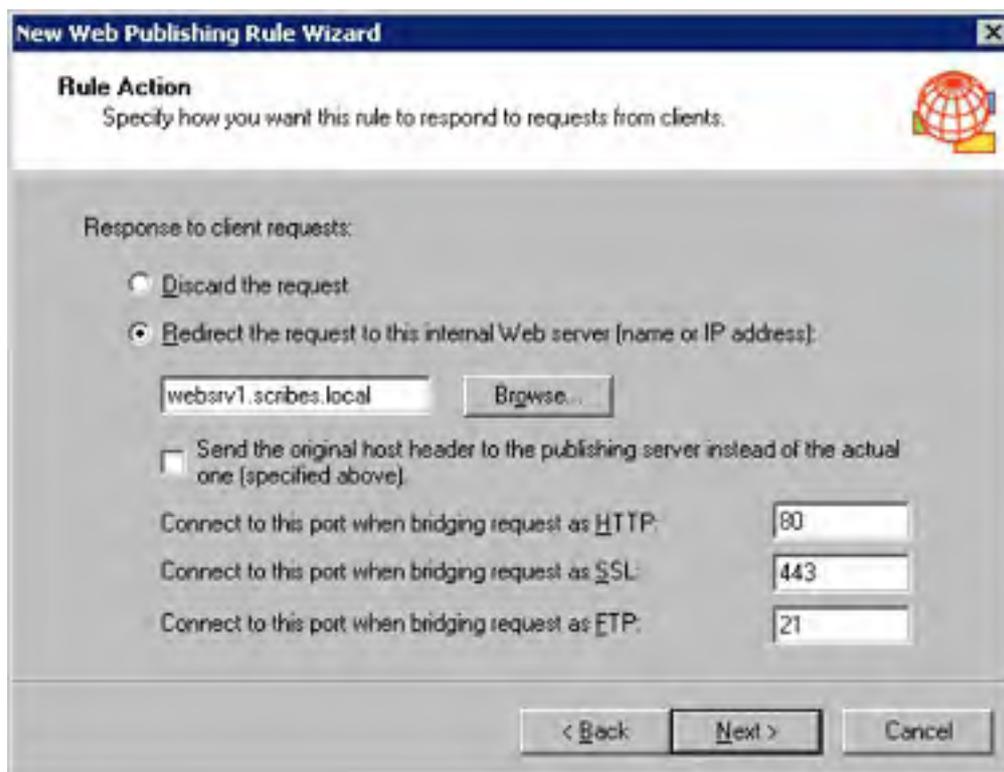

**Figure 31-37.** Specifying a destination set to which you want to allow access.

5. In the Client Type screen, choose how to apply the publishing rule. Most likely you'll select Any Request to apply the rule to all incoming requests. Click Next.
6. If you chose Specific Computers in the previous screen, specify which Client Address Sets to permit to access the Web server. If you chose the Specific Users And Groups option, select the groups to allow in, and then click Next.

When you control access by users and groups, only users with an account that's a member of one of the groups you specify can gain access to the Web server. Additionally, the users must be using the ISA Server Firewall client software. For this reason, avoid controlling incoming access using users and groups.

7. Select the Redirect The Request To This Internal Web Server option, and then enter the IP address or fully qualified domain name of the Web server to which you want to allow access, as shown in Figure 31-38.
8. If you need to change the port addresses, do so and then click Next. For example, if you're hosting a Web site from the same computer that's running ISA Server, you need to configure Internet Information Services (IIS) to use a different port than port 80 because ISA Server uses that port. Typically you'll set up IIS to use port 81, but in any case, enter the port numbers that the Web server uses in the boxes provided.
9. Review the publishing rule and then click Finish to implement the rule.

**Figure 31-38.** Specifying where incoming Web requests should be directed.

**Real World**

**The Last Rule**

Most parts of ISA Server that are configured with rules come preconfigured with a rule named Last. This rule is usually very restrictive (for Web publishing, it denies all access), and serves as the default rule that is applied to any condition that doesn't match any rules you create (which are processed first). To ensure that the security of the network isn't inadvertently compromised, don't modify this rule. Instead, create additional rules that allow the level of access you want.

## Publishing Mail Servers

To provide mail services to external (Internet) clients, you first need to create a publishing rule that gives external users access to the internal mail servers. To do so, use the following procedure:

1. In the console tree of the ISA Management MMC snap-in, navigate to the Publishing object under the stand-alone server or array you want to use, and then click the Secure Mail Server link.
2. Click Next in the first screen of the Mail Server Security Wizard.
3. Select the protocols to allow as shown in Figure 31-39, and then click Next.

**Figure 31-39.** Publishing a mail server.

4. Enter the external IP address of the ISA server (click Browse to locate it), and then click Next.
5. Enter the IP address of the internal mail server, or select the On The Local Host option if the ISA server is also a mail server. Click Next.
6. Review the publishing rule you created and then click Finish.

Once you've published a mail server, you can enable and configure the SMTP application filter (located under the Extensions container in the console tree). This filter allows you to filter out incoming messages based on a number of criteria such as size and attachment type (for example, you could automatically delete incoming messages that may contain a virus, such as messages with .VBS, .BAT, or .EXE extensions).

## Creating Protocol Definitions

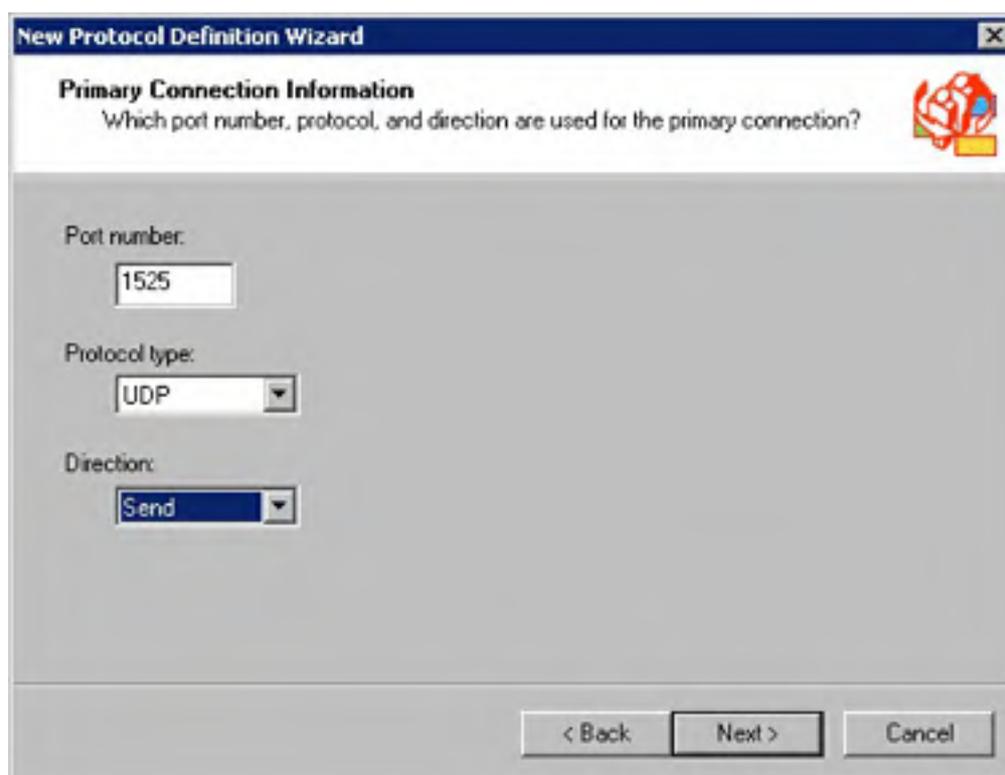

ISA Server comes preconfigured with definitions for most protocols. However, there might come a time when you need to use a protocol that ISA Server doesn't already know about. To use it, you'll need to create a protocol definition for it and then create a protocol rule enabling the use of the new protocol definition (unless you've allowed all IP traffic).

To create a protocol definition, use the following steps:

1. To make the protocol definition available to all arrays in the enterprise, open the Enterprise-Policy Elements-Protocol Definitions container in the console tree. To make the protocol definition available only on a particular server or array, open the Policy Elements-Protocol Definition container located under the desired server.
2. Scan the list of protocol definitions to make sure that there isn't already a suitable definition, and then click the Create A Protocol Definition link if there isn't.
3. In the first screen of the New Protocol Definition wizard, enter the protocol name and then click Next.
4. Enter the port number used by the protocol, the protocol type, and the direction of information transfer, as shown in Figure 31-40, and then click Next.

Do not edit any of the protocol definitions that are shipped with ISA Server unless you know a great deal about TCP/IP *and* you know why you're changing any given protocol.

5. If the protocol uses secondary connections, select the Yes option in the next screen, and then click New to specify a port range, type, and direction for secondary connections. Click Next to continue.

**Figure 31-40.** Creating a new protocol definition.

6. Review the settings and then click Finish. To use the protocol definition, add it to a protocol rule or create a new protocol rule allowing the use of the newly created protocol definition.

## Changing Cache Properties

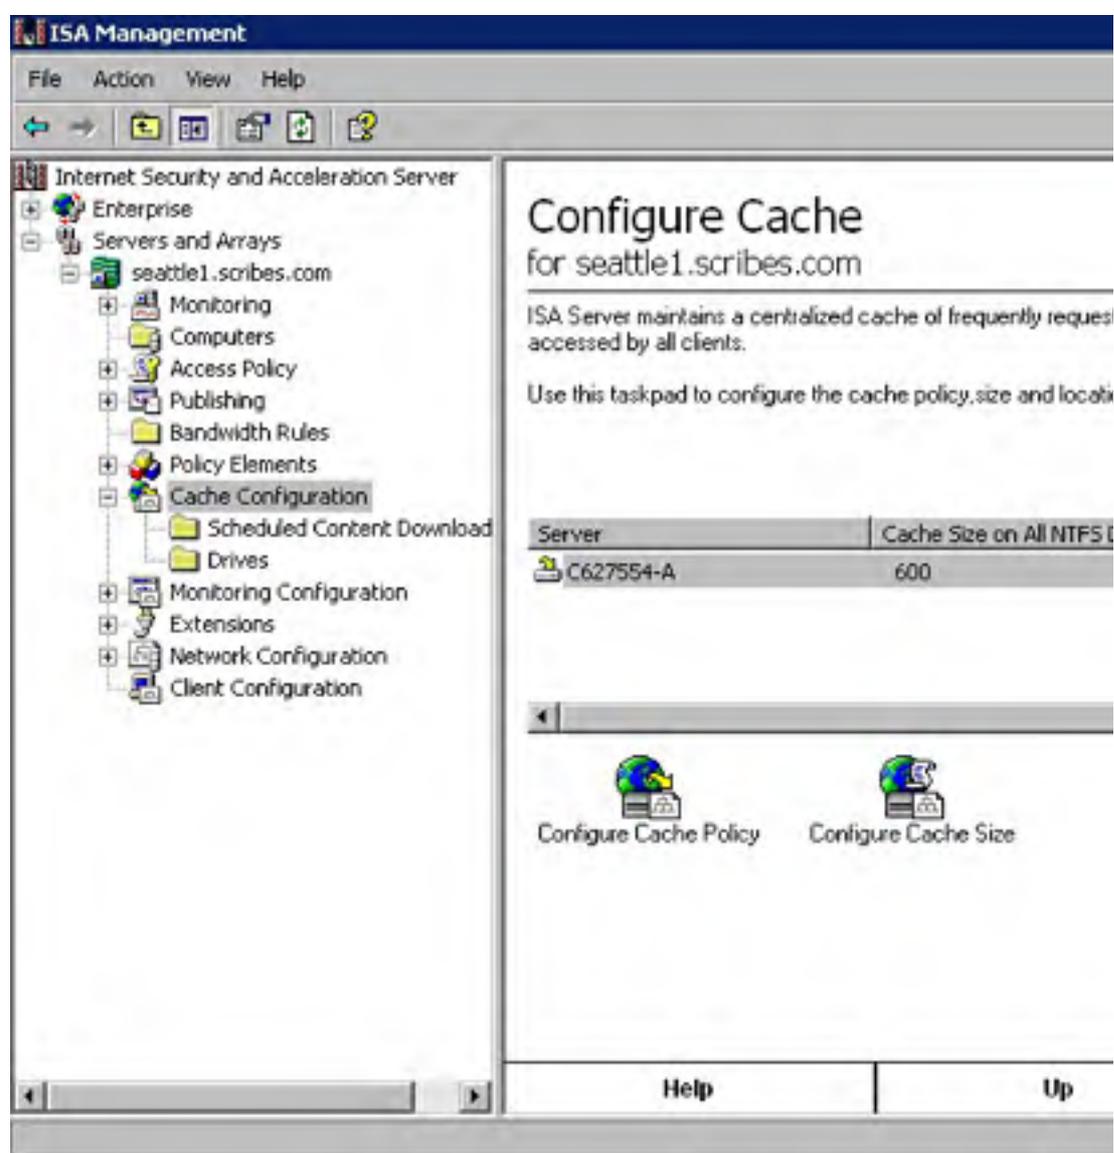

Although most cache configuration is performed when you install ISA Server or go through the Getting Started Wizard (discussed earlier in this chapter), you can configure additional settings or change the settings you specified. Use the following sections to change the size of the cache and what drives are used for caching, and set up specific Web sites or objects for scheduled downloading into the ISA Server cache.

To change the cache policy, click the Configure Cache Policy link in the Cache Configuration taskpad, and then refer to the section entitled [Configuring Cache Policy](#) earlier in this chapter.

## Changing the Size and Location of the Cache

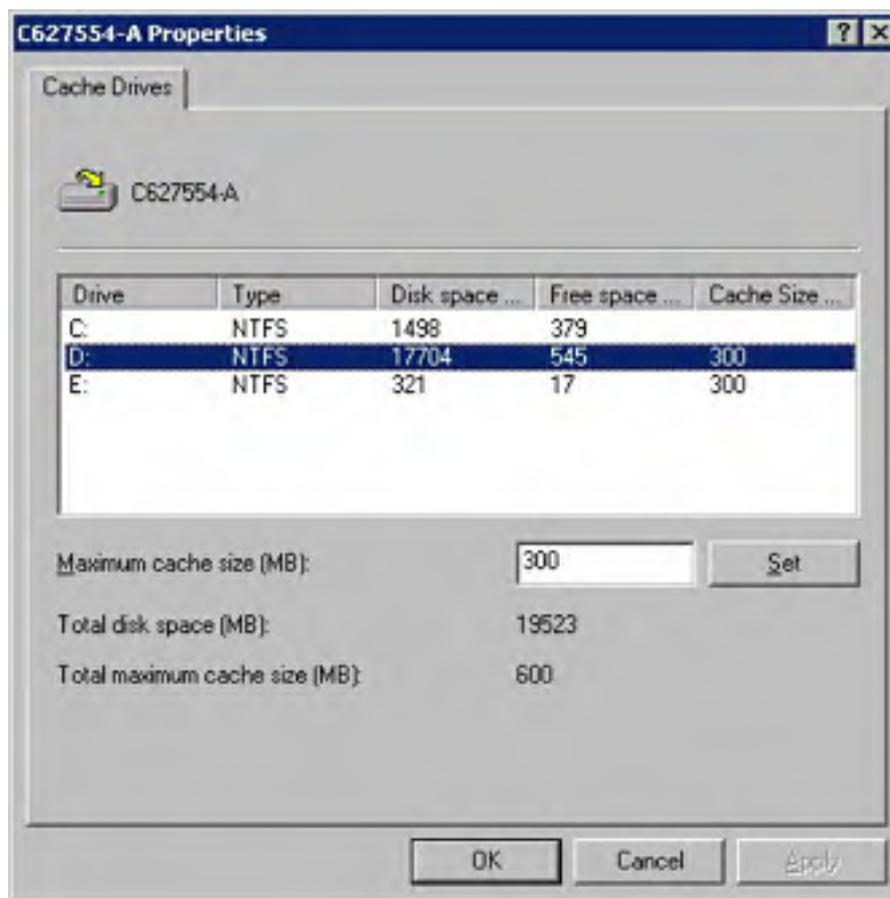

To change which drives are used to store the ISA Server cache and how much disk space is used on each drive, use the following steps:

1. Open the Cache Configuration container located under the desired server or array in the console tree.
2. Click the Configure Cache Size link, as shown in Figure 31-41.

**Figure 31-41.** The Cache Configuration taskpad.

3. In the dialog box shown in Figure 31-42, select a drive from the list and then enter how much disk space to allocate for the ISA Server cache on that drive. Click Set to save the setting, and then configure any other drives. Click OK when you're finished.

**Figure 31-42.** Changing ISA Server's cache location and size.

## Setting Up Content for Scheduled Downloading

You can set up ISA Server to automatically download individual Web pages or even entire Web sites on a set schedule. This ensures that the desired content is always available and fresh in ISA Server's cache.

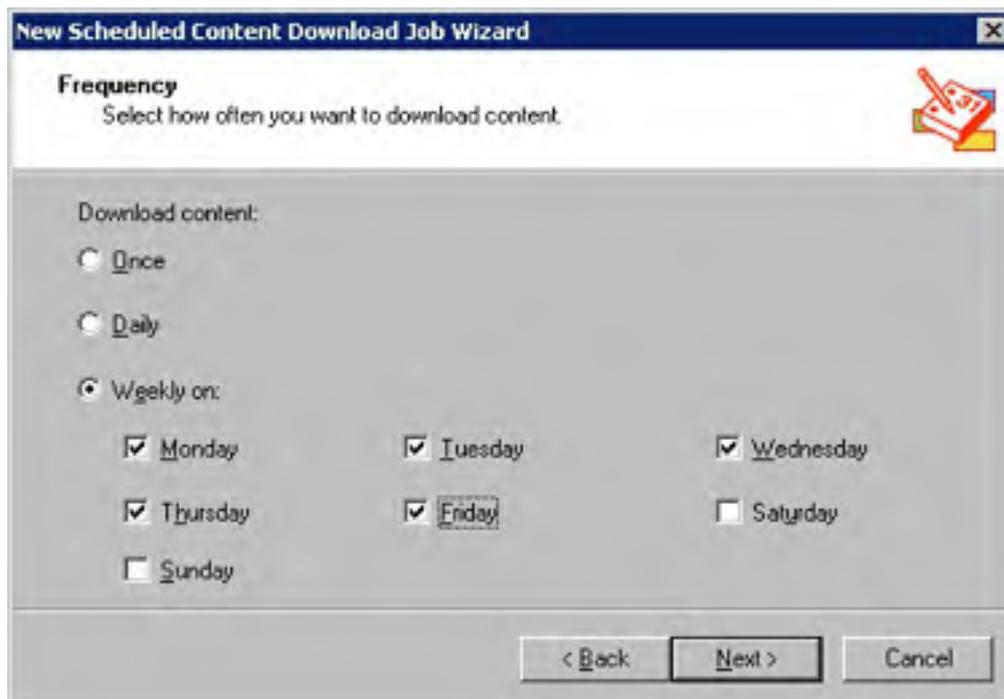

This ability can come in handy in a couple of instances, the most obvious of which is when your users routinely need access to a particular site, such as a reference site or the site of a partner company.

You can also use ISA Server's scheduled download functionality to accelerate performance of the internal Web server for external (Internet) clients, provided you have reverse caching enabled (covered earlier in this chapter). Set up the ISA server to automatically download the Web site from the internal Web server and then when Internet clients request pages from the Web site, they're served directly from the ISA server (this also enhances the security of the network because external clients no longer even access the internal Web server; they stay on the ISA server).

To schedule ISA Server to download content automatically, use the following steps:

1. Open the Cache Configuration-Scheduled Content Download container located under the desired server or array in the console tree.
2. Choose New-Job from the Action menu.
3. Enter a descriptive name for the download job and then click Next.
4. Specify the date and time the download job should begin, and then click Next.

- Specify the frequency with which ISA Server should perform the download job, as shown in Figure 31-43, and then click Next.

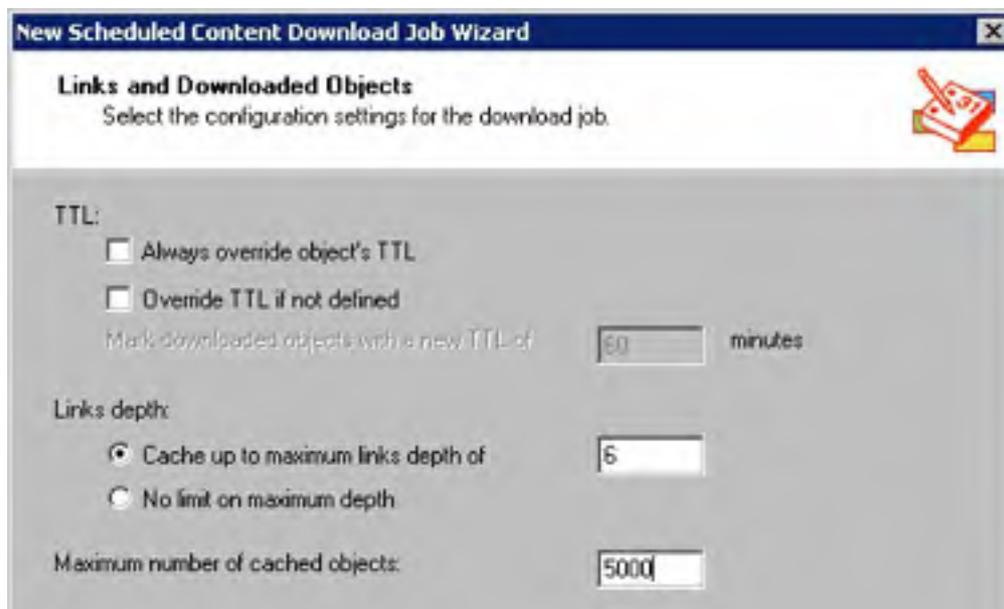

The screenshot shows the 'New Scheduled Content Download Job Wizard' dialog box. The title bar reads 'New Scheduled Content Download Job Wizard'. The main heading is 'Frequency' with the instruction 'Select how often you want to download content.' Below this, there are three radio button options: 'Once', 'Daily', and 'Weekly on:'. The 'Weekly on:' option is selected. Under 'Weekly on:', there are seven checkboxes for the days of the week: Monday, Tuesday, Wednesday, Thursday, Friday, Saturday, and Sunday. Monday, Tuesday, Wednesday, Thursday, and Friday are checked. At the bottom of the dialog, there are three buttons: '< Back', 'Next >', and 'Cancel'.

**Figure 31-43.** Creating a new scheduled download job.

- Enter the URL to download, and specify whether to download only linked pages within the same site by selecting Content Only From URL Domain. You can also control whether or not ISA Server caches dynamic content. Click Next to continue.

If the dynamic content requires user authentication or identification (including the use of cookies), it won't cache properly.

- Specify how ISA Server should deal with the Time to Live (TTL) of objects it downloads, as discussed here and shown in Figure 31-44:
  - Always Override Object's TTL** Gives all downloaded objects the TTL you specify in the box provided (default is 60 minutes)
  - Override TTL If Not Defined** Writes the TTL you specify on downloaded objects only if they don't have a specified TTL

The screenshot shows the 'New Scheduled Content Download Job Wizard' dialog box. The title bar reads 'New Scheduled Content Download Job Wizard'. The main heading is 'Links and Downloaded Objects' with the instruction 'Select the configuration settings for the download job.' Below this, there are two checkboxes: 'Always override object's TTL' and 'Override TTL if not defined'. Below these is a text field 'Mark downloaded objects with a new TTL of' followed by a text box containing '60' and the word 'minutes'. Under 'Links depth:', there are two radio button options: 'Cache up to maximum links depth of' and 'No limit on maximum depth'. The first option is selected, and it is followed by a text box containing '6'. At the bottom, there is a text field 'Maximum number of cached objects:' followed by a text box containing '5000'.

**Figure 31-44.** Specifying how many links ISA Server should download and how it should set their TTL.

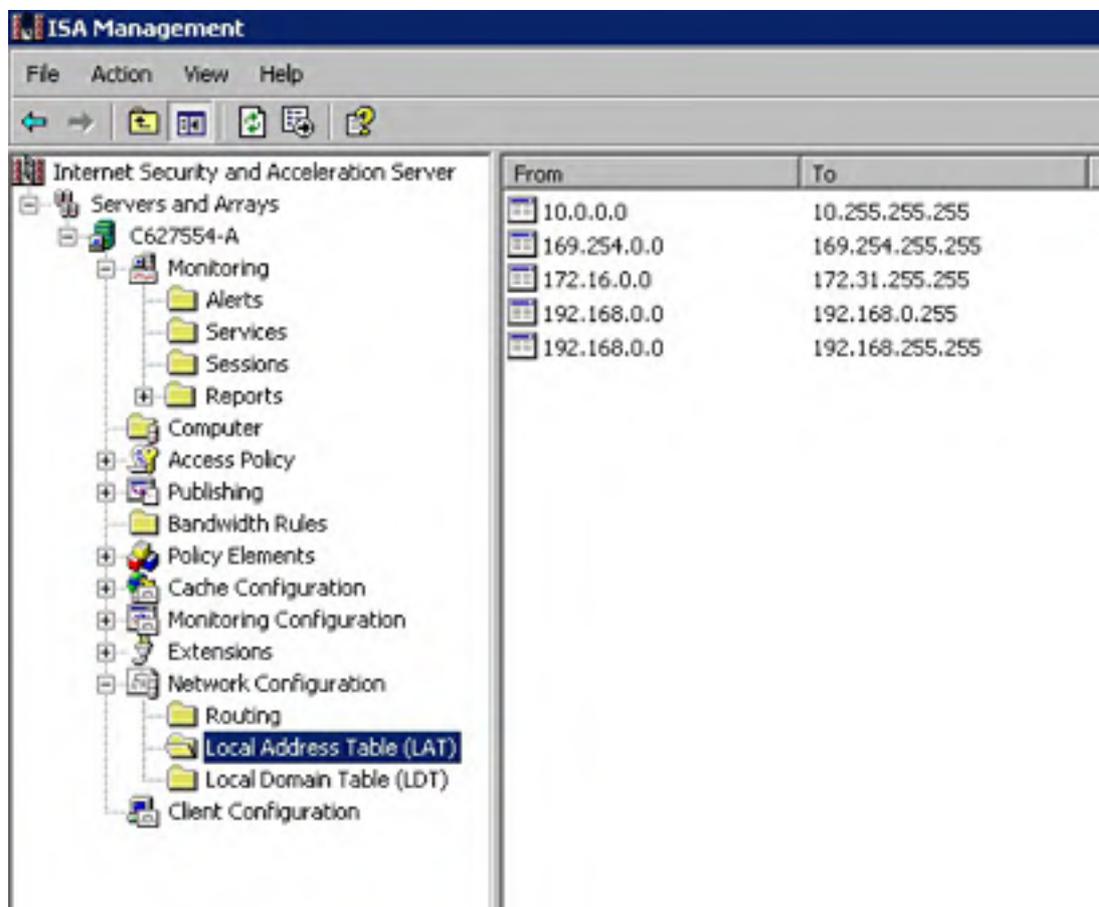

Web page authors can specify a Time to Live (TTL) for Web pages to indicate how long the content is "fresh" (how long it should hang around before getting checked for a new copy). When the TTL expires, ISA Server considers the page invalid and automatically checks for an updated copy if active caching is enabled and the page is popular. If active caching isn't enabled, ISA Server updates the page the next time it's requested.

8. Select the Cache Up To Maximum Links Depth Of option and enter the number of links ISA Server should follow in the box (or just leave No Limit On Maximum Depth selected). ISA Server follows all links on the page you specified and continues following all links on each linked page up to the maximum link depth.
9. Optionally change the maximum number of objects ISA Server caches during the scheduled download operation, and then click Next. Review the settings and then click Finish.

## Configuring the Local Address Table

Your local addresses are maintained in the LAT that was created during initial installation. You can change this LAT at any point using the ISA Management MMC snap-in. To configure the LAT, use the following procedure:

1. Open the Network Configuration container located under the desired server or array in the console tree, and then select the Local Address Table (LAT) object under it in the console tree. This displays the LAT, as shown in Figure 31-45.

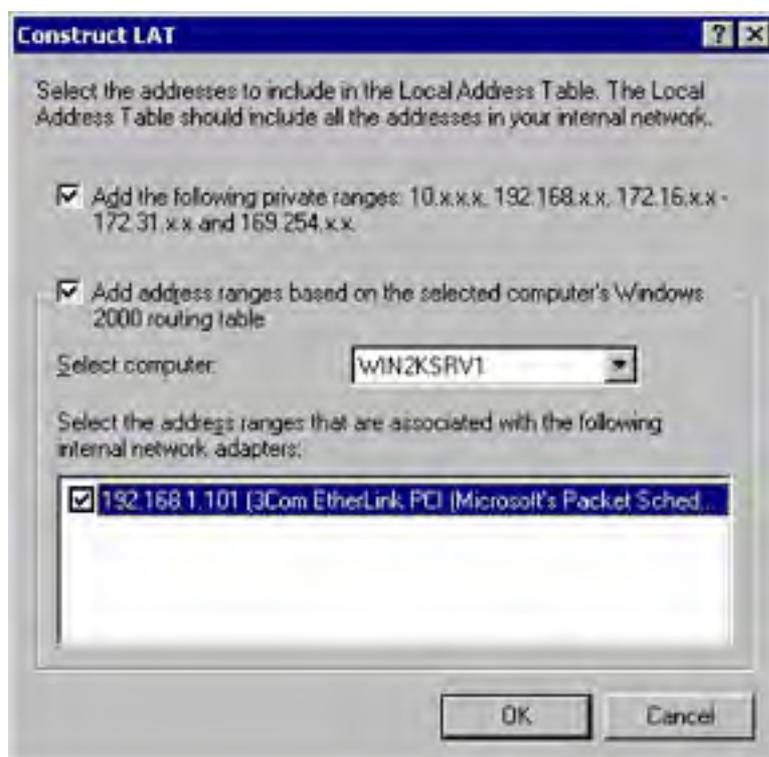

**Figure 31-45.** *The local address table.*

2. To add address ranges manually, choose New-LAT Entry from the Action menu, and then enter the address range in the New LAT Entry dialog box.
3. To reconstruct the LAT, choose Construct LAT from the Action menu to display the dialog box shown in Figure 31-46. To add the private IP addresses automatically, select the Add The Following Private Ranges check box. To allow Windows to use the internal IP routing table, specify the network card or cards connected to the internal network (do *not* select the adapter connected to the Internet or external network). When you've made your selections, click OK.

**Figure 31-46.** *The Construct LAT dialog box.*

4. Click OK to return to the local address table shown in Figure 31-45.
5. To remove any external addresses from the LAT, right-click the incorrect LAT entry and choose Delete from the shortcut menu. To edit the entry, choose Properties from the shortcut menu.

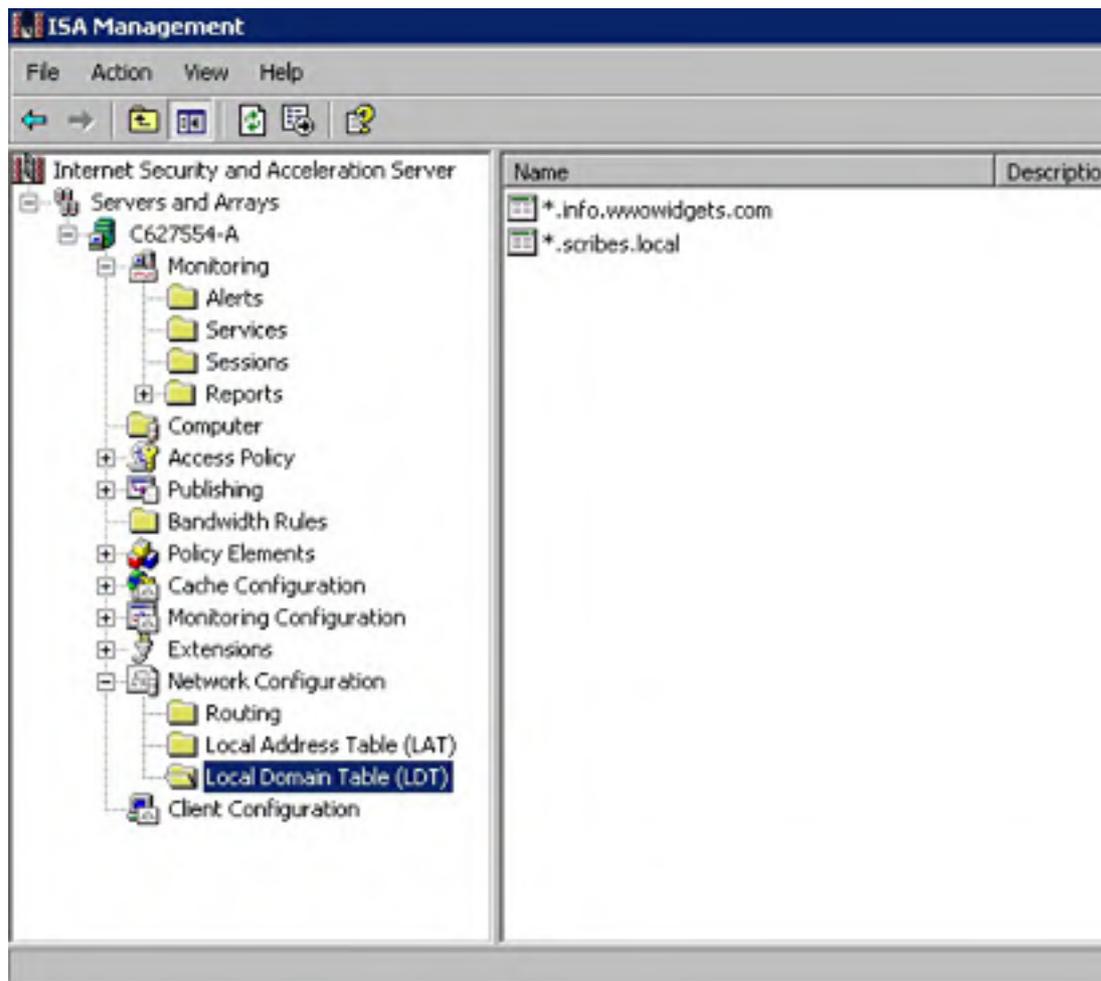

## Configuring the Local Domain Table

Because network namespaces are growing increasingly complex, it is no longer simple to discern the difference between internal network names and external network names. For this reason, you can create a list of domains that are on the local network.

When a Firewall client requests a location by name, it first checks its local copy of the local domain table (LDT), which is updated frequently by the ISA server (SecureNAT clients must use DNS). If the requested location is a member of a local domain, the client bypasses ISA Server and directly accesses the location. Otherwise it goes to the ISA Server to fulfill the request.

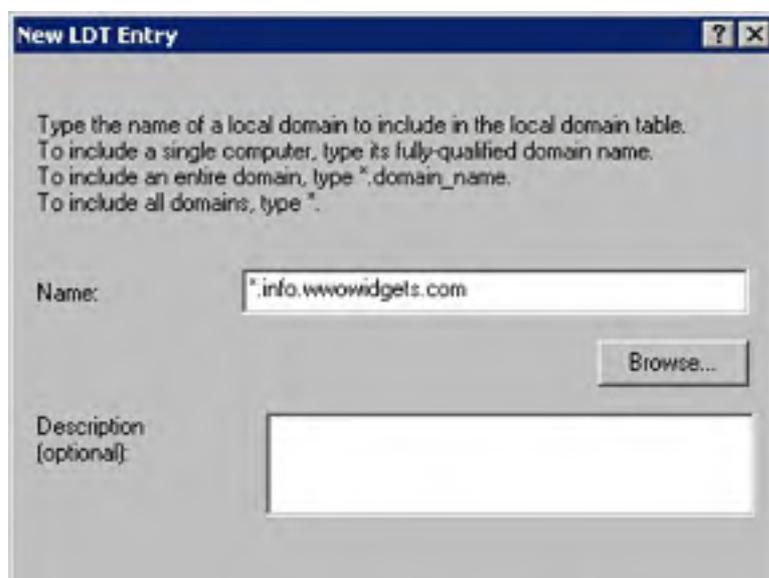

To configure the LDT, use the following steps:

1. Open the Network Configuration container located under the desired server or array in the console tree, and then select the Local Domain Table (LDT) object under it in the console tree. This displays the LDT, as shown in Figure 31-47.

**Figure 31-47.** The local domain table.

2. To add an entry to the LDT, choose New-LDT Entry from the Action menu.
3. In the New LDT Entry dialog box shown in Figure 31-48, enter the local domain or subdomain name, or click Browse to select one. To include all subdomains of the specified domain, precede the domain with an asterisk. Click OK when you're finished.

**Figure 31-48.** *Creating a new LDT entry.*

4. To remove an LDT entry, right-click the entry and choose Delete from the shortcut menu. To edit an entry, right-click it and choose Properties from the shortcut menu.

## Working with VPNs

ISA Server can work with Windows 2000 Routing and Remote Access service to provide a secure network link across the Internet using a virtual private network (VPN) connection.

There are two types of VPN connections that you can set up with ISA Server. You can use a VPN connection as a WAN link to connect two networks together, or you can set up the ISA server as a VPN server and allow clients to securely connect to the local network from across the Internet. Both methods are discussed in the following sections.

### More Info

For background information on VPNs and Routing and Remote Access, see [Chapter 32](#).

## Connecting Two Networks

Until just recently, if you wanted to connect two networks together with a permanent network connection, you needed to use a dedicated WAN link, which can be very expensive and a hassle to set up. However, with the advent of VPN connections, companies can now use their Internet connection to create a virtual WAN link between separate networks at a fraction of the cost and time required by a traditional WAN link.

To connect two networks with a VPN, you first need to set up the VPN link on the ISA server located on the primary network. Then you set up the ISA server located on the other network (both sides of the VPN need to be using an ISA server).

### Setting Up a VPN on the Primary Network

When setting up a VPN connection between two networks, you need to start at one end or the other. Start on the primary network, the main network with which you want to connect other networks.

For example, your company might have a main business location in Seattle with some branch offices scattered around the country. Set up the VPN in Seattle first, and then connect each branch office later, as described in the section entitled [Setting Up a VPN on a Secondary Network](#) later in this chapter.

To set up an ISA server to receive VPN connections from your company's secondary networks, use the following procedure on an ISA server on the primary network:

1. Open the Network Configuration container located under the desired server or array in the console tree.
2. Click the Configure A Local Virtual Private Network (VPN) link.
3. Click Next in the first screen, and then click Yes (if prompted) to start the Windows Routing and Remote Access service.
4. Follow the on-screen directions.

### Setting Up a VPN on a Secondary Network

To finish creating a WAN link between two networks using a VPN connection, after setting up an ISA server on the primary network, follow these steps on an ISA server at the secondary network:

1. Open the Network Configuration container located under the desired server or array in the console tree.
2. Click the Configure A Remote Virtual Private Network (VPN) link.
3. Click Next in the first screen, and then click Yes (if prompted) to start the Windows Routing and Remote Access service.
4. Follow the on-screen directions.

### Allowing Client VPN Connections

Setting up ISA Server to accept incoming VPN connections from clients such as home users or traveling employees is simple:

1. Open the Network Configuration container located under the desired server or array in the console tree.
2. Click the Configure A Client Virtual Private Network (VPN) link.
3. Click Next in the first screen, and then click Yes (if prompted) to start the Windows Routing and Remote Access service.
4. Click Finish. ISA Server configures Routing and Remote Access to accept properly authenticated and encrypted VPN connections, and creates a static packet filter to allow L2TP and PPTP protocols to work with the IP Security (IPSec) protocol. Click Yes when asked if you want to restart the Routing and Remote Access service.

To accept L2TP connections, you need to configure the server with a server certificate. Certificates are discussed in [Chapter 20](#).

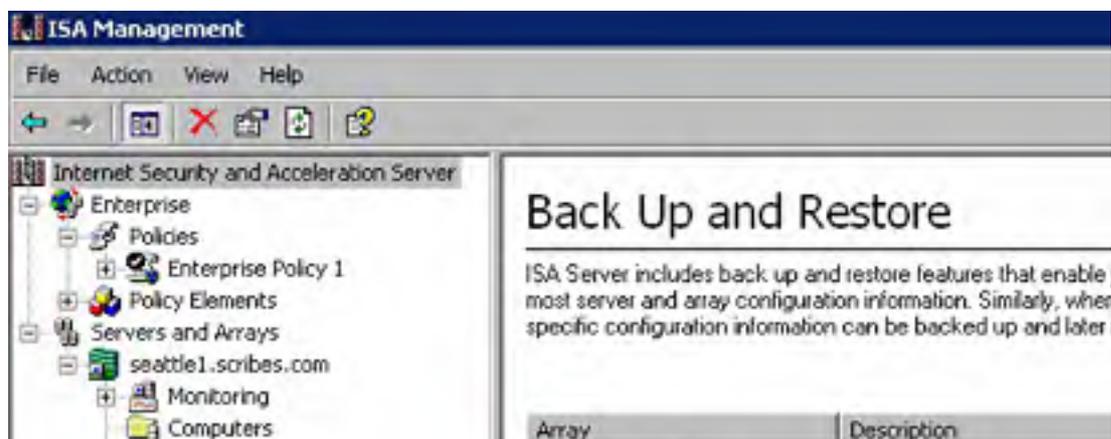

### Backing Up and Restoring ISA Server

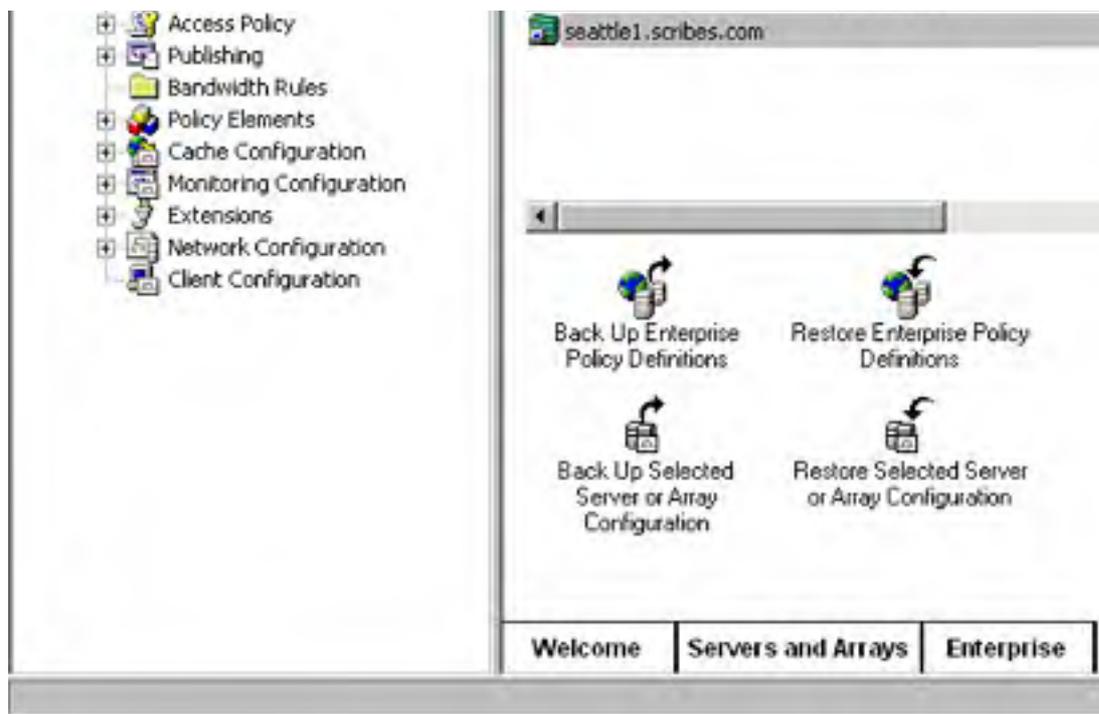

You can (and *should*) back up the ISA Server configuration after every major configuration change, such as changing enterprise policies, changing array membership, or changing the cache configuration. This allows you to restore most of the configuration changes should you have to reinstall ISA Server or re-create the settings on another machine.

Backing up a stand-alone ISA Server is no different from backing up a normal Windows 2000 Server; use Backup as described in [Chapter 35](#) (all configuration information is stored in the registry or configuration files located on the local hard drive).

Backing up enterprise policies or arrays is a little different however, because the configuration information is stored in Active Directory. To back up enterprise policies or an ISA Server array, you need to use ISA Server's backup tool, as described in the following steps:

1. Click the Internet Security And Acceleration Server object in the console tree (it's the highest level object).
2. Click the Backup tab at the bottom of the taskpad to display the Backup taskpad, shown in Figure 31-49.

**Figure 31-49.** The Backup taskpad.

3. Click the Backup Enterprise Policy Definitions link to back up enterprise policies, or select an array and then click the Backup Selected Server Or Array Configuration link to back up an array's settings.
4. Enter the path and filename for the backup file (or click Browse) and enter a description of the file in the boxes provided (see Figure 31-50).

**Figure 31-50.** Backing up enterprise or array configuration settings.

Be careful about where you save the backup file. Place it in a secure folder on an NTFS volume.

To restore a backed-up configuration, restore the server to an operational state (with ISA Server installed) and then follow these steps:

1. Click the Internet Security And Acceleration Server object in the console tree (it's the highest level object).
2. Click the Backup tab at the bottom of the taskpad to display the Backup taskpad, shown in Figure 31-49.
3. Click the Restore Enterprise Policy Definitions link to restore enterprise policies, or select an array and then click the Restore Selected Server Or Array Configuration link to restore an array's settings.

4. Click Yes when asked if you want to overwrite existing settings.
5. Click Browse to locate the backup file, click Open, and then click OK.
6. Review the backup information and then click OK to restore the backup.

## Working with Clients

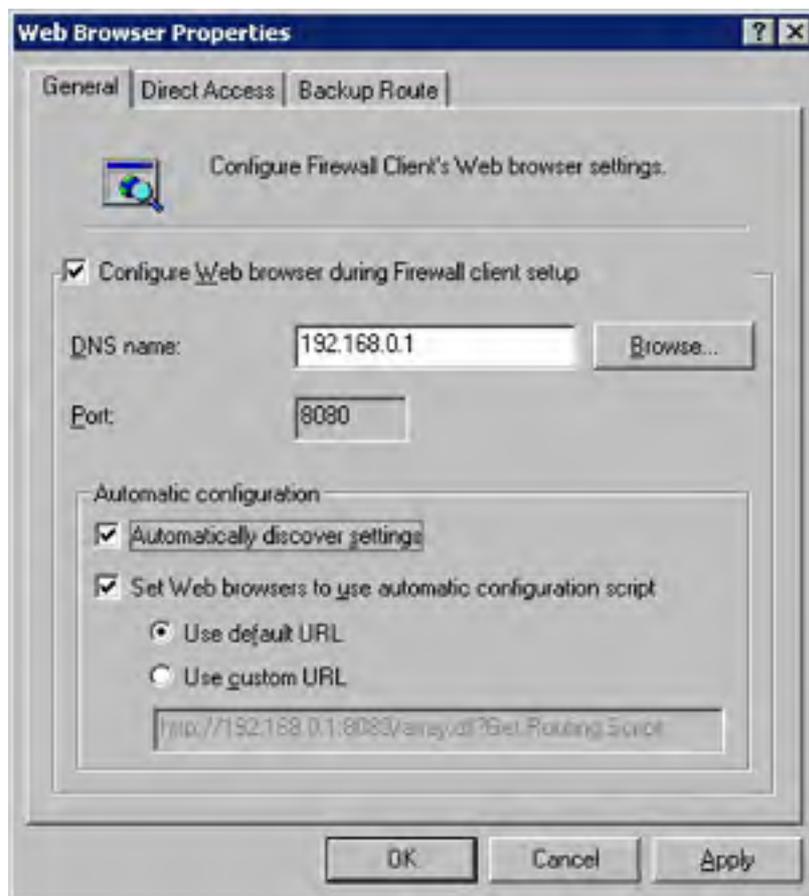

Configuring clients to work with ISA Server is easy, but there are a few things to set up or change on the ISA server, and of course, you'll also need to configure client systems.

The next sections discuss how to change the way ISA Server configures firewall and Web browser clients, how to set up DHCP and DNS to permit clients to automatically locate a nearby ISA server, and how to manually set up clients to work with ISA Server.

## Changing Default Settings for Web Browser Clients

Although the default settings for Web browser clients are adequate, there are a few settings to change, such as whether clients use the IP address or the computer name to connect to the server, and whether the Web browser is automatically configured during client setup. You can also modify the automatic browser configuration script. To change these settings, follow these steps:

1. Open the Client Configuration container located under the desired server or array in the console tree, and then double-click the Web Browser object.
2. To prevent the Firewall client software from configuring the client's Web browser when installed, in the Web Browser Properties dialog box, shown in Figure 31-51, clear the Configure Web Browser During Firewall Client Setup check box. This preserves the client browser's current Web proxy settings.

**Figure 31-51.** Changing the way Web browser clients are configured.

3. To specify that clients should connect to the ISA server using its IP address instead of its DNS name, enter the IP address of the ISA server's internal network adapter in the DNS Name box.
4. If the network contains many roaming clients (such as laptops) and you've set up the network's DHCP and DNS servers to support Web Proxy Auto Discover (WPAD) as discussed in the section entitled [Setting Up ISA Server Auto Discovery](#), later in this

chapter, select the Automatically Discover Settings check box. This allows clients to automatically discover the nearest ISA server when they launch their Web browser.

Automatic Discover only works with Microsoft Internet Explorer 5 and later Web browsers. Autoconfiguration scripts work with Internet Explorer 3.02 or later and Netscape Navigator 2 or later.

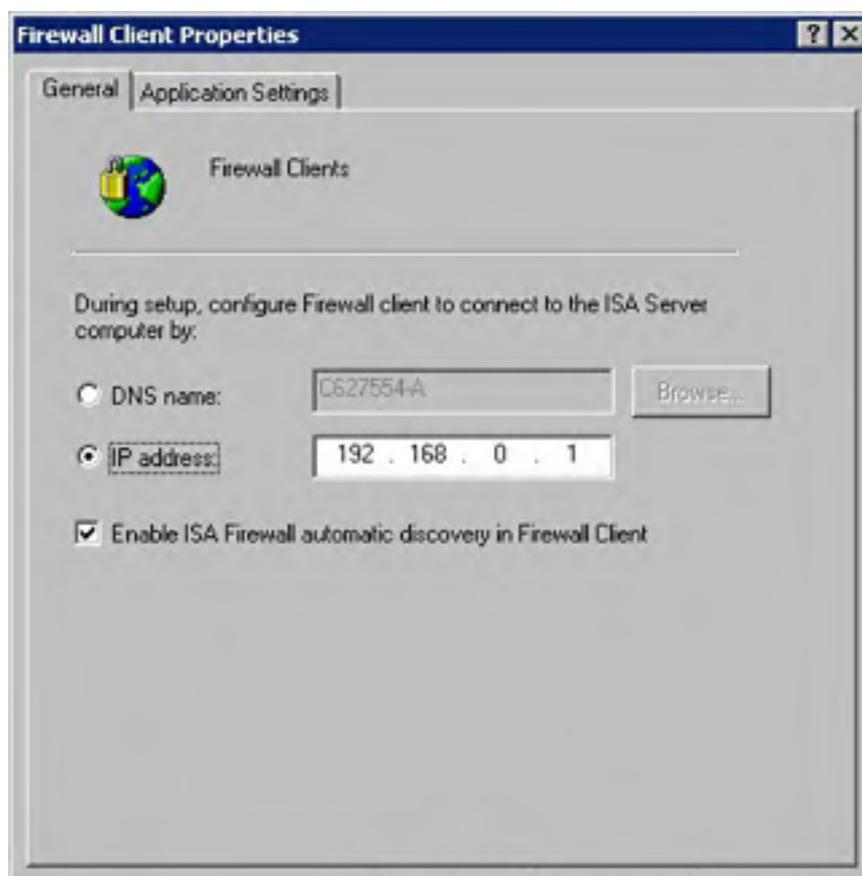

5. To specify that Web browsers should use an automatic configuration script to get their Web proxy settings, select the Set Web Browsers To Use Automatic Configuration Script check box. ISA Server automatically creates a configuration script, but you can use your own instead by selecting the Use Custom URL option and entering the URL of the script.
6. Use the Direct Access tab to specify which computers clients should access directly (thereby bypassing the ISA server).
7. Use the Backup Route tab to optionally specify a backup route for clients to use if the ISA server is unavailable (such as a direct connection to the Internet, or another ISA server).
8. Click OK when you're done.

## Changing Default Settings for Firewall Clients

For the most part, ISA Server's default settings for Firewall clients are appropriate, but you might want to force Firewall clients to connect through an IP address to the ISA server, or make clients automatically detect the nearest ISA server (if you have the network set up appropriately, as discussed in the next section).

To change these settings, or to change the way applications pass through the ISA Server firewall, use the following steps:

1. Open the Client Configuration container located under the desired server or array in the console tree, and then double-click the Firewall Client object.
2. To specify that clients should connect to the ISA server using its IP address instead of its DNS name, enter the IP address of the ISA server's internal network adapter in the DNS Name box, as shown in Figure 31-52.

**Figure 31-52.** Changing Firewall client settings.

3. If the network contains many roaming clients (such as laptops) and you've set up the network's DHCP and DNS servers to support Winsock Proxy Auto Discover (WSPAD) as discussed in the section entitled [Setting Up ISA Server Auto Discovery](#) later in this chapter, select the Enable ISA Firewall Automatic Discovery In Firewall Client check box. This allows clients to automatically discover the nearest ISA server when they obtain a DHCP lease.
4. To change the way ISA Server interacts with applications such as RealPlayer, click the Application Settings tab. Most of the time, you won't need to alter these settings. Consult the Microsoft Knowledge Base at <http://support.microsoft.com> or contact the software developer if you do.

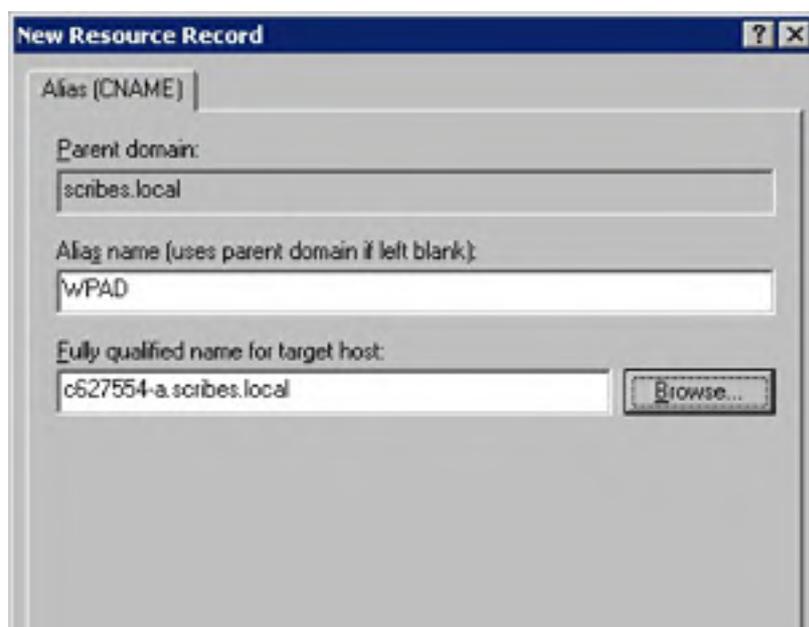

## Setting Up ISA Server Auto Discovery

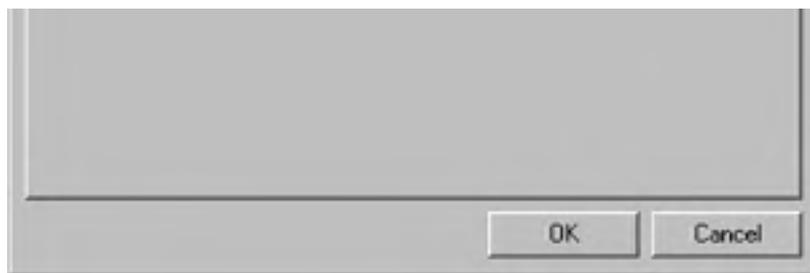

Normally, for a client to access the Internet through an ISA server, the client needs to either install the Firewall client software (for Windows clients), configure TCP/IP settings to take the ISA server as the default gateway (this can be done using DHCP), or set up the Web browser to use the ISA server as the proxy server.

Unfortunately, if the client then moves to another location on the network where it can't access the original ISA server, such as might be the case with a laptop user who visits a different division of the company, it might lose Internet connectivity. So if the network uses multiple ISA servers in different locations, set up the network to provide clients with the ability to automatically discover the nearest ISA server.

To do this, you should configure the DHCP server as well as the DNS server. Use the following steps to accomplish this task:

1. Open the DNS Administration MMC snap-in by clicking Start, pointing to Programs, pointing to Administrative Tools, and then choosing DNS (make sure DNS is installed and configured properly first).
2. Right-click the forward lookup zone containing the ISA server and choose New Alias from the shortcut menu.
3. Type *WPAD* in the Alias Name box, as shown in Figure 31-53.
4. Enter the fully qualified domain name of the ISA server or click Browse to locate the server in the DNS namespace. Click OK when you're done.
5. Open the DHCP Administration MMC snap-in by clicking Start, pointing to Programs, pointing to Administrative Tools, and then choosing DHCP (make sure DHCP is installed and configured properly first).

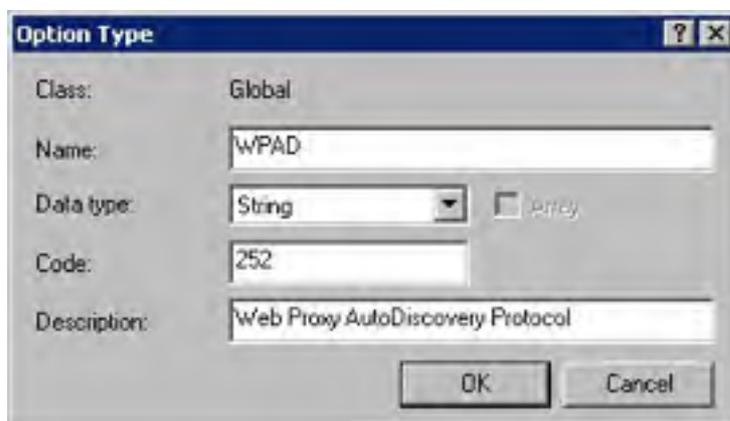

**Figure 31-53.** Setting up DNS for Web Proxy auto discovery.

6. Right-click the desired DHCP server in the console tree and choose Set Predefined Options from the shortcut menu.

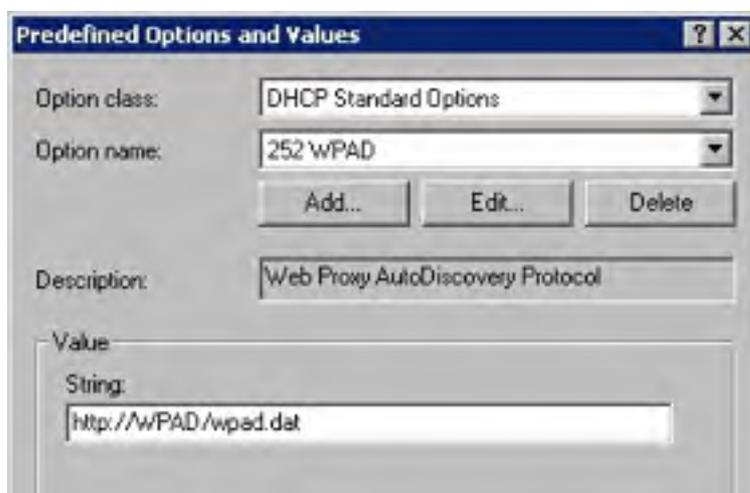

You should perform this procedure on all DHCP servers that service clients that you want to automatically locate an ISA server.

7. In the Predefined Options And Values dialog box, click Add.
8. In the Name box, type *WPAD*, as shown in Figure 31-54.

**Figure 31-54.** Setting up DHCP for Web Proxy auto discovery.

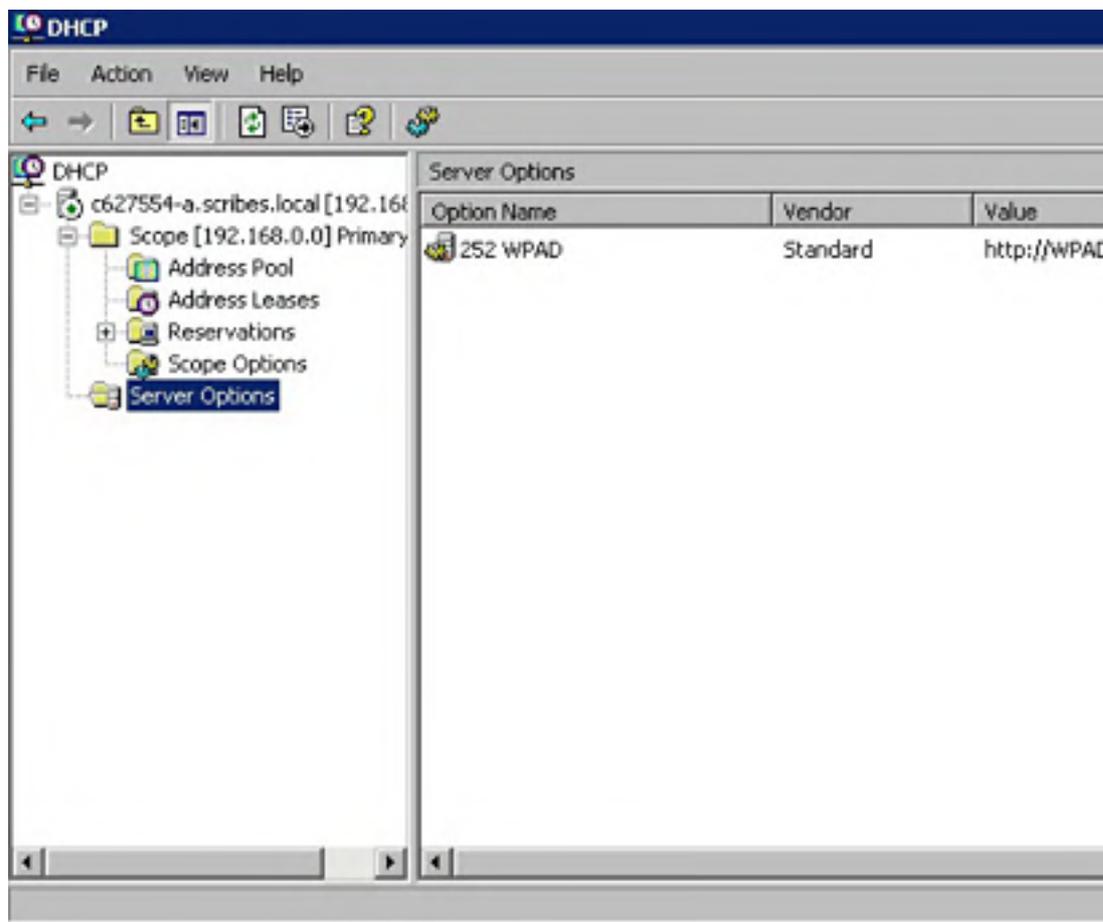

9. Select String from the Data Type box.
10. In the Code box, type 252.
11. Optionally enter a description, such as Web Proxy AutoDiscovery Protocol, and then click OK.
12. Back in the Predefined Options And Values dialog box (shown in Figure 31-55), type *http://WPAD/wpad.dat* in the String text box if you've configured DNS to work with autodetection as described in steps 1 through 4. Otherwise type *http://isa\_server/wpad.dat*, where *isa\_server* is the DNS name or IP address of the ISA server, and then click OK.

**Figure 31-55.** Setting up DHCP for Web Proxy auto discovery.

13. Select the DHCP server you're configuring from the console tree, right-click the Server Options folder, and choose Configure Options from the shortcut menu.
14. Scroll down and select the check box next to 252 WPAD in the Available Options box. Click OK. Your server options should reflect the addition of the WPAD protocol, as shown in Figure 31-56.

**Figure 31-56.** WPAD set up as a DHCP server option.

## Setting Up Client Systems

As discussed at the beginning of this chapter, there are three ways that clients can connect to an ISA server: using the Firewall client software, using the ISA Server as the default gateway in the client's TCP/IP properties (this is a SecureNAT client), and configuring a Web browser to use the ISA server as a proxy server.

The following sections discuss how to use each method on a client system.

### Installing the Firewall Client

If you're on a big network and the client systems are running fairly recent versions of Windows (Windows 3.x and Windows NT versions 3.5 and earlier need not apply), you can use ISA Server's Firewall client software. This allows you to manage access policies through user groups, among other things.

To install the Firewall client software, use the following procedure:

1. Connect to the `server_name\msplnt` share (where `server_name` is the DNS name of the

ISA server).

2. Double-click the Setup file in the directory to install the client software.
3. Use the install program to specify the desired folder in which to install the software. ISA Server automatically configures the Web browser to use the ISA server as its proxy server as well (unless you changed this in the default settings for Firewall clients, described earlier in this chapter).

Do not install the Firewall client on an ISA server.

If you have any significant number of clients to set up as Firewall clients, use Windows Server's software deployment features (discussed in [Chapter 25](#)) to mass deploy the software.

## Configuring SecureNAT Clients

SecureNAT clients are easy to set up. All you have to do is configure the TCP/IP properties for the computer or device to use the ISA server as the default gateway. (We're not going to tell you how to do this here. For help with configuring TCP/IP properties for Windows-based systems, see [Chapter 6](#). Otherwise consult the manual or help system for the computer or device.)

Better yet, you can specify an ISA server as the default gateway in the DHCP server's scope or server options. This ensures that any client obtaining an IP address from the DHCP server is automatically set up as a SecureNAT client.

SecureNAT clients are only supported in ISA Server's Firewall Mode. If you have set up ISA Server in Cache Mode only, SecureNAT clients are not supported. You will need to configure them as Web Proxy clients if they are non-Windows computers, or as Firewall clients for supported Windows computers.

## Configuring Web Proxy

To configure Internet Explorer to use the ISA server, use the following procedure:

1. Open Internet Options in Control Panel.
2. Click the Connections tab.
3. Click LAN Settings, as shown in Figure 31-57.
4. If the network network's DHCP and DNS servers are configured to support Web Proxy Auto Discover (WPAD) as discussed in the section entitled [Setting Up ISA Server Auto Discovery](#) earlier in this chapter, select the Automatically Detect Settings check box, shown in Figure 31-58. This allows clients to automatically discover the nearest ISA server when they launch their Web browser, which is useful for roaming clients such as laptops.

**Figure 31-57.** The Connections tab of the Internet Properties dialog box.

**Figure 31-58.** Setting up a Web browser to use ISA Server as a Web proxy.

5. To specify that the Web browsers should use an automatic configuration script to get their Web proxy settings, select the Use Automatic Configuration Script check box. The default location of the automatic configuration script created by ISA Server is *http://server\_name/array.dll?Get.Routing.Script*, where *server\_name* is the DNS name of the ISA server.
6. Alternatively, to manually specify the proxy server, select the Use A Proxy Server check box and then enter the IP address or domain name of the ISA server in the box provided. Enter the port used by ISA Server as well (8080 by default). To bypass the ISA server for locations on the local network, select the Bypass Proxy Server For Local Addresses check box.
7. Click OK when you're done.

## Monitoring ISA Server

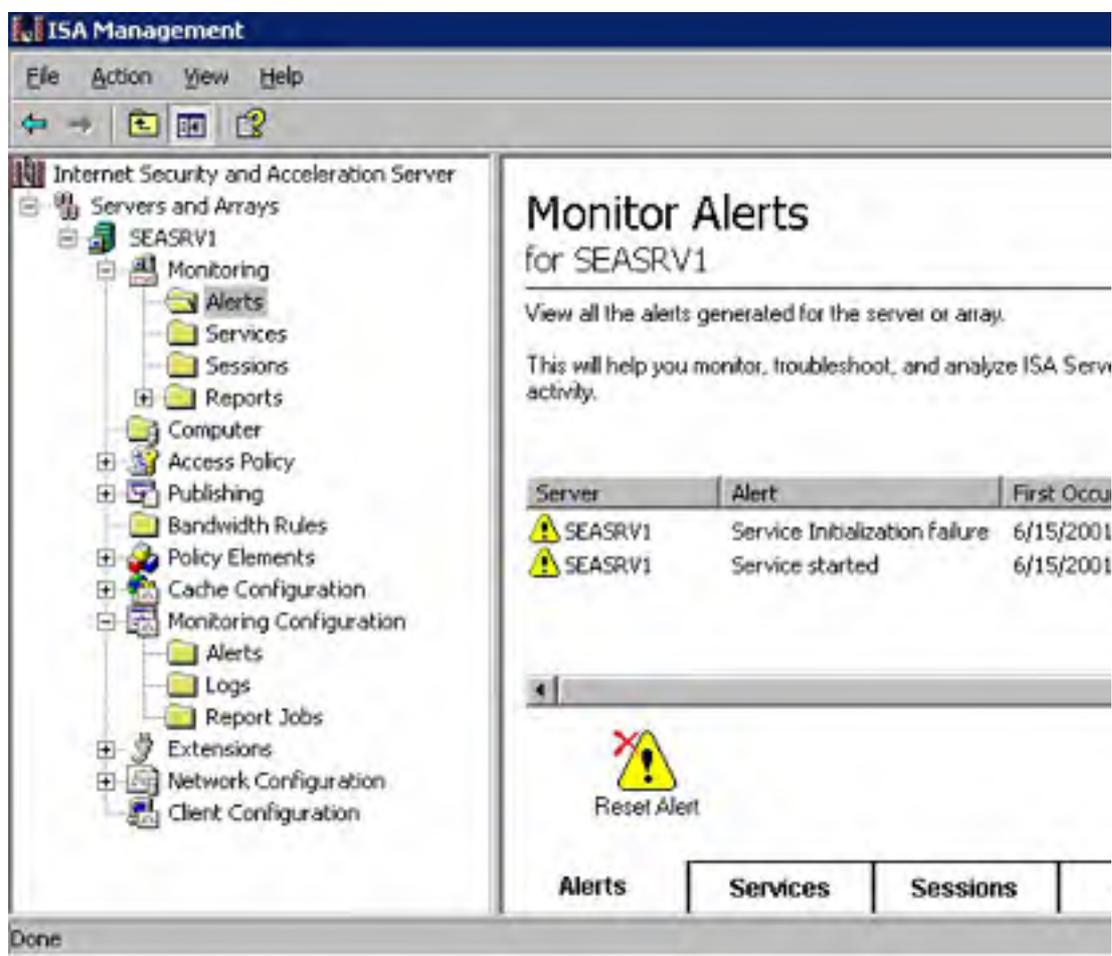

There are a number of ways that you can monitor an ISA server. You can use ISA Server's alerts functionality, you can view the status of ISA Server's services and user sessions, and you can create usage reports. In addition to these methods, ISA Server automatically logs certain data, which you can analyze in external programs if you want.

## Working with Alerts

ISA Server comes configured to alert you when any of a number of errors or problems occurs. Additionally, you can set up alerts to perform certain actions when they occur, such as send an e-mail message or run a program.

To work with alerts, use the following steps:

1. To view alerts generated on the ISA server, open the Monitoring object under the desired server or array, and then select the Alerts folder, shown in Figure 31-59.

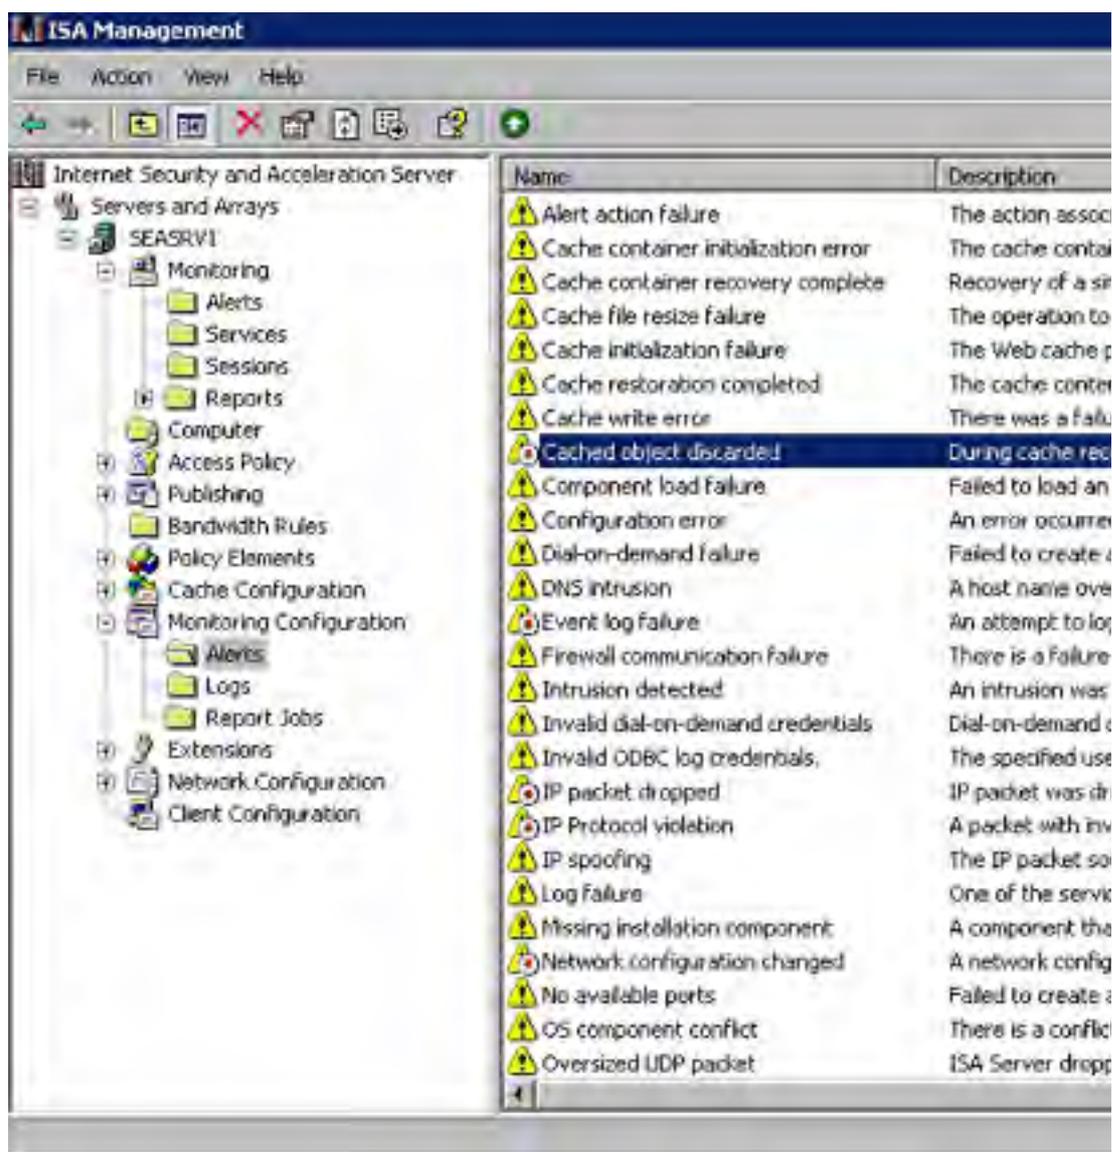

**Figure 31-59.** The Alerts folder.

Most alerts are written to Event Viewer as well as the Alert folder. You can turn this feature off on an individual alert basis.

2. To reset an alert that doesn't automatically reset itself, select the Alert and click the Reset Alert link.

- To view a list of alerts configured on the ISA server, open the Monitoring Configuration object under the desired server or array, and then open the Alerts folder, shown in Figure 31-60.

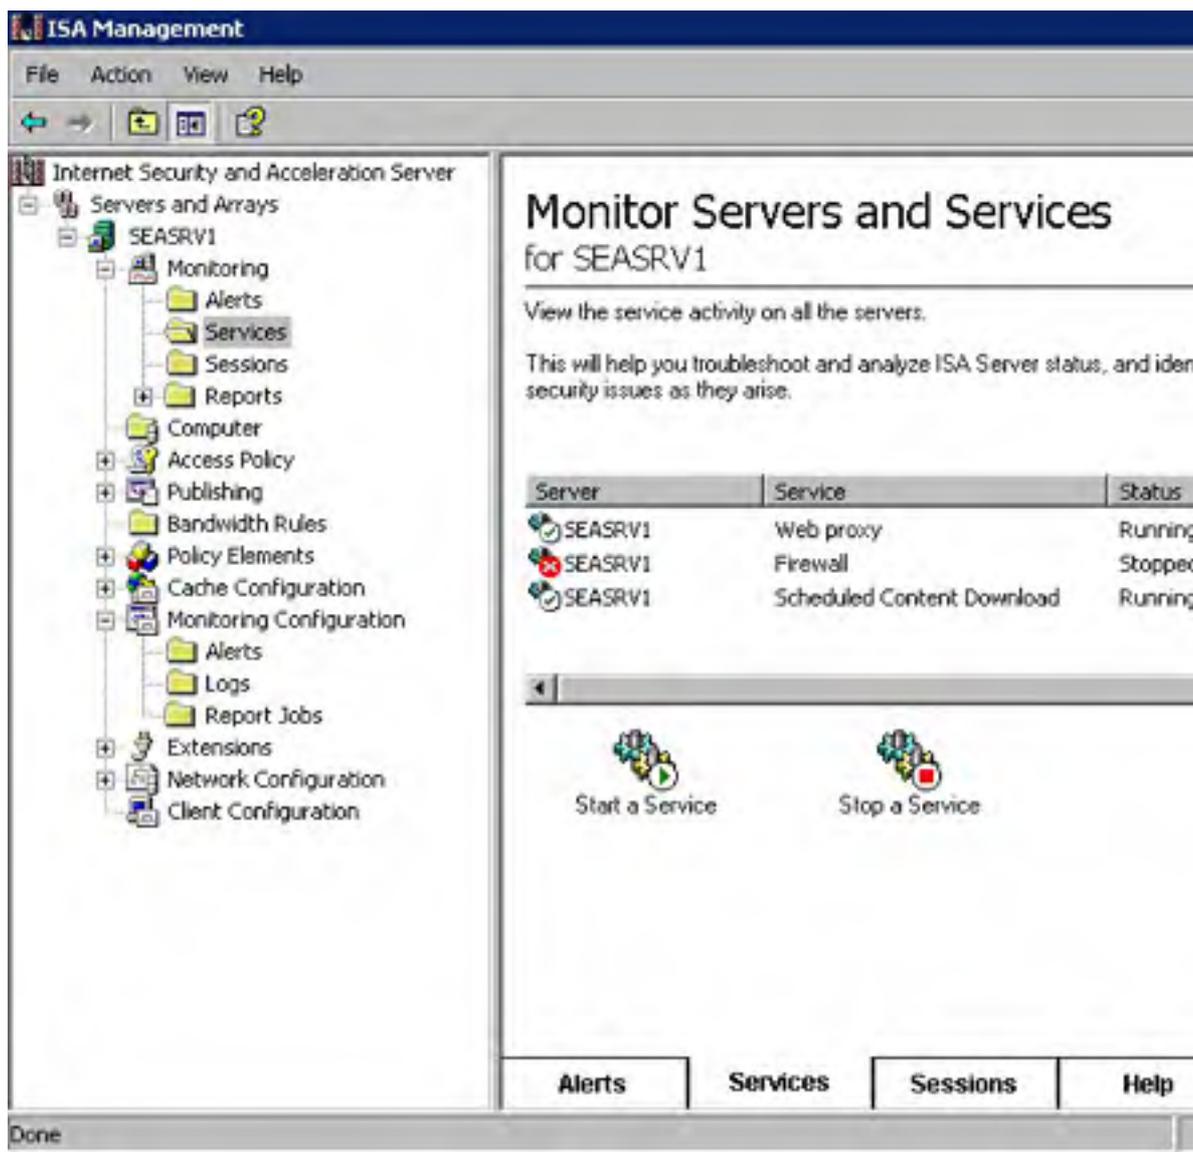

**Figure 31-60.** ISA Server alerts.

- To temporarily disable an alert (you can easily enable it later), select the alert and then click the Enable or Disable toolbar button (the button changes depending on whether an alert is enabled or disabled to begin with).
- Double-click an alert to modify its properties, and then use the Events and Actions tabs to control what events should trigger the alert and what actions should occur when the alert is triggered.
- To create a new alert, choose New-Alert from the Action menu, and then use the wizard to specify the conditions for the alert.

## Viewing Service and Session Status

To view the current status of the three main services (Web Proxy, Firewall, and Scheduled Content Download), open the Monitoring object under the desired server or array, and then click the Services folder. To start or stop a service, select it and then click the Start A Service or Stop A Service link, as shown in Figure 31-61.

**Figure 31-61.** Viewing ISA Server's services.

To view the current client sessions on the ISA server, open the Monitoring object under the desired server or array, and then click the Sessions folder. To disconnect a session, select the session and click the Disconnect A Session link.

## Working with Reports

ISA Server provides a handy tool that you can use to obtain information on the server's usage statistics. There are two parts to using reports: creating them and viewing them. To create and view a report, use the following steps:

1. To create a report, open the Monitoring Configuration object under the desired server or array, and then open the Report Jobs folder.
2. Choose the Action menu's New-Report Job command.
3. Enter a name for the job and a description in the General tab.
4. Click the Period tab and specify how much time the report should cover (daily, weekly, monthly, yearly, or a custom period).

- Click the Schedule tab and specify when to start the report and how often to create it, as shown in Figure 31-62.

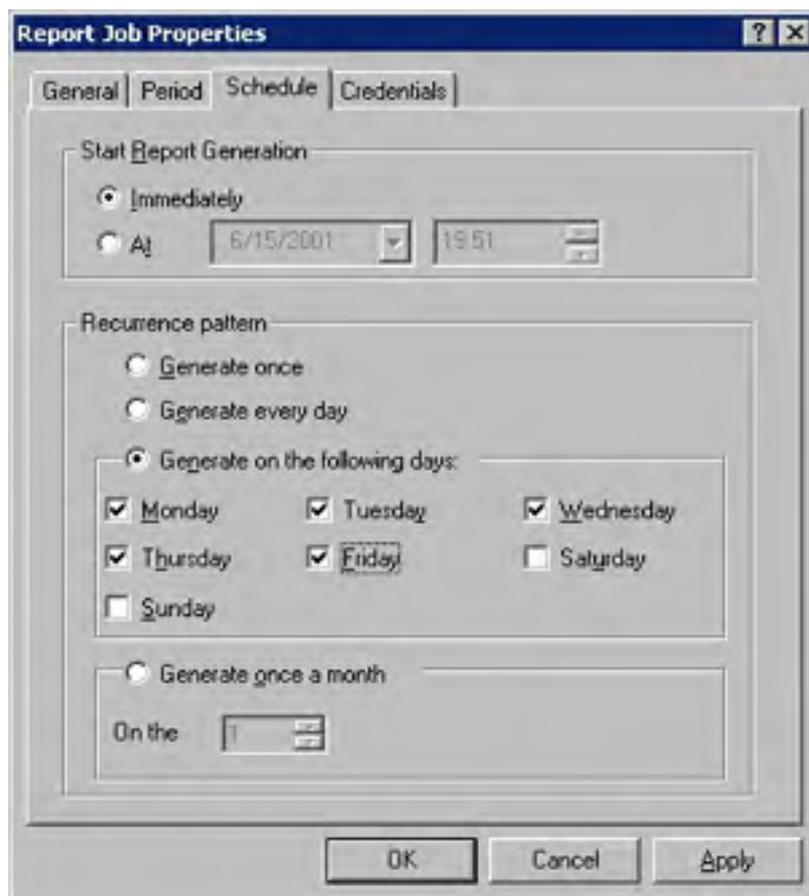

Figure 31-62. Creating a report job.

- Click the Credentials tab and enter the user name, domain, and password that are authorized to access and create report information on the desired server. Click OK when you're done.
- To view reports that have been already run (their start time must come to pass first), open the Monitoring object under the server or array the report was run on, and then open the Reports folder. Open the folder containing the type of report you want to view, and then double-click the desired report to display the report in the Web browser (see Figure 31-63).

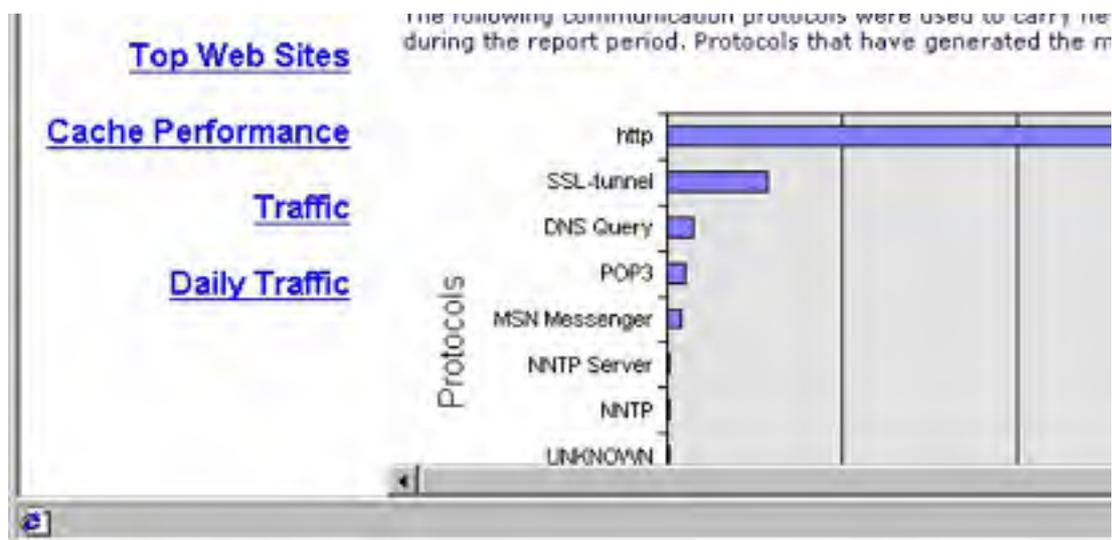

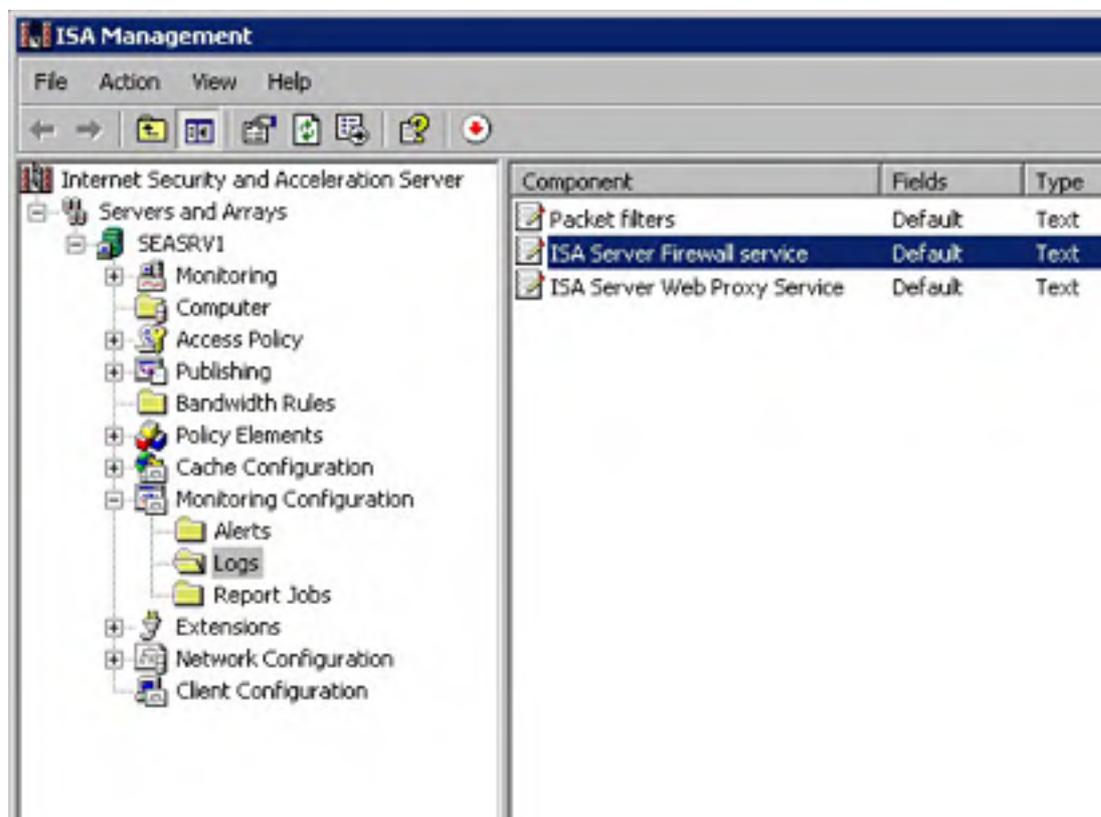

Figure 31-63. A report.

## Working with Logs

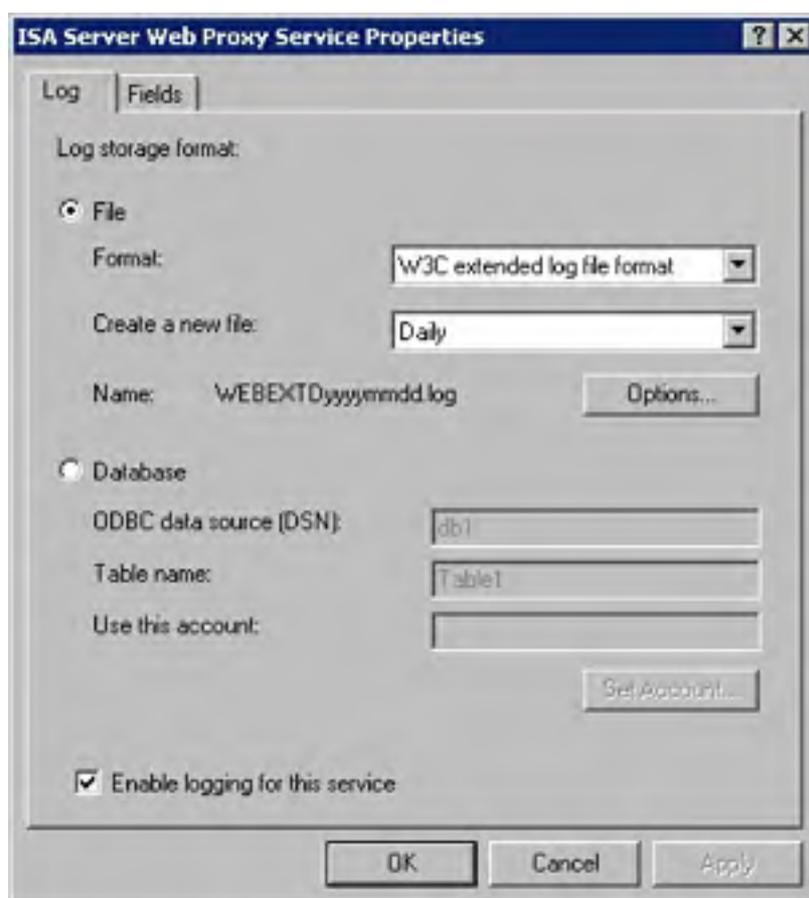

Besides alerts and reports, ISA Server automatically creates log files with information about the Firewall service, the Web Proxy service, and ISA Server's packet filters. What you do with this information is up to you—perhaps you want to perform your own data analysis on it using Microsoft Excel or a specialized statistical package—but there are several aspects of this data collection that you can control. For example, you can decide whether to use standard text files or to go to a database for more detailed analysis, as well as the level of detail stored. To configure logging, follow these steps:

1. Open the Monitoring Configuration object under the desired server or array, and then open the Logs folder, shown in Figure 31-64.
2. Double-click a log to configure its properties.
3. To disable logging for the specified service, clear the Enable Logging For This Service check box, shown in Figure 31-65.

**Figure 31-64.** *The Logs folder.*

**Figure 31-65.** *The properties for a log.*

4. To store the log as a file, leave the File option selected and use the following settings to configure how the file is stored:
  - **Format** Selects the method used to format the text file. The W3C extended log file format provides the most information, but you can also use the ISA Server file format if you don't need as much data.
  - **Create A New File** Specifies how often to create a new log file.

Click Options to change log file settings, such as where the log files are stored, whether to compress the log files, and how many log files to store before deleting the oldest ones.

5. To store the log in a database, choose the Database option and then use the following settings:
  - **ODBC Data Source (DSN)** The ODBC connection name. You need to set up this connection to the database beforehand using the ODBC Control Panel tool or another database configuration tool.

- **Table Name** The table in the data source in which to store the log information.
  - **Use This Account** Click Set Account to specify which user account to use when connecting to the database.
6. Click the Fields tab to control what fields are logged, and then click OK when you're finished.

## Real World

### Performance Monitoring

When you install ISA Server, it installs a preconfigured performance monitoring chart for use with the Performance Monitor MMC snap-in, as shown in Figure 31-66. You can use this chart to monitor the overall health and success of Proxy Server. For more on performance monitoring, see [Chapter 33](#).

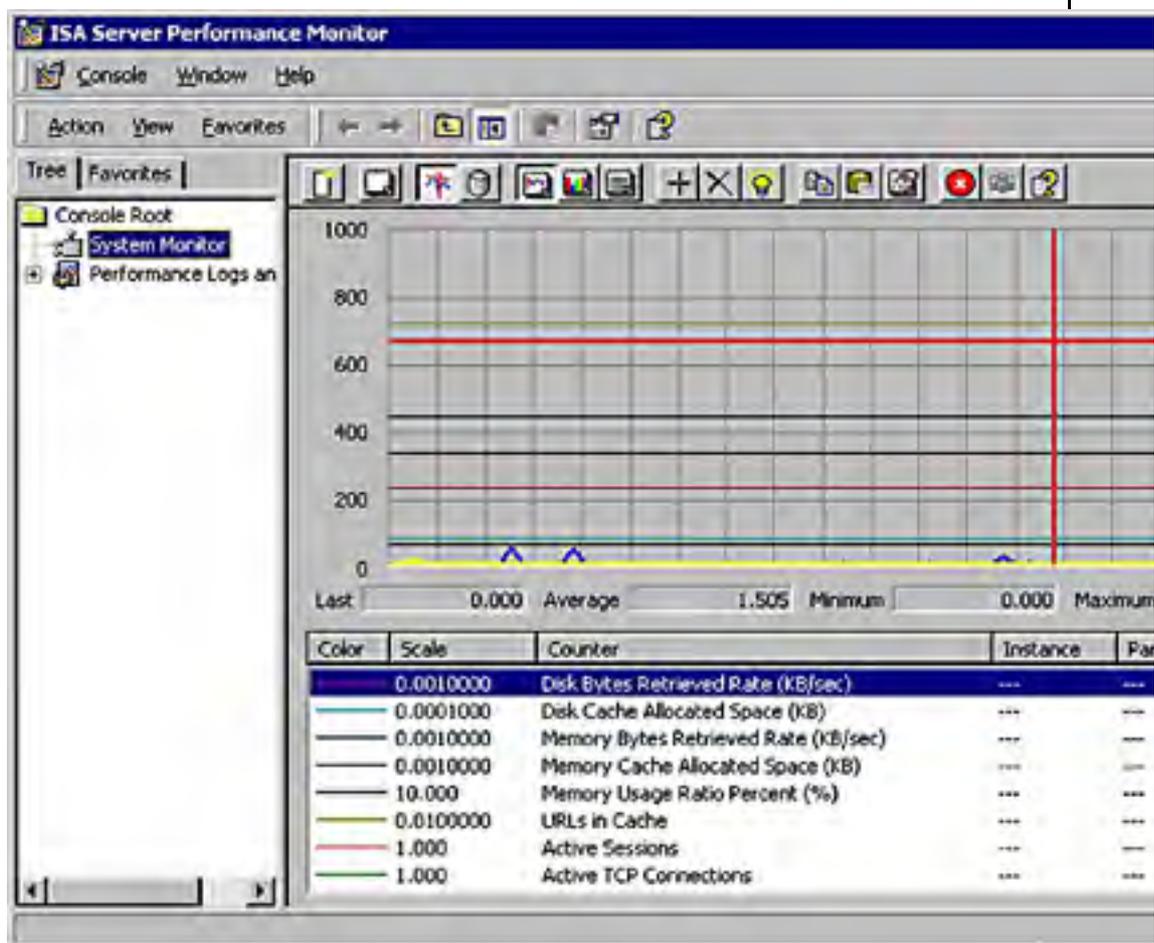

Figure 31-66. The ISA Server Performance window.

## **Summary**

ISA Server is Microsoft's top-of-the-line Internet sharing and firewall program. It protects your network from the Internet, and also boosts the performance of your Internet connection for internal clients. After installing ISA Server, you can use the Getting Started Wizard to perform most of the configurations necessary for the product. Further administration tasks can be performed from the ISA Management console tree, and include such things as making Web servers available to external clients, creating VPNs, and setting up clients.

The next chapter covers remote access and routing.

# Chapter 32

## Connection Services

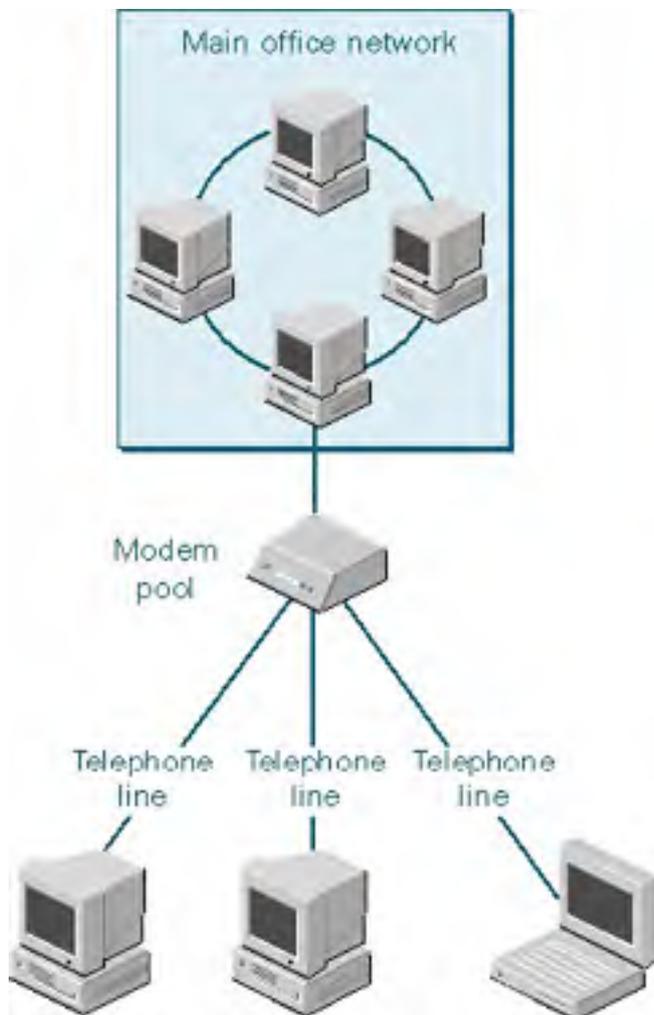

Routing and remote access services have been around in one form or another—under the names Remote Access Service (RAS), Routing and Remote Access Service (RRAS), and Dial-Up Networking—in every version of Microsoft Windows NT. In Microsoft Windows 2000, this service is called Routing and Remote Access, although you might still see the acronym RRAS used.

A computer running Microsoft Windows 2000 Server and Routing and Remote Access acts as a remote access server. This server authenticates users and enables the use of services typically available to a LAN-connected user (file and print sharing, applications, messaging, and so forth). The remote access server can connect remote users to the network using both virtual private network (VPN) and dial-up technology. Windows 2000 also supports Remote Authentication Dial-In User Service (RADIUS), the well-known authentication method used by many Internet service providers (ISPs). The user signs in with a name and password, which is then passed on to a server that authenticates the user and authorizes access.

Routing and Remote Access is a very large subject. This chapter focuses on new models and functionalities in Windows 2000. As in many areas of network administration, the complexities of Routing and Remote Access are more apparent than real. However, it is possible to plunge in and create an amazing amount of confusion if you don't first understand the concepts underlying the options.

## How Dial-Up Remote Access Works

Dial-up remote access, also called Dial-Up Networking, allows an off-site computer to tap into an office computer's resources using a modem. Figure 32-1 shows the usual dial-up connections made to a network.

**Figure 32-1.** Dial-up connections to a network.

Remote or mobile users using a dial-up communications link can access network resources as if they were directly connected. Windows 2000 remote access servers can connect to clients running Microsoft Windows XP Professional, Windows 2000, Windows NT, Windows 95/98, Windows for Workgroups, MS-DOS, or Apple Macintosh. Typically the client connects over a standard telephone line or over an ISDN line to a modem, modem pool, or ISDN "modem."

## Understanding Virtual Private Networks

A virtual private network is an extension of a private network across a public network such as the Internet. Using a VPN, connections across the public network can transfer data in a form that resembles a private Point-to-Point Tunneling Protocol (PPTP) link. VPNs use the routing infrastructure of the Internet, but to the user it appears as though the data were being sent over a dedicated private link.

The appeal of a VPN is the Internet and its global presence. Communication links can be made quickly, cheaply, and safely across the world. Dedicated private lines aren't required, and security can be configured at very high levels. In its *2001 Network Technology Adoption Forecasts US/Canada*, Infonetics Research confirmed that VPN spending is continuing to grow despite a general IT spending slowdown. The study reported that 56 percent of large organizations (companies with more than 1000 employees) already had site-to-site VPNs in 2000 and this percentage would increase to 84 percent in 2005. Small companies with 20 to 100 employees are expected to grow from 13 percent in 2000 to 50 percent by 2005.

### Real World

#### When a VPN Isn't Appropriate

Although VPNs are great methods of connectivity for branch offices and remote users of every stripe, there are conditions under which a VPN isn't appropriate:

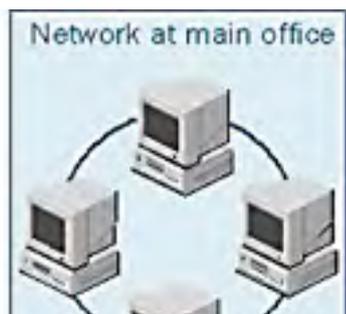

- When performance at any price is the primary concern
- When most traffic is synchronous, as in voice and video transmissions
- When using an application with unusual protocols that are not compatible with TCP/IP

In these situations, a dedicated private line is almost always the best choice.

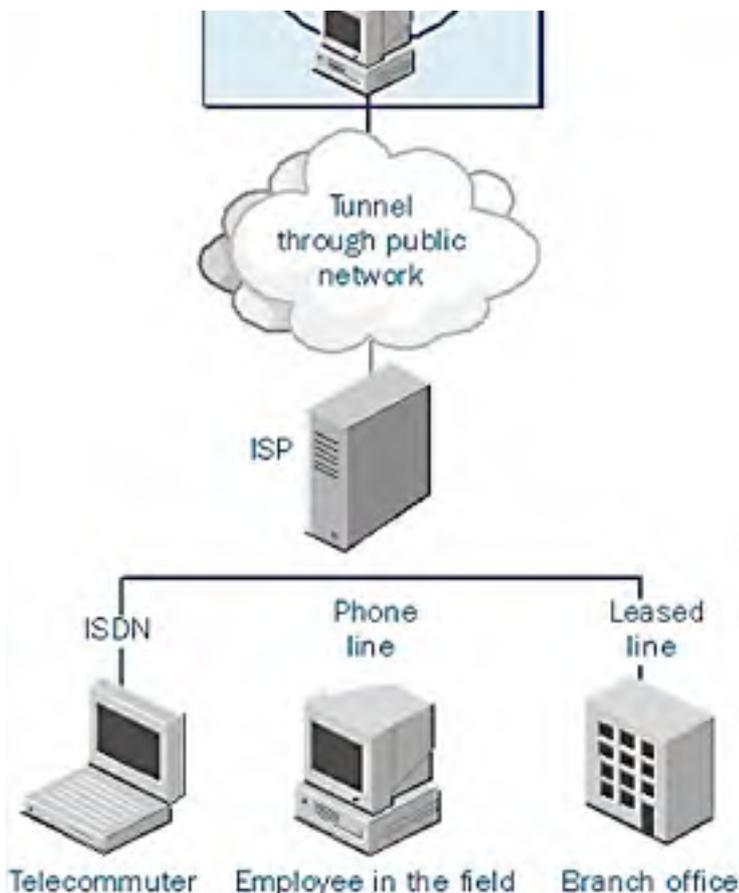

## How VPNs Work

In a virtual private network, both ends of the connection make a link to the Internet. (Technically, they can link to any public network, but it's almost always the Internet.) The link can take the usual forms—a regular telephone line, an ISDN line, or a dedicated line of some sort. Instead of sending a packet as the originating node produces it, the VPN, using a tunneling protocol, encapsulates the packet in an additional header. The header provides routing information so that the encapsulated data can traverse the intermediate internetwork. For privacy, the data is encrypted and, if packets are intercepted, they cannot be unencrypted without the encryption keys.

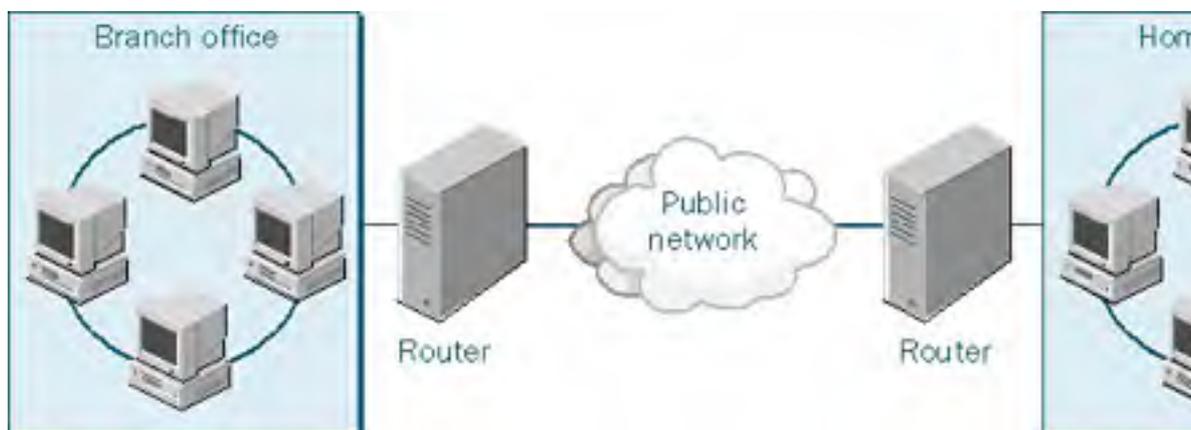

This technology allows a remote user in Connecticut, for example, to establish a dial-up connection with any ISP and, through that connection, make a direct connection to a server on the company network in California. It's quick, it's cheap, and it's easy to set up. Figure 32-2 shows a VPN set up so that traveling employees, telecommuters in home offices, and employees in branch offices can all connect to the main network at a company's headquarters. Each component is connecting to the ISP through a different type of communications channel, but all are part of the same VPN. Figure 32-3 shows a more typical VPN, in which the connection is made from one router to another.

**Figure 32-2.** A virtual private network.

**Figure 32-3.** A router-to-router VPN.

## Components of a VPN

A VPN connection in Windows 2000 consists of a VPN server, a VPN client, a VPN connection (the portion of the connection in which the data is encrypted), and the tunnel (the portion of the connection in which the data is encapsulated). The tunneling is done through one of the tunneling protocols included with Windows 2000, both of which are installed with Routing and Remote Access:

- **Point-to-Point Tunneling Protocol (PPTP)** An extension of the Point-to-Point protocol (PPP) in use for many years, PPTP was first used in Windows NT 4.
- **Layer Two Tunneling Protocol (L2TP)** A combination of PPTP and Layer Two Forwarding (L2F), a tunneling protocol developed by Cisco Systems. L2TP employs Internet Protocol security (IPSec) for encryption, so the VPN client and server must support both L2TP and IPSec.

**More Info**

For more information about the VPN protocols, see RFC 2637, "Point-to-Point Tunneling Protocol," and RFC 2661, "Layer Two Tunneling Protocol." Both can be found at (among other places) <http://www.vpnc.org/rfc.html> on the Internet.

## Installing a Remote Access Server

To allow the connection of multiple, simultaneous dial-up clients, you must have modem-pooling equipment (hereafter referred to as the modem bank) with the appropriate connections to the local telecommunications provider. A typical modem bank for Windows 2000 includes an adapter that installs in the computer running Windows 2000 Server. Make sure that the modem equipment is in the Windows 2000 Hardware Compatibility List (HCL), and that all the protocols needed for the dial-up connections are installed on this server.

## Configuring the Connection to Dial-Up Networking Clients

To enable Routing and Remote Access, follow these steps:

1. Launch Routing And Remote Access from the Administrative Tools folder on the Programs menu.
2. By default, the local computer is shown as a server. To enable Routing and Remote Access on the local computer, right-click the computer in the console tree, and choose Configure And Enable Routing And Remote Access from the shortcut menu.
3. The Routing And Remote Access Server Setup Wizard starts. To continue, click Next.
4. In the Common Configurations dialog box, select Remote Access Server and click Next.
5. Verify that the remote client protocols are listed. (If they are not, you have to cancel this wizard and install them.) Click Next.
6. Select your choice for IP address assignment. Automatic assignment is strongly recommended. Click Next.
7. In the Managing Multiple Remote Access Servers dialog box, select the option of not using a RADIUS server. (If you will have multiple remote access servers, see the section entitled [Using RADIUS for Multiple Remote Access Servers](#), later in this chapter.) Click Next, then click Finish. The Routing and Remote Access service starts and initializes automatically.

## Setting Remote Access Policies

In Windows NT 4.0 and Windows NT 3.51, remote access is granted based solely on whether the user's account has dial-in permission. The permission is configured in User Manager or the Remote Access Administration utility. In Windows 2000, remote access is somewhat more complicated. Authorization is determined by a combination of the dial-in properties for the user account and the remote access policies. With remote access policies, connections can be authorized or denied based on the time of day, the Windows 2000 group to which the user belongs, the type of connection being requested, and many other variables. By default, only one policy is in place when you install Routing and Remote Access: Allow Access If Dial-In Permission Is Enabled. However, this policy operates quite differently, depending on which administration model you use.

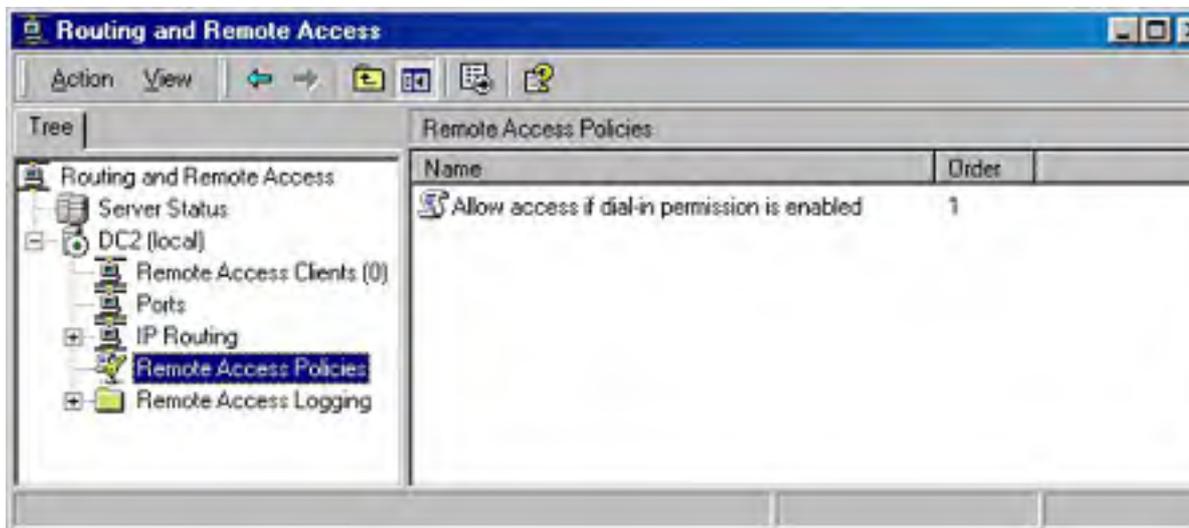

### Real World

#### Authorization and Authentication

The similarity between the words "authorization" and "authentication" can cause some confusion, and it's important to understand the differences. *Authorization* is the process of giving a user access to system objects based on the user's identity. *Authentication* is the process of identifying a user. In remote access connections, this is done when the client sends the user's credentials (user name and password) to the server using an authentication protocol. Authentication ensures that the individual is who he or she claims to be, but says nothing about the access rights of the individual.

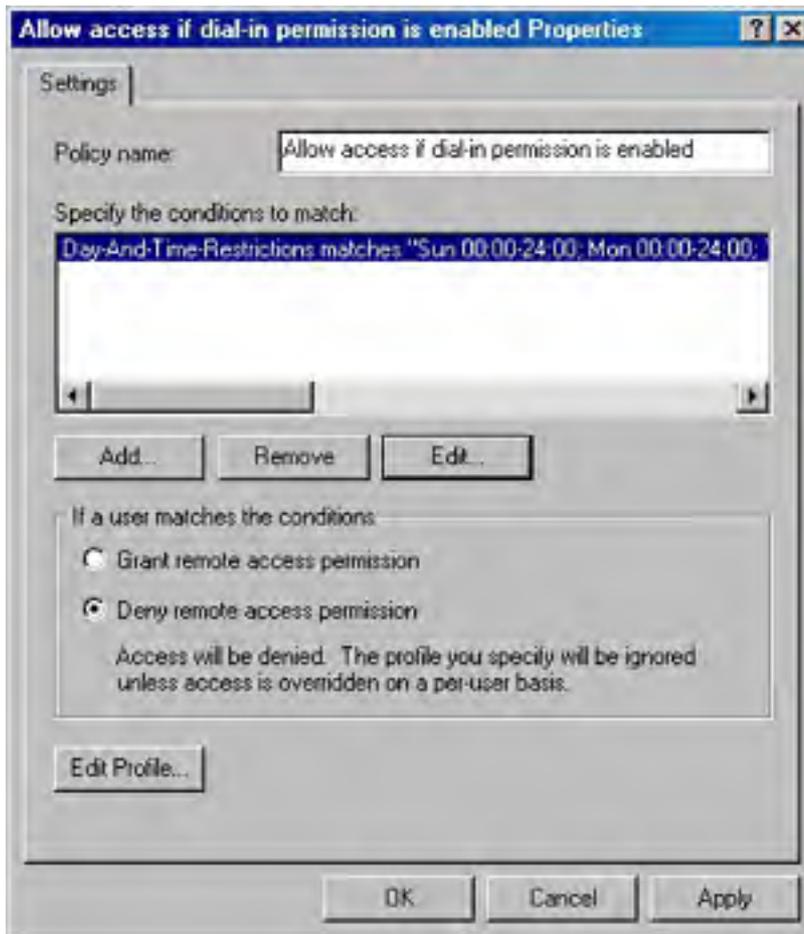

## Understanding the Default Policy

When you launch Routing and Remote Access from the Administrative Tools folder and click Remote Access Policies in the console tree, the details pane lists a single policy (Figure 32-4). This policy is called Allow Access If Dial-In Permission Is Enabled, and it is referred to often in this chapter. Understanding what it does and doesn't do is essential to grasping the administration of remote access.

**Figure 32-4.** The default remote access policy.

Right-click the policy in the details pane, and choose Properties from the shortcut menu to open the dialog box shown in Figure 32-5. This policy has a single condition that must be matched by anyone seeking remote access. Click Edit to view the condition. As you can see, the condition is Any Day, Any Time. You might not think that access at any day, any time is a condition, but it is. It's just not a restrictive condition, and it makes this policy essentially transparent.

**Figure 32-5.** *The Properties dialog box for the default remote access policy.*

Close the Time Of Day Constraints dialog box to return to the policy's Properties dialog box. The area labeled If A User Matches The Conditions contains two options: Grant Remote Access Permission and Deny Remote Access Permission. You might think that the default setting of Deny Remote Access Permission would prevent anyone from dialing into this remote server, but you would be mistaken. Whether these options actually allow or prevent a connection depends on the dial-in permission of the user account.

The confusion arises because people tend to use the terms "permission" and "policy" as if they were interchangeable. Permission is in fact set on the user account, and it is granted by default. The dial-in permission set on the user account overrides the permission option in this Properties dialog box except in the case of the native-mode administration model (described in the next section), in which all user accounts are set to Control Access Through Remote Access Policy.

Read the sections on administrative policies that follow carefully, and study the logic diagrams. The administrative approach you choose should be as simple as possible while still meeting your needs.

## Choosing an Administrative Model for Remote Access Policies

In Windows 2000, you can choose from among three models for administering remote access permissions and connection settings:

- Access by user
- Access by policy in a Windows 2000 mixed-mode domain
- Access by policy in a Windows 2000 native-mode domain

An essential part of planning for remote access is determining which models you can use and deciding on an appropriate one. There is enough variation among the models that attempting to mix them is a recipe for confusion. No matter which model you choose, plan on thoroughly testing your chosen access policies to make sure that you're getting the results you intend.

### Administering Access by User

In the access-by-user administrative model, remote access permissions are determined by the remote access permissions in the Dial-In tab of the Properties dialog box for the user account. To enable or disable remote access permission for individual users, set Remote Access Permission to either Allow Access or Deny Access, as in Windows NT Server. This administrative model is by far the simplest, and it works very well when the number of remote users is small and the access issue is uncomplicated.

If remote access permission for the user account is set to either Allow Access or Deny Access, the remote access permission setting on the remote access policy is effectively overridden. Access by user can be administered with multiple policies, but doing so can be complicated because a connection attempt might be rejected even when the remote access permission on the user account is set to Allow Access. If a connection attempt matches the conditions of a policy but does not match the profile settings or does not match any of the remote access policies, the connection attempt is rejected, as shown in Figure 32-6. In the access-by-user administrative model, you can control access in three ways:

- **Explicit allow** The remote access permission for the user account is set to Allow Access, and the connection attempt doesn't conflict with a policy or the settings of the profile and the dial-in properties of the user account.
- **Explicit deny** The remote access permission for the user account is set to Deny Access.
- **Implicit deny** The connection attempt doesn't match the conditions set in any remote access policies.

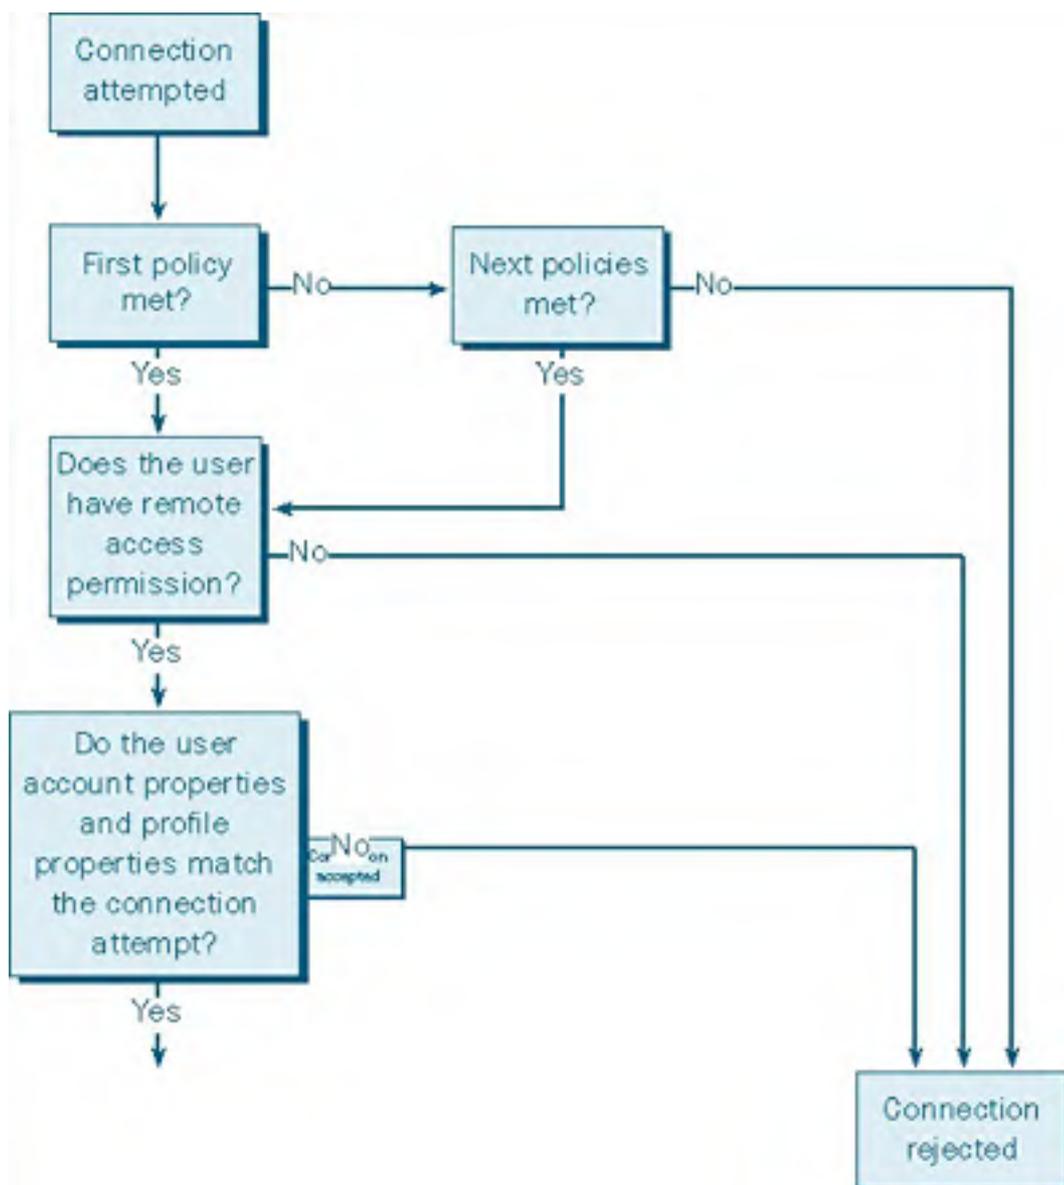

The access-by-user administrative model can be used on a stand-alone remote access server, a remote access server on a Windows 2000 native-mode domain, a remote access server on a Windows 2000 mixed-mode domain, or a remote access server on a Windows NT 4 domain.

### Granting Access by User

The access-by-user model resembles the administrative model of Windows NT 4. Individual user accounts are set to Allow Access or Deny Access. The default policy in Routing and Remote Access, Allow Access If Dial-In Permission Is Enabled, is in place with the following settings:

- The single condition of day and time restrictions is set to allow access at all times on all days.
- The profile is set to the default settings.
- The Deny Remote Access Permission option is selected.

But wait! If Deny Remote Access Permission is selected, isn't remote access permission denied? No; it means basically *nothing* in this scenario. Access is determined solely by the settings in the Properties dialog box for the individual user account. Figure 32-6 shows the progression of a connection under the access-by-user administrative model.

**Figure 32-6.** Progression of a connection attempt when administering access by user.

## Administering Access by Policy for a Mixed-Mode Domain

In the access-by-policy administrative model for a Windows 2000 mixed-mode domain, the remote access permission on every user account is set to Allow Access, the default remote access policy is deleted or demoted, and separate remote access policies are created to define the types of connections that are allowed. On a remote access server running Windows 2000 that is a member of a Windows 2000 mixed-mode domain, the Control Access Through Remote Access Policy option is not available for remote access permission on the user account. If a connection attempt corresponds to the conditions of a policy (subject to the profile and user account dial-in settings), the connection is accepted.

The access-by-policy administrative model also applies to a remote access server running Windows 2000 that is a member of a Windows NT 4 domain.

In the access-by-policy administrative model for a Windows 2000 mixed-mode domain, you can control access in three ways:

- **Explicit allow** The connection attempt matches the conditions of a policy, subject to the settings of the profile and the dial-in properties of the user account.
- **Explicit deny** The connection attempt matches the conditions of a policy but not the

settings of the profile. You can do an explicit deny in this model by editing the profile and enabling the Restrict Dial-In To This Number Only option in the Dial-In Constraints tab and typing a number that does not correspond to any dial-in number being used by the remote access server.

- **Implicit deny** The connection attempt does not match the conditions of any remote access policies.

If you do not delete the default remote access policy, Allow Access If Dial-In Permission Is Enabled, all users can obtain a remote access connection.

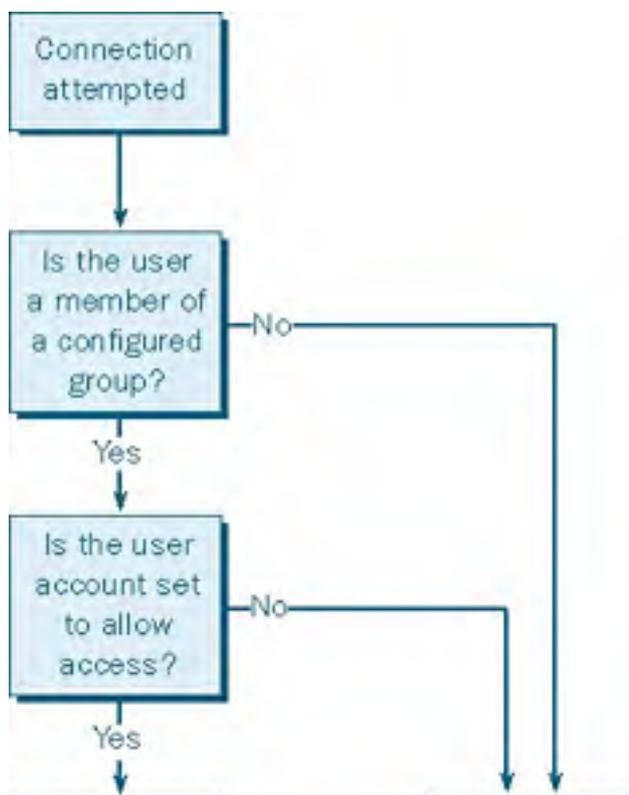

The access-by-policy administrative model for mixed-mode domains can be used with Windows NT servers running Routing and Remote Access if the Windows NT servers are configured as RADIUS clients to a Windows 2000 Internet Authentication Service (IAS) server. A Windows NT server running RAS cannot use access by policy. You must upgrade the server to Windows NT RRAS (or to Windows 2000) to employ the remote access policy authorization.

### Granting or Denying Access by Group Membership

To allow connections for users by group membership, all user accounts must have Remote Access Permission in the Dial-In tab set to Allow Access. To set up the access by groups, the administrator makes the following settings:

- In Routing and Remote Access, delete the default policy, Allow Access If Dial-In Permission Is Enabled.
- Create a new policy named Accept If Member Of Selected Groups.
- Add the *Windows-Groups* attribute to the policy.
- Select the group or groups to be granted access.
- On the policy, select the Grant Remote Access Permission option.

In this case, the Grant Remote Access Permission option means what it says. Figure 32-7 shows the progression of a connection attempt when a remote user dials in and access is controlled by group membership.

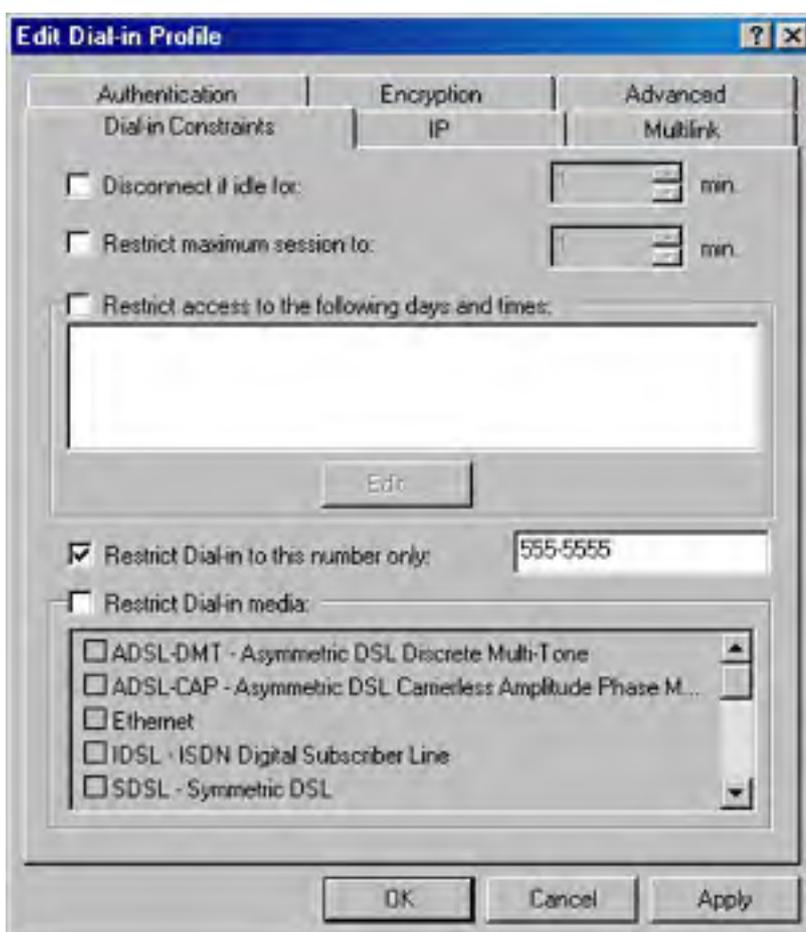

**Figure 32-7.** Progression of a connection attempt when administering access by group membership.

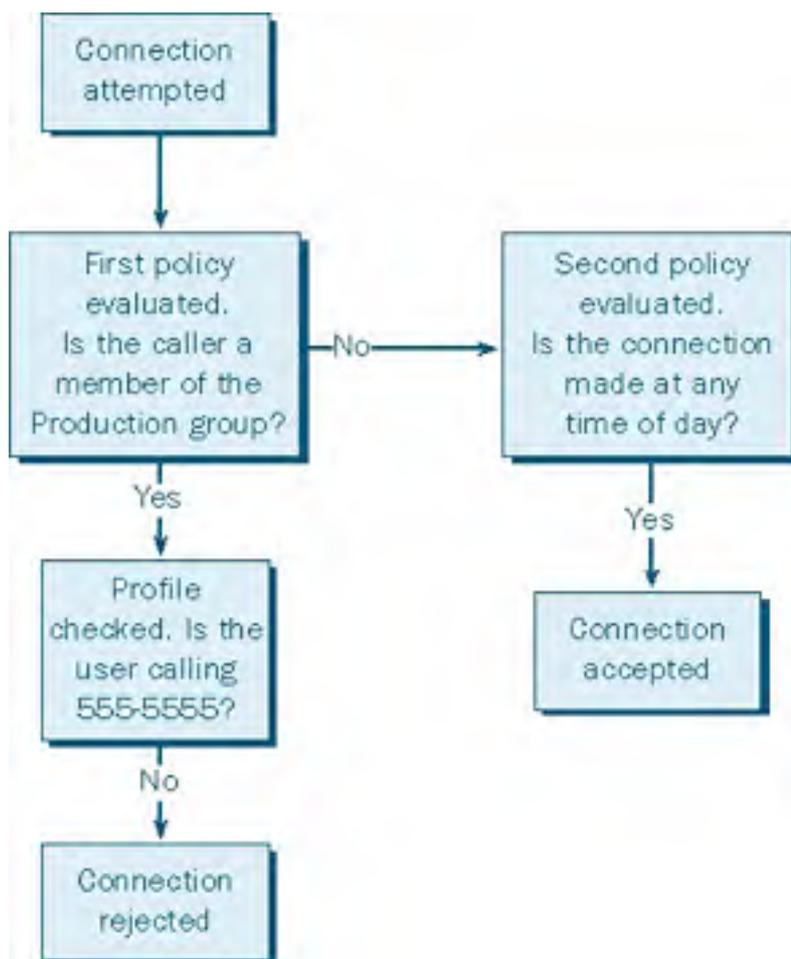

Perhaps it would be easier in your situation to specify who *isn't* allowed access than to specify who is. For example, employees in production might have user accounts on the network but have no need for dial-in access. In this case, you need to make the following settings:

- Leave the default policy, Allow Access If Dial-In Permission Is Enabled, in place.
- Create a new policy named Reject Production Group.
- Add the *Windows-Groups* attribute to the policy.
- Select the Production group.
- On the policy, select the Deny Remote Access Permission option.
- Click Edit Profile and, in the Dial-In Constraints tab, select Restrict Dial-In To This Number Only and type in a number that is not a dial-in number of the remote access server, as shown in Figure 32-8.
- In the details pane of the Routing and Remote Access snap-in, right-click the new policy and select Move Up so that it is the first to be evaluated.

**Figure 32-8.** Configuring the dial-in constraints to deny access to a group.

Figure 32-9 shows the logic of the connection attempt when access is denied by group membership.

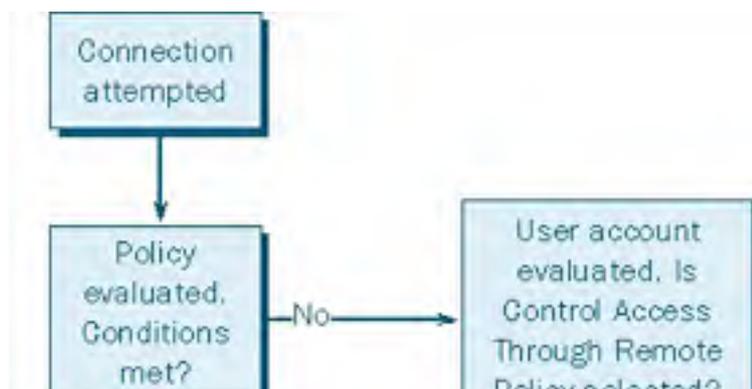

**Figure 32-9.** Progression of a connection attempt when the policy is to deny access by group membership.

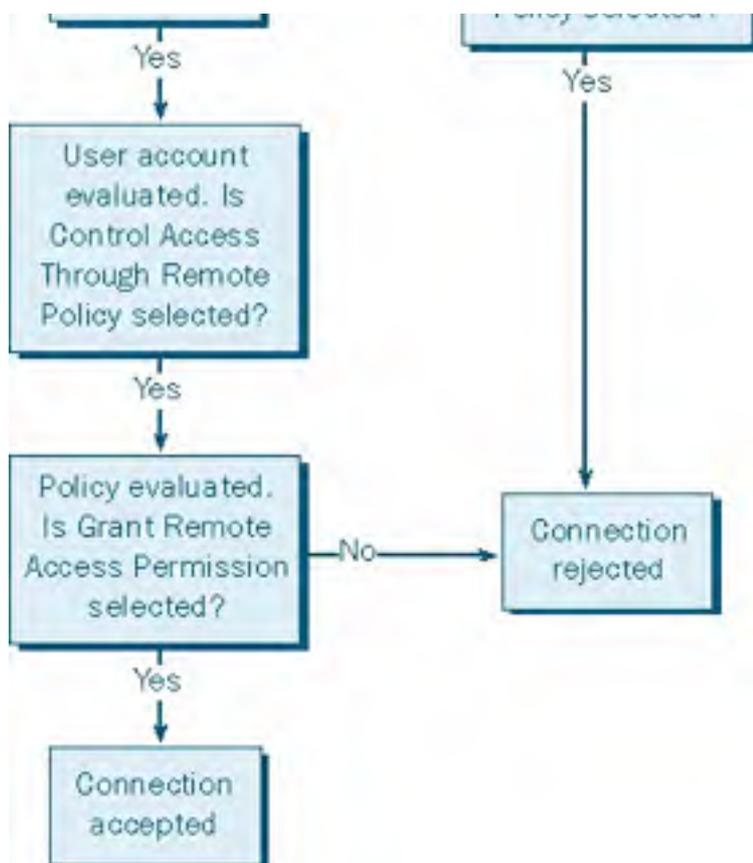

### Administering Access by Policy for a Native-Mode Domain

In a Windows 2000 native-mode domain, you can use the access-by-policy administrative model, which has the following settings:

- The remote access permission on every user account is set to Control Access Through Remote Access Policy.
- Remote access permissions are determined by the remote access permission setting on the remote access policy.

These settings mean that the Remote Access Permission setting on the remote access policy determines whether remote access permission is allowed or denied. Figure 32-10 shows the progression of a connection attempt in a native-mode domain.

**Figure 32-10.** Progression of a connection attempt when administering access by policy in a native-mode domain.

In the access-by-policy administrative model for a Windows 2000 native-mode domain, you can control access in three ways:

- **Explicit allow** The remote access permission on the remote access policy is set to Grant Remote Access Permission, and the connection attempt matches the conditions of the policy, subject to the settings of the profile and the dial-in properties of the user account.
- **Explicit deny** The remote access permission on the remote access policy is set to Deny Remote Access Permission, and the connection attempt matches the conditions of the policy.
- **Implicit deny** The connection attempt does not match the conditions of any remote access policies.

If you use the access-by-policy administrative model for a native-mode domain, don't add remote access policies, and don't change the default remote access policy (Allow Access If Dial-In Permission Is Enabled), then no users are allowed remote access. By default, the remote access permission on the default remote access policy is set to Deny Remote Access Permission. If you change the setting to Grant Remote Access Permission, all users are allowed remote access.

The access-by-policy administrative model for a Windows 2000 native-mode domain also applies to stand-alone remote access servers that are not members of a domain. You can't use the access-by-policy administrative model for a Windows 2000 native-mode domain if you have Windows NT 4 RAS or RRAS or IAS servers because a native-mode domain by definition has no Windows NT servers.

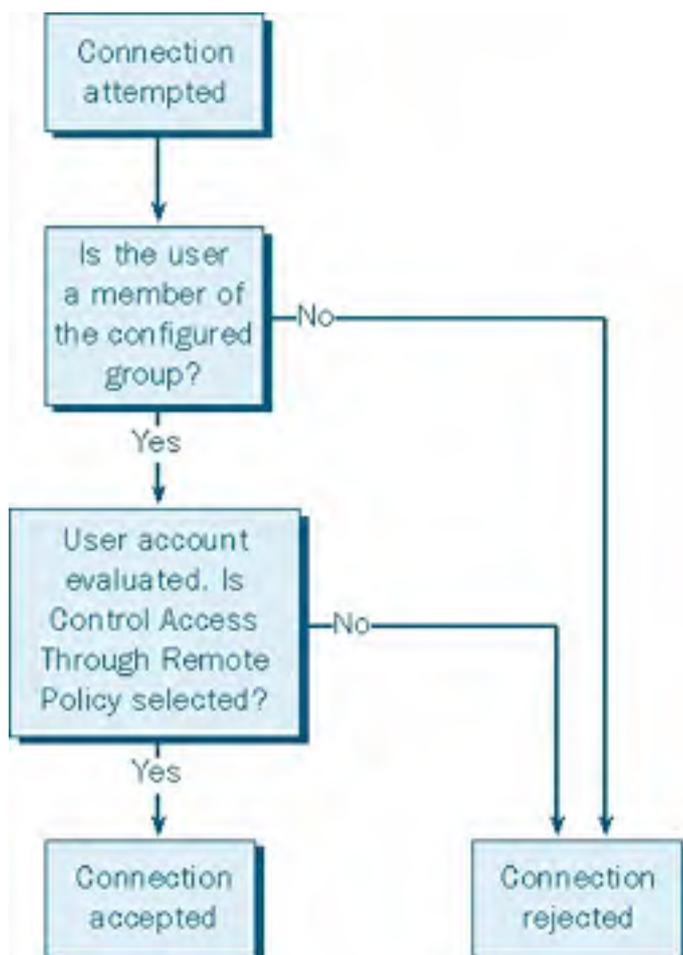

If you use the access-by-policy administrative model for a Windows 2000 native-mode domain and you do not use groups to specify which users get access, verify that the Guest account is disabled and that its remote access permission is set to Deny Access.

## Granting or Denying Access by Group Membership

In a native-mode domain, setting access by policy requires that all user accounts have the Control Access Through Remote Access Policy option selected in the Dial-In tab of the user account's Properties dialog box. To allow access by specified groups, the administrator must do the following:

- Delete the default policy, Allow Access If Dial-In Permission Is Enabled.
- Create a new policy called Accept If Member Of Selected Groups.
- Add the *Windows-Groups* attribute to the policy.
- Select the group or groups to be granted access.
- On the policy, select the Grant Remote Access Permission option.

Figure 32-11 shows the progression of a connection attempt with this policy setting.

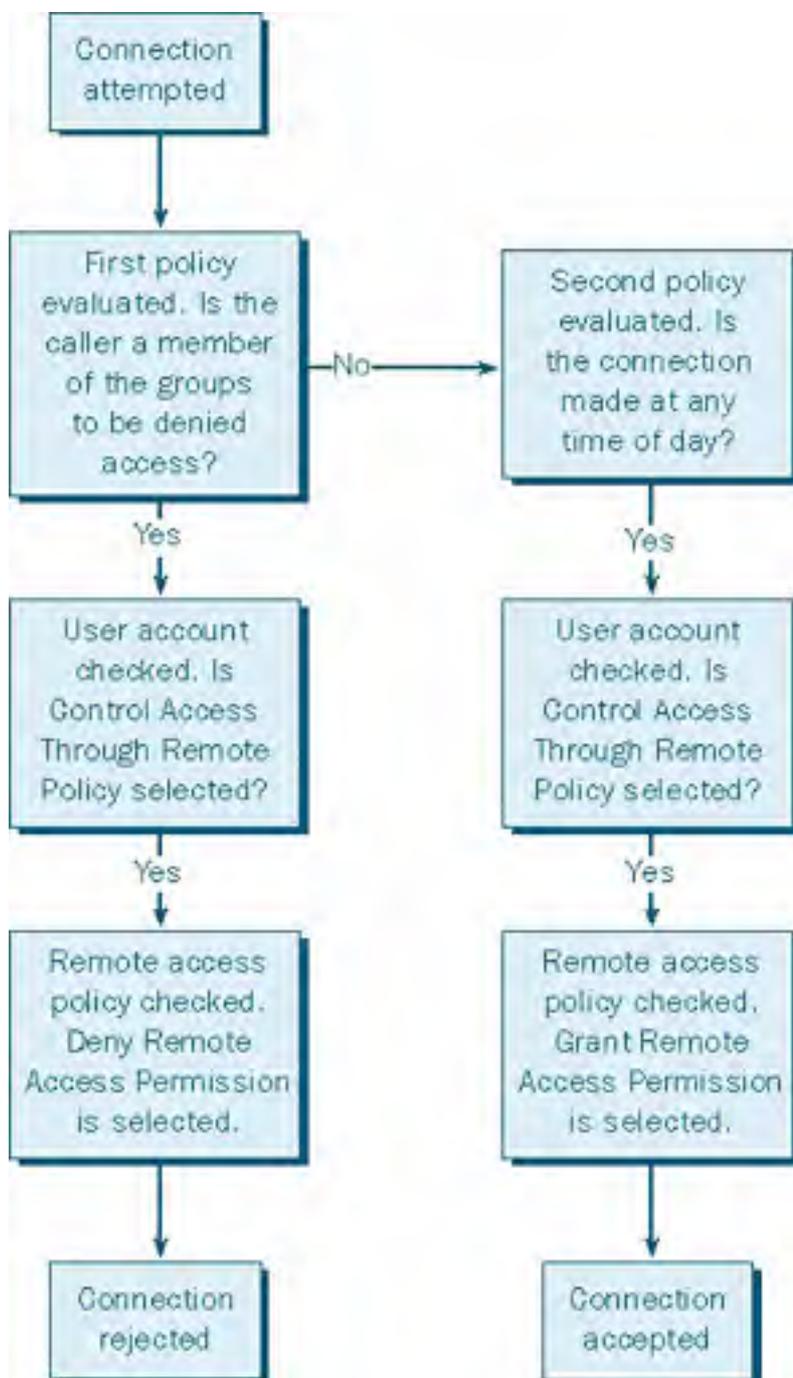

**Figure 32-11.** Progression of a connection attempt when the policy is to allow access by group membership in a native-mode domain.

In a native-mode domain, you can easily reverse the criteria just described and deny access based on group membership. This policy also requires that all user accounts have the Control Access Through Remote Access Policy option selected in the Dial-In tab of the user account's Properties dialog box. As in the mixed-mode domain, two policies are needed: one to reject members of a specified group and another to allow a connection made by anyone else. Follow this procedure to deny access based on group membership:

- Leave in place the default policy, Allow Access If Dial-In Permission Is Enabled. Select the Grant Remote Access Permission option on the default policy.
- Create a new policy named Deny Configured Group.
- Add the *Windows-Groups* attribute to the policy.
- Add the groups that are to be denied remote access.

- On the new policy, select the Deny Remote Access Permission option.
- In the details pane of Remote Access Policies, right-click the new policy and select Move Up so that it is the first to be evaluated.

Figure 32-12 shows the logical progression when a connection attempt is made with these settings in effect.

**Figure 32-12.** Progression of a connection attempt when access is controlled by groups in a native-mode domain.

#### Real World

**Windows NT 4 Remote Access in a Windows 2000 Domain**

In a Windows 2000 domain, a server running Windows NT 4 and either RAS or RRAS can't authenticate the credentials of domain accounts unless it (the Windows NT server) is also a domain controller. A Windows NT server that is not a domain controller does not have permission to read Active Directory and therefore can validate only local accounts. This same restriction applies when you have a remote access server (running Windows NT *or* Windows 2000) in a Windows NT domain that needs to validate user accounts in a trusted Windows 2000 domain.

The recommended solution is to upgrade the Windows NT 4 server to Windows 2000. This provides the best functionality and maintains an acceptable level of security.

However, if security is of less importance, you can upgrade the Windows NT server to a domain controller (which exposes the SAM to external attack) or loosen the normal Active Directory security so that the remote access server can read the user account properties. Open a command prompt window on a domain controller and type:

```
net localgroup "Pre-Windows 2000 Compatible Access" everyone /add
```

This adds the special identity Everyone to the Pre-Windows 2000 Compatible Access group so that the remote access server can use NT LAN Manager security to read the domain user accounts. Once again, be aware that doing this substantially weakens the security of your network. Upgrading any RRAS servers to Windows 2000 is a far superior solution.

## Configuring a Remote Access Policy

A remote access policy consists of three elements that make up a rule for analyzing remote connections: the conditions, the profile, and the remote access permission for the policy. The remote access permission was discussed earlier, in the section entitled [Understanding the Default Policy](#). Recall that the remote access permission for the policy applies only when an administration-by-policy model is being employed.

## Specifying Conditions of Remote Access Policies

When granting or denying access by group membership in the previous sections, you added the *Windows-Groups* attribute as a condition that users making connection attempts had to match (Figure 32-13). Table 32-1 describes this and other attributes that can be included in a remote access policy.

**Figure 32-13.** The remote access attributes that can be added to policies.

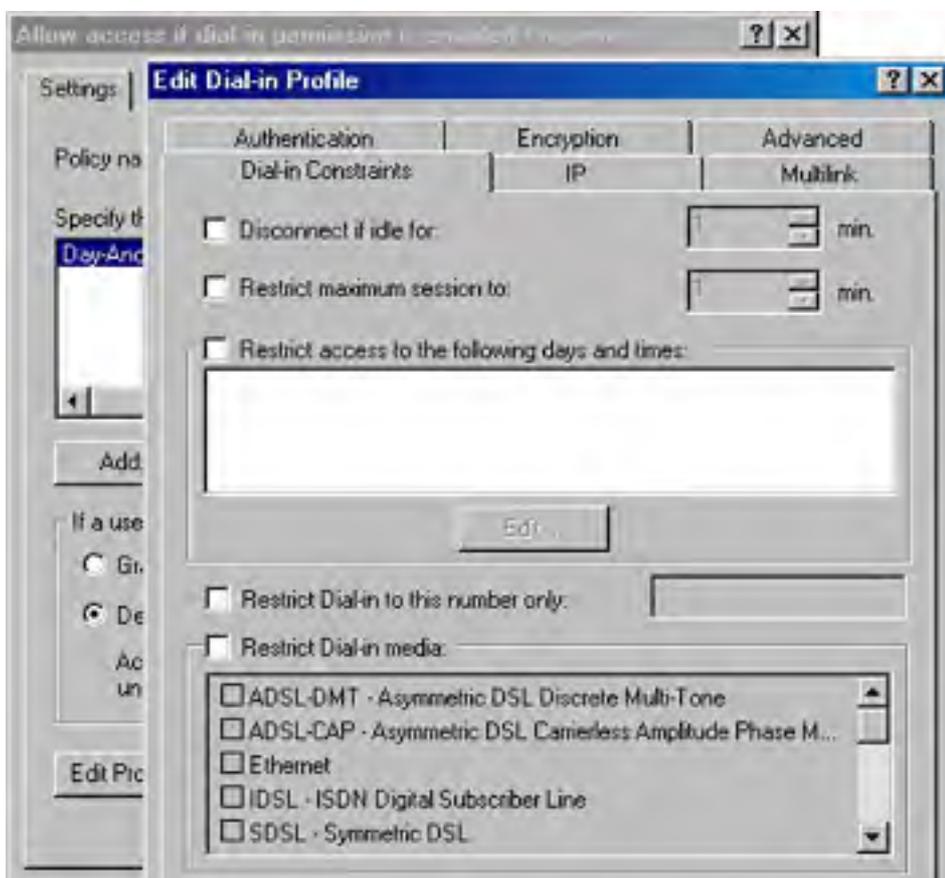

**Table 32-1.** Attributes for remote access policies

Attribute Name	Description
Called-Station-Id	Phone number of the remote access server. To receive this information, the phone line, hardware, and hardware drivers must support the passing of the information. Otherwise, the called station ID is set manually for each port.
Calling-Station-Id	Phone number used by the caller. If you configure a caller ID number for a user, the phone system, remote server, and all connecting hardware must support the passing of caller ID information. If any link in the connection does not support caller ID, the connection attempt is denied.
Client-Friendly-Name	(IAS server only) Name of the RADIUS client computer that is seeking authentication.
Client-IP-Address	(IAS server only) IP address of the RADIUS client.

Client-Vendor	(IAS server only) Vendor of the network access server that is a RADIUS client. Used to configure different policies for different manufacturers.
Day-And-Time-Restriction	Days and times for connection attempts.
Framed-Protocol	Protocol such as PPP, SLIP, Frame Relay, or X.25 to be used for framing incoming packets.
NAS-Identifier	(IAS server only) String to identify the originating network access server (NAS).
NAS-IP-Address	(IAS server only) IP address of the originating NAS.
NAS-Port-Type	Medium used by the originating caller. Examples are analog telephone and ISDN lines.
Service-Type	Type of service the caller requests. Examples are framed (PPP) and login (Telnet).
Tunnel-Type	Tunneling protocols to be used. Examples are PPTP and L2TP.
Windows-Groups	Groups that the caller is a member of.

## Configuring Profiles in Remote Access Policies

The profile in a remote access policy is a set of conditions that applies when a connection is authorized. The profile applies whether the condition has been authorized by permission in the user account or by permission in the policy. To see the profile that applies to a policy, open the policy's Properties dialog box and click Edit Profile. The Edit Dial-In Profile dialog box has six tabs that can be configured (Figure 32-14). Each tab is discussed in the sections that follow.

**Figure 32-14.** *Settings in the remote access policy profile.*

## Specifying Dial-In Constraints

In the Dial-In Constraints tab, you can set the following limitations on the dial-in connection:

- **Disconnect If Idle For** The time after which an idle connection is terminated. By default, no connection is automatically terminated when idle.
- **Restrict Maximum Session To** The time after which a connection is disconnected. By default, there is no time limit on connections.
- **Restrict Access To The Following Days And Times** The days and hours when a connection is allowed. This check box is cleared by default. The remote access server will not disconnect a connection that is active at a time when connection attempts aren't allowed.
- **Restrict Dial-In To This Number Only** The specific number that a user must call for a connection to be allowed.
- **Restrict Dial-In Media** The type of medium the caller must be connecting with, such as ISDN, T1, or ADSL. If the medium specified doesn't match the medium being used, the call is rejected.

## Specifying IP Address Policies

The IP tab defines the IP address policies for the profile:

- **IP Address Assignment Policy** By default, the server supplies an IP address for the connection, but you can specify that the server must supply an address or that the client can request an IP address.
- **IP Packet Filters** Specifies the types of packets that are allowed (or not allowed) in the traffic to the client or from the client or both. Packet filtering can be based on such things as the source and destination IP addresses, protocol type, source or destination port, and so forth.

## Enabling Multilink and the Bandwidth Allocation Protocol

In the Multilink tab, you can choose settings to enable Multilink and the Bandwidth Allocation Protocol (BAP). The server must have Multilink and BAP enabled for these settings to be enforced in the profile. Enabling Multilink allows clients to combine multiple physical connections into a single logical connection. If you enable Multilink, you should also enable BAP so that links can be dynamically added or dropped as needed. (Multilink has no mechanism for adapting to changing bandwidth needs.) In the Multilink tab, choose from the following options:

- **Multilink Settings** Disables Multilink completely or sets the maximum number of ports that a connection can use. This option defaults to the server's setting.
- **Bandwidth Allocation Protocol Settings** Causes a Multilink connection to be reduced automatically if the lines fall below a specified capacity for a specified length of time.

## Specifying Authentication Methods

In the Authentication tab, you set the authentication methods that are allowed for the connection. The same authentication methods must be enabled on the remote access server for the properties of the profile to be enforced. For more on authentication methods, see the section [Configuring Authentication for a Remote Access Server](#) in [Chapter 19](#).

## Specifying an Encryption Method

The Encryption tab lets you set the encryption properties for this profile. The settings are as follows:

- **No Encryption** Allows a nonencrypted connection. To require encryption, clear this check

box.

- **Basic** Uses Microsoft Point-to-Point Encryption (MPPE) with a 40-bit key for dial-up and PPTP connections. For L2TP over an IPsec-based VPN, uses 56-bit Data Encryption Standard (DES) encryption.
- **Strong** Uses MPPE with a 56-bit key for dial-up and PPTP connections. For L2TP over an IPsec-based VPN, uses 56-bit DES encryption.

### **Setting Advanced Attributes**

In the Advanced tab, you can set RADIUS attributes that are sent to the RADIUS client by the IAS server. These attributes are specific to RADIUS authentication and are ignored by the remote access server.

## Configuring a Remote Access Server

Some of the profile settings described in the previous section must have corresponding entries on the remote access server. This section covers those settings as well as other specific configurations that can be performed on a server. To make configuration changes to a remote access server, open Routing And Remote Access, right-click the server name in the console tree, and choose Properties from the shortcut menu. The various settings available in the Properties dialog box are as follows:

- **Authentication Settings** To access the authentication settings, click the Security tab in the server's Properties dialog box, and then click Authentication Methods. By default, Microsoft's Challenge Handshake Authentication Protocols (MS-CHAP and MS-CHAP v2) are selected.
- **IP Routing And Assignment** The IP tab on the server's Properties dialog box gives access to the IP parameters. By default, the profiles in remote access policies use the server's settings for IP addresses. In turn, the server defaults to allowing IP routing and to assignment of IP addresses using DHCP. If you need to use a static address pool, choose that option and provide a range of addresses to be assigned to connections.
- **Multilink And The BAP** Click the PPP tab to access the options for enabling Multilink and the BAP. See the section [Enabling Multilink and the Bandwidth Allocation Protocol](#), earlier in this chapter, for more information.
- **Other Protocols** In the PPP tab, click Software Compression to enable (or remove) support for the Microsoft Point-to-Point Compression (MPPC) protocol. You can also select the Link Control Protocol (LCP) Extensions to PPP.

### More Info

For more information about the MPPC protocol, see RFC 2118, "Microsoft Point-to-Point Compression Protocol." See RFC 1570, "PPP LCP Extensions," for more about the LCP extensions.

## Configuring a Virtual Private Network

The uses and types of virtual private networks were described earlier in this chapter and in some detail in [Chapter 18](#). This section outlines the steps involved in configuring and using a VPN for PPTP connections across the Internet.

### Configuring the Internet Connection

Your connection to the Internet will be over a dedicated line of some sort—most typically T1, Fractional T1, or Frame Relay. You'll need to be sure that the WAN adapter is in the Windows 2000 HCL. The WAN adapter includes drivers that are installed in the Windows 2000 operating system, allowing the WAN adapter to appear as a network adapter. The WAN adapter needs to be configured with the IP address and subnet mask assigned for your domain or supplied by an ISP, as well as with the default gateway of the ISP router.

### Configuring the Remote Access Server as a Router

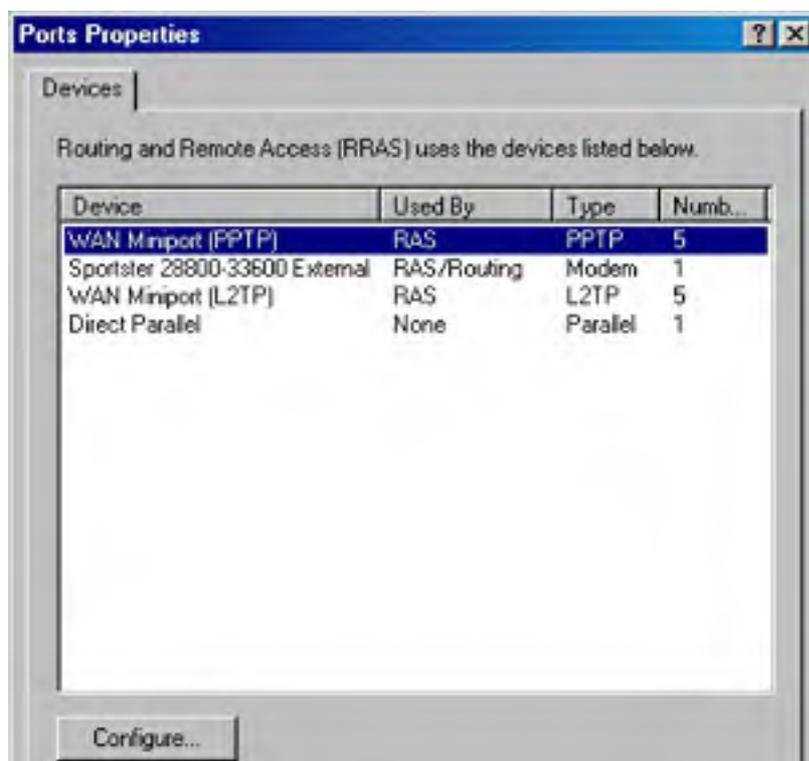

For the remote access server to forward traffic properly inside your network, you must configure it as a router with either static routes or routing protocols, so that all of the locations of the intranet are reachable from the remote access server.

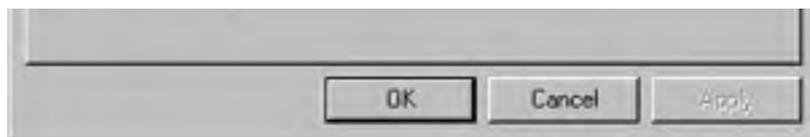

To configure the server as a router, open Routing And Remote Access, right-click the server name, and choose Properties from the shortcut menu. In the General tab, select the Enable This Computer As A Router option. Then indicate whether you want the router to handle local area network routing only or LAN and demand-dial routing. Click OK to close the Properties dialog box.

### Configuring PPTP Ports

You'll need to confirm that you have the number of PPTP ports you need. To verify the number of ports or to add more, follow these steps:

1. Launch Routing And Remote Access from the Administrative Tools folder.
2. In the console tree, click the appropriate server, and then right-click Ports and choose Properties from the shortcut menu.
3. In the Ports Properties dialog box (Figure 32-15), select WAN Miniport (PPTP), and click Configure.

**Figure 32-15.** Configuring the PPTP ports.

4. In the Configure Device dialog box, you can set a maximum number of ports for the device and specify whether the device is to be used for incoming connections only or for both incoming and outgoing connections.
5. Click OK when you're finished.

## Configuring PPTP Filters

Most networks need to filter packets based on their incoming or outgoing addresses. To set the PPTP filters, follow these steps:

1. Launch Routing and Remote Access from the Administrative Tools folder.
2. In the console tree, expand the appropriate server, then IP Routing, and then General.
3. In the details pane, right-click the interface to be filtered, and choose Properties from the shortcut menu.
4. Click either Input Filters or Output Filters and supply the source, destination, and/or protocol to be filtered. (The last step in configuring a VPN is to set up remote access policies, as described earlier in this chapter.)

Filtering can be a tricky business, so proceed with caution. It's all too easy to filter too much or too little. Consult the online Help files of Windows 2000 Server for additional information.

## Elements of a Router-to-Router VPN Connection

A router-to-router VPN is typically used to connect remote offices over a permanent link such as a dedicated T1 line. However, a router-to-router VPN can also be configured to be available *on demand*, which means that the connection is made only when needed. This section describes the components of a Windows 2000 router-to-router VPN connection.

### VPN Clients

The client is the calling router that initiates the VPN connection. For router-to-router connections, you can use computers running Windows 2000 Server, or Windows NT Server 4 with RRAS, as VPN clients.

### VPN Servers

The VPN server is the answering router that accepts the connection from the calling router. Computers running Windows 2000 Server and computers running Windows NT Server 4 with RRAS can be set up as VPN servers.

### LAN and Remote Access Protocols

LAN protocols such as TCP/IP and IPX are used to transport information. Windows 2000 Server supports the routing of LAN protocol packets by using the PPP remote access protocol in a router-to-router VPN connection.

### Tunneling Protocols

Tunneling protocols encapsulate one network protocol inside another. VPN clients and VPN servers use tunneling protocols to manage tunnels and send tunneled data. Windows 2000 includes PPTP and L2TP. Windows NT Server 4 with RRAS includes only PPTP.

### Demand-Dial Interfaces

The VPN client (the calling router) must have a demand-dial interface configured for

- The host name or IP address of the interface of the VPN server on the Internet.
- A PPTP port (for a PPTP-based VPN connection) or an L2TP port (for an L2TP-based connection).
- The user account credentials (user name, domain, password) for a user account that can be validated by the VPN server.

The answering router (the VPN server) must have a demand-dial interface with the same name as the user account being used by the calling router (the VPN client). The interface must be configured for a PPTP port (for a PPTP-based VPN connection) or an L2TP port (for an L2TP-based connection). The section entitled [Adding a Demand-Dial Interface](#), later in this chapter, describes how to set up a demand-dial interface.

## User Accounts

The calling router needs a user account with dial-in permissions either through the user account or through remote access policies.

## Static Routes or Routing Protocols

To be able to forward packets across the router-to-router VPN connection, each router has to have the appropriate routes in the routing tables. Routes are added to the routing tables of both routers either as static routes or by enabling a routing protocol to operate across a persistent router-to-router VPN connection. Static routing is best for a small, single-path internetwork. The section entitled [Setting Up Static Routes and Routing Protocols](#) later in this chapter, describes how to add routes to the routing tables.

## Security Options

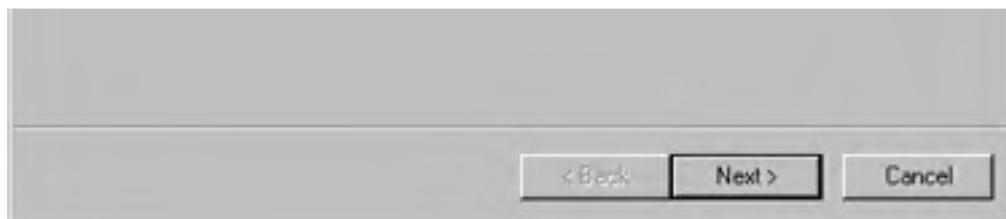

Because a Windows 2000 remote access router validates the router-to-router VPN connection, you can use all of the security features of Windows 2000 remote access, including data encryption, RADIUS, smart cards, and callback. See [Chapter 19](#) for more on security considerations.

## Adding a Demand-Dial Interface

To add a demand-dial interface to a router, follow these steps:

1. Launch Routing and Remote Access from the Administrative Tools folder.
2. In the console tree, click the appropriate router.
3. Right-click Routing Interface. Choose New Demand-Dial Interface from the shortcut menu to start the Demand Dial Interface Wizard. Click Next.
4. Enter a name for the demand-dial interface (Figure 32-16). Use a name that will help you recall the connection being made, such as the name of the branch office or network to which you're connecting. Click Next.

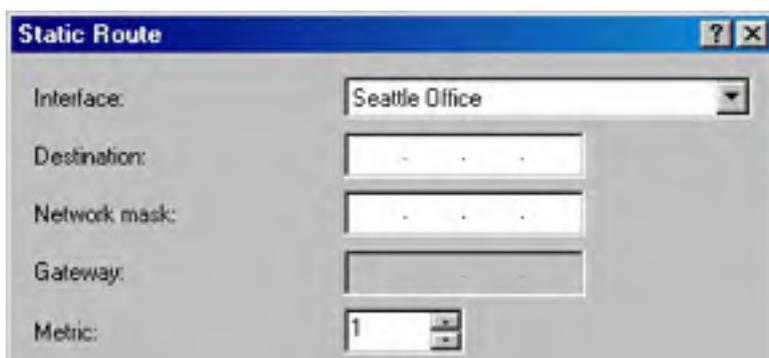

**Figure 32-16.** Supplying a name for the demand-dial interface.

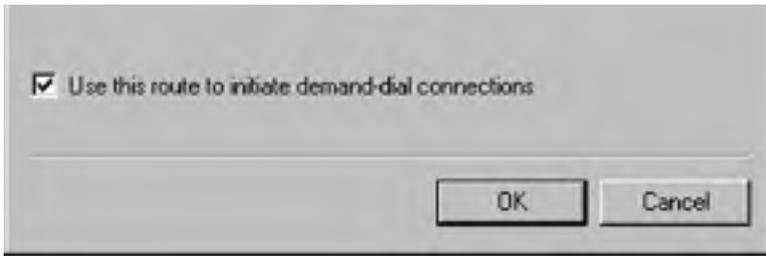

5. Choose a connection type:
  - If you're not using VPN on this interface, select the Connect Using A Modem option, and click Next.  
  
Enter the phone number to be called. In addition to the primary number, you can click Alternates and specify additional numbers to be tried automatically if the primary number can't be reached.
  - If you select Connect Using Virtual Private Networking (VPN), click Next to open the VPN Type screen. Choose the tunneling protocol appropriate for your needs. Click Next.  
  
In the Destination Address screen, provide either the host name or the IP address for the remote router. Click Next.
6. Under Protocols And Security, select all of the conditions that apply to the connection. If you select either the Add A User Account So A Remote Router Can Dial In option or the Use Scripting To Complete The Connection With The Remote Router option (this second option is not a valid option for the VPN interface type) or if you select both options, the wizard presents a screen to configure each of the items.
7. Supply the Dial Out Credentials requested, including the user account name and password.
8. When you're finished, the new interface is added to the routing interfaces in Routing and Remote Access. Right-click the name of the interface and choose Properties to change or add to the configuration.

## Setting Up Static Routes and Routing Protocols

As mentioned earlier, for routers to be able to forward packets across the router-to-router VPN connection, each router has to have the appropriate routes in the routing table. Routes can be added as static routes to the routing tables of both routers. To add a static route to the routing table, follow these steps:

1. Launch Routing And Remote Access from the Administrative Tools folder.
2. Click the appropriate router, and then click IP Routing.
3. Right-click Static Routing and choose New Static Route from the shortcut menu. (You can also view the existing IP routing table from this menu.)
4. In the Static Route dialog box, select the interface and supply the IP address for the destination router (Figure 32-17).

**Figure 32-17.** *Configuring a static route to be added to the routing table.*

The route must also be configured on the corresponding router at the other end of the VPN. For a persistent connection, you can add a routing protocol instead of a static route. To do so, right-click General under IP Routing and choose New Routing Protocol from the shortcut menu.

## **Using the Internet Authentication Service**

The Internet Authentication Service is the central component in Windows 2000 for authenticating, authorizing, and auditing users who connect to a network through a VPN or dial-up access. The IAS server is used with a RADIUS server. RADIUS is the authentication protocol most commonly used by ISPs. IAS uses data stored on a domain controller to verify the authentication requests received through the RADIUS protocol.

### **IAS Authentication**

IAS uses the authentication protocols within PPP to authenticate users. These include Challenge Handshake Authentication Protocol (CHAP) and its Windows-specific variant, Microsoft Challenge Handshake Authentication Protocol (MS-CHAP). Other methods of authentication include Extensible Authentication Protocol (EAP) for smart cards, certificates, and one-time passwords. Other methods are also supported, based on the telephone number that the user calls or calls from, although these methods are inherently less secure.

## Installing and Configuring IAS

To use IAS for dial-up or VPN connections, you must perform several tasks, including installing IAS, configuring clients and servers, and setting remote access policy. This section describes each of these tasks in turn.

### Installing IAS

The first step is to install IAS on the primary and backup remote servers. You might need the Windows 2000 Server or Advanced Server CD-ROM. To install IAS, follow these steps:

1. On the remote server, open Control Panel.
2. Open Add/Remove Programs and click Add/Remove Windows Components.
3. In the Windows Components Wizard, select Networking Services and click Details.
4. Select Internet Authentication Service. Click OK to close the Details dialog box.
5. Click Next, and IAS is installed. You might be asked for the Windows 2000 CD-ROM during the installation.

### Configuring IAS

The default IAS configuration is correct in most cases. If your remote access scenario is very complex, you might need to change the configuration. To check the configuration, follow these steps:

1. Launch Internet Authentication Service from the Administrative Tools folder.
2. In the console tree, right-click Internet Authentication Service and choose Properties from the shortcut menu.
3. In the Service tab, you can change the description or the event logging options.
4. Click the RADIUS tab to view the default UDP ports. If your RADIUS authentication and accounting ports differ, make the changes here.
5. Click the Realms tab to change the realm information. Click OK when you're finished.

#### More Info

A *realm* is a security authentication device used by Kerberos version 5. The uses of realms are spelled out in RFC 1510, "The Kerberos Network Authentication Service (V5)."

### Configuring Clients for IAS

The next step is to add the network access servers (NASs) and, if you're using a VPN, the PPTP servers as clients on the primary IAS server. To add clients, follow these steps:

1. Launch Internet Authentication Service from the Administrative Tools folder.
2. In the console tree, right-click Clients and choose New Client from the shortcut menu.
3. Supply a friendly name for the client, and click Next.
4. Supply the client address and a shared secret.
5. Click Finish when you're done.

A *shared secret* is a password used between an IAS server and other servers connected to it.

The shared secret must be the same on both machines and must follow general password rules—it's case sensitive, can use alphanumeric and special characters, and can be up to 255 characters long. Because shared secrets are embedded in the software and you don't have to type them in all the time as you do passwords, you can easily make them quite long. Longer shared secrets are more secure than short ones.

## **Real World**

### **How RADIUS Works**

RADIUS authenticates users through a series of communications between the client and the server. Once a user is authenticated, the client provides that user with access to the appropriate network services.

Using a modem, the user dials in to a modem connected to an IAS server. Once the modem connection is completed, the server prompts the user for a name and password. The server creates a data packet—the *authentication request*—from this information. The packet includes information identifying the specific server sending the authentication request, the port that is being used for the modem connection, and the user name and password.

The authentication request is sent over the network from the RADIUS client to the RADIUS server. If the RADIUS server cannot be reached, the RADIUS client can route the request to an alternate server. When an authentication request is received, the authentication server validates the request and then decrypts the data packet to access the user name and password information. This information is passed to the appropriate security system (Kerberos version 5 in Windows 2000).

If the user name and password are correct, the server sends an authentication acknowledgment that includes information regarding the user's network system and service requirements. If at any point in this logon process conditions are not met, the RADIUS server sends an Authentication Reject to the server and the user is denied access to the network.

## Using RADIUS for Multiple Remote Access Servers

When you have more than one Windows 2000 remote access server, the administration of remote access policies can become cumbersome very quickly. Instead, you can configure a single computer running Windows 2000 and IAS as a RADIUS server and configure the remote access servers as RADIUS clients. The IAS server provides centralized remote access authentication, authorization, accounting, and auditing. Assuming that you've already configured the remote access servers to provide access for dial-up or VPN clients, you can accomplish this by performing the procedures listed next. Each of these procedures is described in the sections that follow:

- Configure the remote access servers for RADIUS authentication.
- Configure the remote access servers for RADIUS accounting.
- Configure the IAS server.

To provide redundancy and fault tolerance, configure a primary and a secondary IAS server, and copy the remote access policies from the primary server to the secondary one. Then configure each remote access server with two RADIUS servers that correspond to the two IAS servers. If the primary IAS server becomes unavailable, the remote access servers will automatically fail over to the secondary IAS server.

## Configuring a Remote Server for RADIUS Authentication

When you configure the properties of a remote access server running Windows 2000, you need to select RADIUS as the authentication provider. To change a server to RADIUS authentication, follow these steps:

1. Right-click the server name in Routing and Remote Access and choose Properties from the shortcut menu.
2. Click the Security tab. Under Authentication Provider, select RADIUS Authentication, and then click Configure.
3. Provide the server name—the host name or IP address of the IAS server. If you already have IAS installed, you do not need to change the shared secret. Otherwise, you need to change it. The remote access server running Windows 2000 and the IAS server share a secret that is used to encrypt messages sent between them. The two servers must share the same secret.
4. Click OK when you're finished.

The remote access server sends its authentication requests to the UDP port on which the IAS server listens. The default value of 1812 is based on RFC 2138, "Remote Authentication Dial-in User Service (RADIUS)," and does not need to be changed when you're using an IAS server.

## Configuring the Remote Server for RADIUS Accounting

When you configure the properties of a remote access server running Windows 2000, you need to select RADIUS accounting as the accounting provider.

To change a server to RADIUS accounting, follow these steps:

1. Right-click the server name in Routing and Remote Access and choose Properties from the shortcut menu.
2. Click the Security tab. Under Accounting Provider, select RADIUS Accounting, and then click Configure.
3. Provide the server name—the host name or IP address of the IAS server.

4. If you already have IAS installed, you do not need to change the shared secret. Otherwise, you need to change it. Note that the remote access server running Windows 2000 and the IAS server share a secret that is used to encrypt messages sent between them. Both the remote access server and the IAS server must share the same secret. Click OK.

## Configuring the IAS Server for RADIUS

You need to register each of the remote access servers as clients on the IAS server. Once the remote access servers are configured to use RADIUS authentication, only the remote access policies stored on the IAS server are used, so if one of the remote access servers contains the remote access policies that are applied to all of the remote access servers, you need to copy the remote access policies to the IAS server. To copy the policies from a remote server to the IAS server, open a command window and type `netsh aaa show config <path\file>.txt`. The path can be relative, absolute, or a UNC path. This command creates a text file that includes all of the configuration settings.

Copy the text file to the destination IAS server, and open a command prompt on the destination machine. Type `netsh exec <path\file>.txt`. A message appears telling you whether the update was successful. This procedure does not work unless both the source and destination computers are running the same version of Windows 2000.

## **Summary**

Consistent and reliable remote access is a necessity for many, if not most, organizations today. Windows 2000 includes tools for setting up access ranging from a simple dial-in connection to multiple remote access servers running virtual private networks. In the next chapter, we move on to a new section of the book, which deals with performance tuning, disaster prevention, and disaster recovery.

## Performance Monitoring and Tuning

Performance monitoring is the process of identifying bottlenecks that might be slowing down Microsoft Windows 2000 Server or the network on which it is running. To maximize the performance of a Windows 2000 system, you must be able to recognize bottlenecks wherever they exist and take action to eliminate them. This chapter covers the system and network monitoring tools that Windows 2000 provides, which enable you to detect bottlenecks and tune your system to its optimum performance level. These tools include Event Viewer, System Monitor, and Network Monitor. You should also refer to the section entitled [Performance and Memory Tuning](#) in [Chapter 6](#) for basic tuning procedures.

### More Info

For further information about performance monitoring and tuning, pick up a copy of *Microsoft Windows 2000 Performance Tuning Technical Reference* by John Paul Mueller and Irfan Chaudhry (Microsoft Press, 2000). Also refer to the information at these Microsoft sites: <http://www.microsoft.com/windows/server/Technical/management/MonitorRel.asp> and <http://www.microsoft.com/windows2000/en/server/help>. You can also refer to the following Technet articles, which can be found at <http://www.microsoft.com/technet>: "Monitoring Network Activity," "Understanding Counter Organization," and "Understanding Memory Usage in Windows 2000."

## What Is a Bottleneck?

Simply put, a *bottleneck* is a condition in which one resource is preventing another resource from functioning at its best. For example, when one application monopolizes the system processor to the exclusion of all other operations, there is a bottleneck at the processor. Bottlenecks can occur in virtually any Windows 2000 subsystem or on any element of the network.

Bottlenecks might occur for any of several reasons:

- Resources are not sharing workloads equally.
- The system does not have sufficient resources.
- Settings are configured incorrectly.
- A resource is malfunctioning.
- A program is monopolizing a particular resource.

## Using Event Viewer

Event Viewer is a utility designed to track events recorded in the application, security, and system logs. It enables you to gather information about software, hardware, and system problems and track Windows 2000 security events. When you start Windows 2000, the Event Log service starts automatically. Event Viewer takes the form of a Microsoft Management Console (MMC) snap-in. It is named Eventvwr.msc and can be found in the %SystemRoot%\System32 folder. When you launch Event Viewer from the Administrative Tools folder on the Programs menu, you see the Event Viewer console (Figure 33-1).

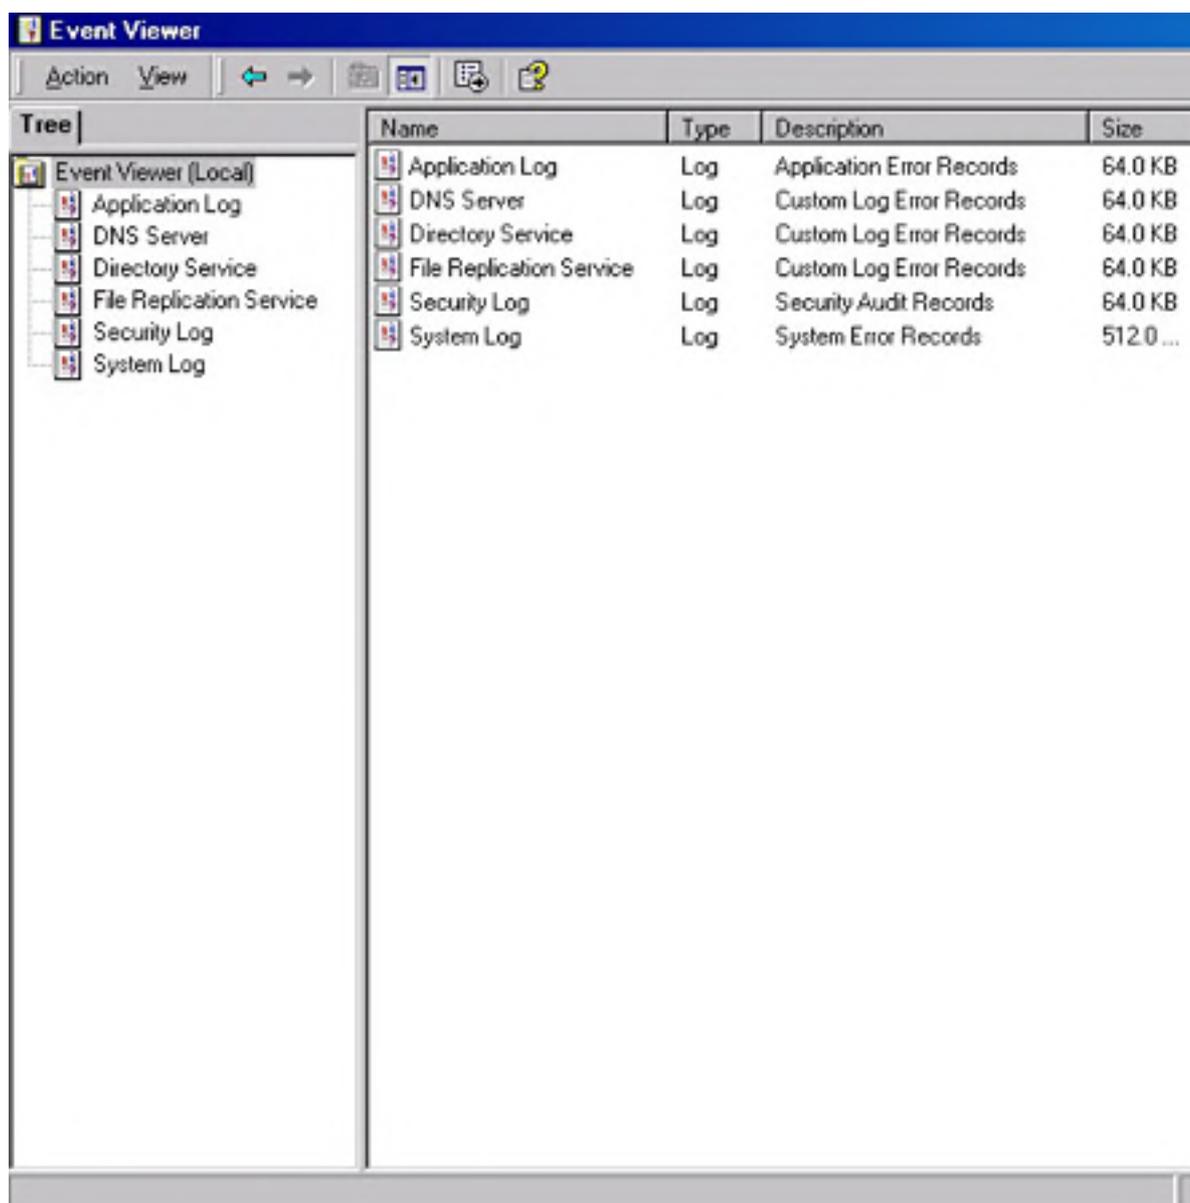

Figure 33-1. The Event Viewer console.

## Event Log Files

Windows 2000 records events in three kinds of logs:

- **Application log** Contains events logged by programs or applications. For example, a database program might log a file error in the program log. Application and program developers determine the events that are logged. All users can view this log.
- **Security log** Records security events such as invalid and valid logon attempts and events

related to resource use, such as creating, opening, or deleting files. The security log is turned off by default. The administrator can turn on the security log to record events by setting auditing attributes or events through the Group Policy feature in Windows 2000. For example, if you have enabled auditing for logging on, all attempts to log on to the system are recorded in the security log. An auditing policy can also be set in the registry to cause the system to halt when the security log becomes full. Only administrators can view this log. More information on setting auditing policy can be found in [Chapter 10](#).

- **System log** Contains events logged by the Windows 2000 system components. For example, the log records the failure of a system component that is meant to load during startup. The event types logged here are predetermined by Windows 2000. All users can view this log.

By default, each log file has a maximum size of 512 KB and logs are overwritten as necessary, provided that the events are older than seven days. You can change the size of each log file by selecting the log you want to modify and choosing Properties from the Action menu of Event Viewer. In the Maximum Log Size box in the General tab, specify the new log size in kilobytes. The maximum log size can be as large as the capacity of the hard disk and memory. You can also decrease the size of the log file, but you have to clear the log of events first.

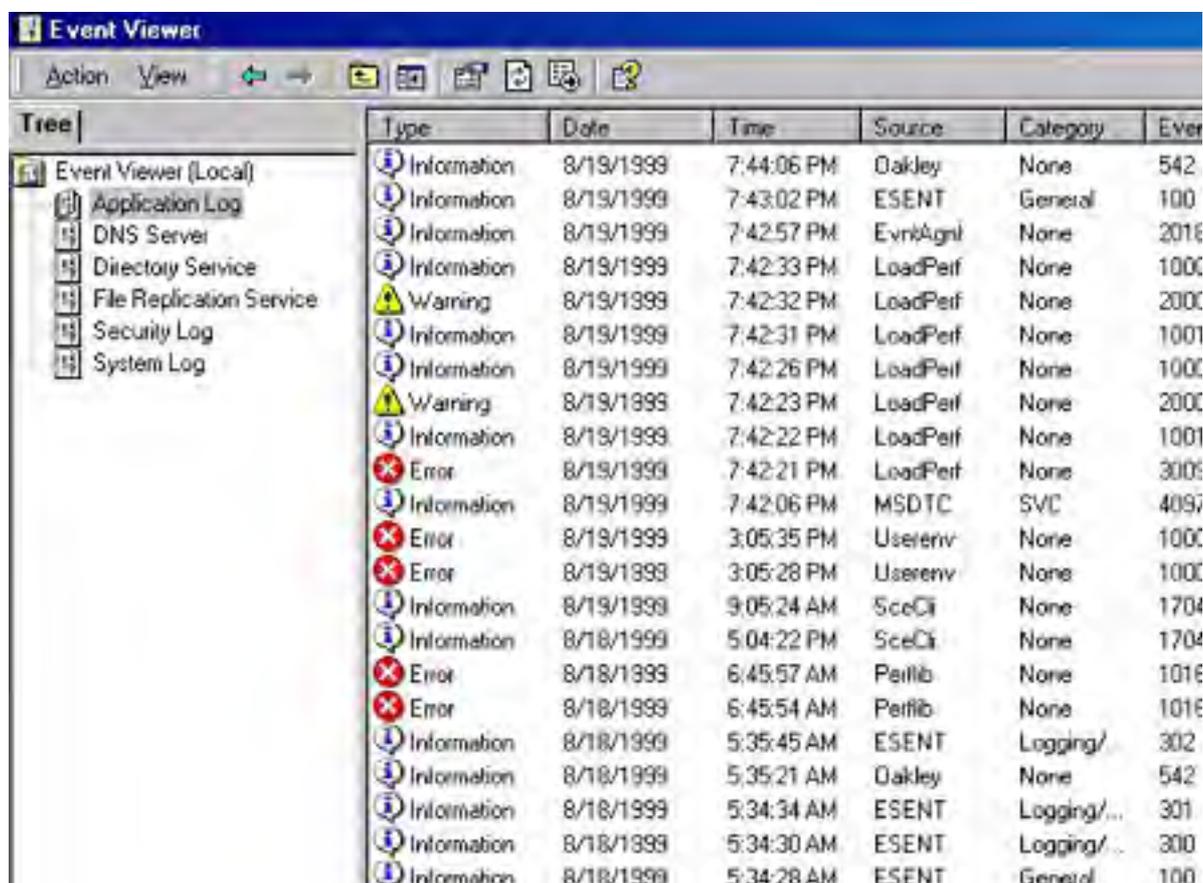

Logging stops if the log file becomes full and cannot overwrite itself because the events in the log are not old enough or because you have the log set to be cleared manually. You can specify the event logging parameters for specific logs with the Event Log Wrapping options in the General tab of the Properties dialog box for each log. Choose Overwrite Events As Needed, Overwrite Events Older Than x Days, or Do Not Overwrite Events. (Event Log is also covered as part of day-to-day administration in [Chapter 10](#).)

## The Components of an Event

The two key components in the interpretation of an event are the event header and the event description. The event description is the most useful piece of information because it indicates the significance of the event.

### The Event Header

Event headers are displayed in columns in the Event Viewer console (Figure 33-2).

Type	Date	Time	Source	Category	Event ID
Information	8/19/1999	7:44:06 PM	Oakley	None	542
Information	8/19/1999	7:43:02 PM	ESENT	General	100
Information	8/19/1999	7:42:57 PM	EvrntAgnl	None	2016
Information	8/19/1999	7:42:33 PM	LoadPerf	None	1000

**Figure 33-2.** Event headers in the Event Viewer console.

Event headers are broken down into the following components:

- **Type** Lists the severity of the event. Events in the application and system logs are classified as Information, Warning, or Error. Events in the security log are classified as Success Audit or Failure Audit. Event Viewer represents these classifications as symbols in its normal list view. These symbols include the following:
  - **Information** Describes the successful operation of a service, driver, or application. For example, when the Event Log service is started successfully, it is recorded as an Information event.
  - **Warning** Indicates events that (although not necessarily significant) pose a possible future problem. For example, when the hard disk is at or near capacity, you are advised to delete some files.
  - **Error** Indicates that a significant problem has occurred, such as loss of functionality or loss of data. For example, if a service such as Net Logon fails to load, it is logged in Event Viewer as an error.
  - **Failure Audit** Lists a failed attempt to perform an audited security event. For example, if a user tries to log on and fails, that attempt is logged as a Failure Audit event.
  - **Success Audit** Lists a successful attempt to perform an audited security event. For example, when a user logs on successfully, it is logged as a Success Audit event.
- **Date** Indicates the date the event occurred.
- **Time** Indicates the (local) time the event occurred.
- **Source** Lists the software that logged the event. The software can be a program name, a component of the system, or a component of a large program, such as a driver name.
- **Category** Shows the way the event source classifies the event; primarily used in the security log. Security audits are one of the event types that are classified here.
- **Event** Lists a number that identifies the particular event type. The name of the event type is usually contained in the first line of its associated description.
- **User** Indicates the user name of the user for whom the event occurred. If a server process caused the event, the user name is the client ID. If impersonation is not taking place, the primary ID is displayed here. Impersonation occurs when one process is permitted to take on the security attributes of another process. The security log entry lists both the primary and the impersonation IDs when applicable.
- **Computer** Specifies the name of the computer on which the event took place.

## The Event Description

Double-clicking a specific event in Event Viewer displays a text description in the Event Detail tab of the Properties dialog box (Figure 33-3) that is often helpful in the analysis of the event. Binary data is also generated for some events and can be helpful in interpreting those events because it is generated by the program that originated the event records. If you retain event descriptions, save them as binary data files. Don't save event descriptions in text format or comma-delimited text format, because these formats discard binary data.

**Figure 33-3.** The Event Properties dialog box.

## Archiving an Event Log

You can save an event log to a file by right-clicking the log name in Event Viewer and choosing Save Log File As from the shortcut menu. You can archive event logs in one of the following three formats:

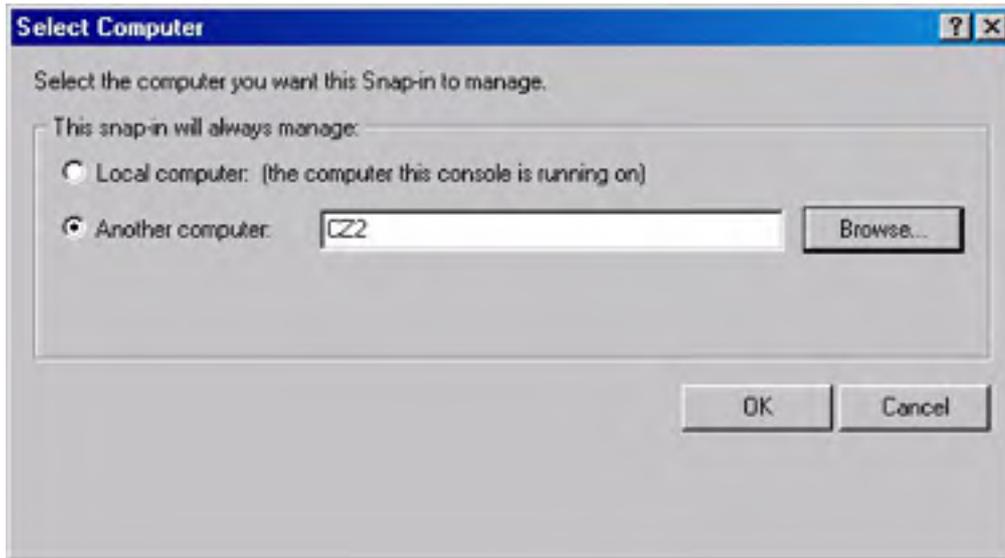

- **Log format** Allows you to view the log in Event Viewer. Its extension is .EVT.
- **Text format** Lets you use the detail contained in this file in a program such as Microsoft Word. Its extension is .TXT.
- **Comma-delimited text format** Enables you to use the data in a spreadsheet or flat-file database. Its extension is .CSV.

Archived logs save the event description in the following order: date, time, source, type, category, event, user, computer, description. The entire log file is saved, regardless of any filtering options you might have set. The information is saved sequentially, even if you have established a sort order for the events.

You can open an archived log file from the Action menu by pointing to New and then choosing Log View. In the Add Another Log View dialog box, select Saved (Opens A Previously Saved Log), and click Browse to search for the log name in the Open dialog box. You can open only an archived log file with the .EVT filename extension in Event Viewer. (Archived log files with .TXT and .CSV extensions can be opened in any word processing program.) The information displayed in an archived log cannot be updated by refreshing.

## Viewing an Event Log on Another Computer

You can connect to another computer to view its event log by right-clicking Event Viewer (Local) at the top of the tree and choosing Connect To Another Computer. In the Select Computer dialog box (Figure 33-4), you can browse for or enter the name of the other computer whose event log you want to view.

**Figure 33-4.** *The Select Computer dialog box.*

Event Viewer enables you to view machines running Microsoft Windows NT Workstation or Windows 2000 Professional, a server or domain controller running Windows NT Server or Windows 2000 Server, or a server running LAN Manager 2.x. You can configure a low-speed connection for the remote machine you want to view. To do this, select the log you want to view from the console tree, choose Properties from the Action menu, and then select the Low Speed Connection option.

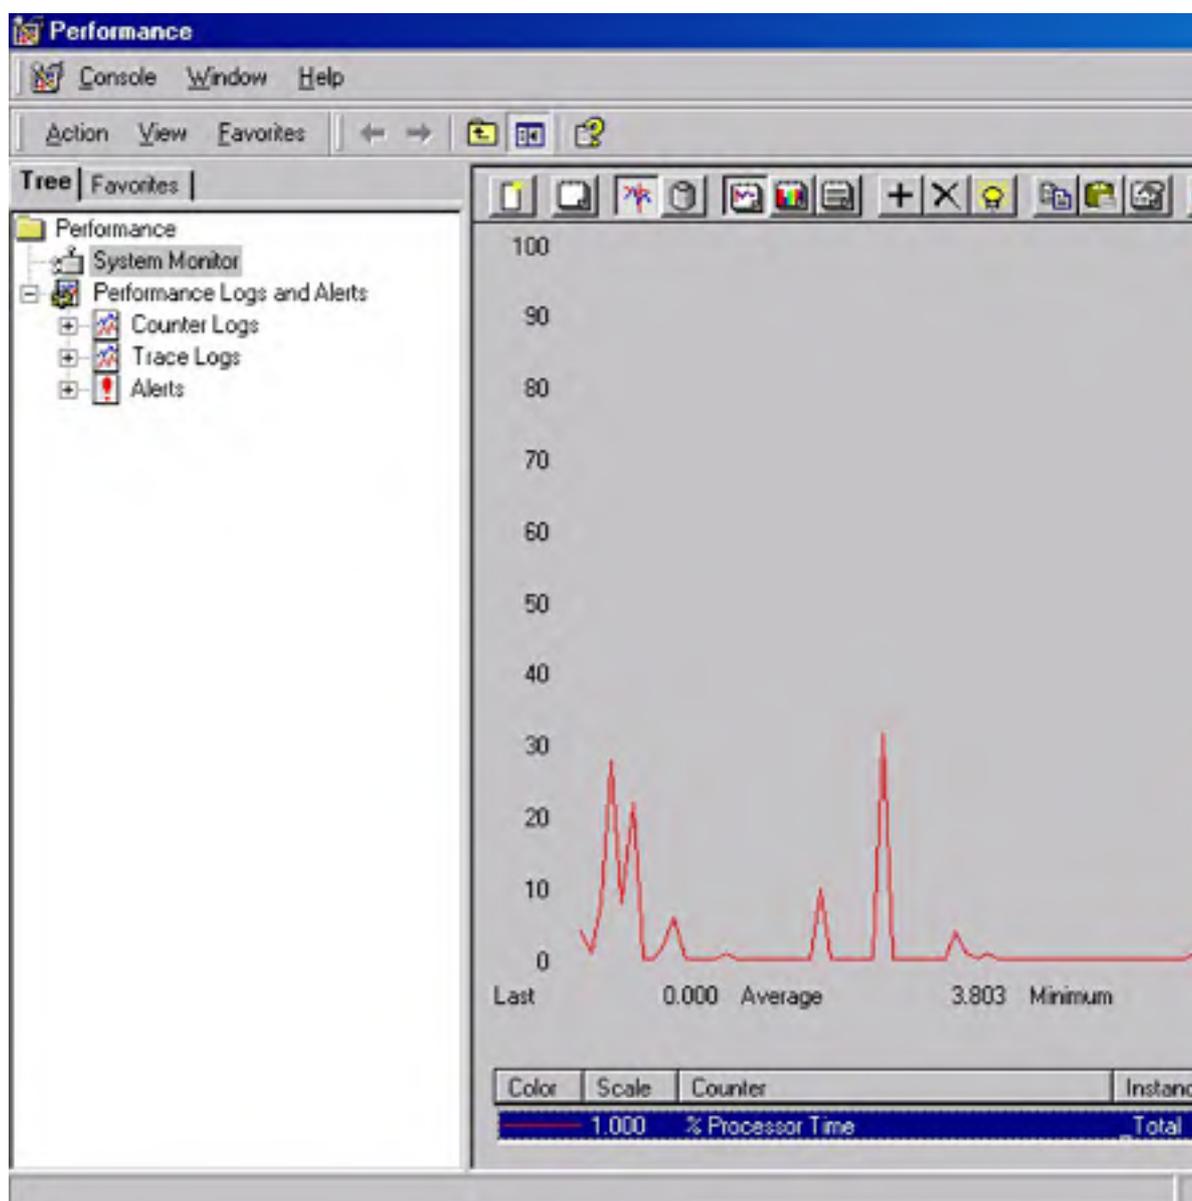

For more sophisticated monitoring and analysis of a large network of computers, consider using Microsoft Systems Management Server (SMS), or Microsoft Operations Manager (MOM), or both. Information on these products is available at <http://www.microsoft.com/smsserver> and <http://www.microsoft.com/mom>.

## Using System Monitor

System Monitor is a utility designed to track various processes on a Windows 2000 system in real time, using a graphical display. You can use the data from System Monitor to target processes and components that need to be optimized, monitor the results of tuning and configuration efforts, understand and observe trends in workloads and their effect on resource usage, and assist with tasks such as planning for upgrades. System Monitor takes the form of an MMC snap-in. It is named Perfmon.msc and can be found in the `%SystemRoot%\System32\` folder.

## Running System Monitor

When you launch System Monitor from the Administrative Tools folder on the Programs menu, you see the main console (Figure 33-5). The console tree in the left pane lists the MMC snap-ins associated with System Monitor, and the details pane is reserved for the graphic view where the counters you want to monitor are charted.

**Figure 33-5.** The System Monitor console.

System Monitor uses three types of items to monitor the system: objects, counters, and instances:

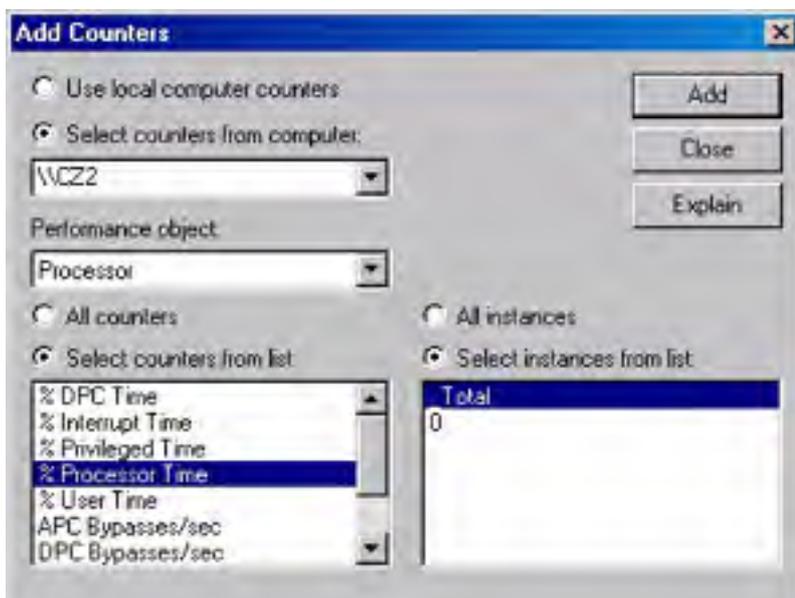

- **Object** A collection of counters associated with a resource or service that generates data

that you can evaluate. Each time an object performs a function, its corresponding counters are updated. A range of objects typically corresponding to major hardware components is built into the operating system. Some programs you install add other components and their corresponding objects. The following are the objects you'll use most frequently:

- **Browser** Monitors the Browser service for a domain or workgroup.
  - **Cache** Monitors disk cache usage.
  - **Memory** Monitors memory performance for physical and virtual memory.
  - **Objects** Monitors the number of events, mutexes, processes, sections, semaphores, and threads on the computer at the time of data collection.
  - **Paging File** Monitors pagefile usage.
  - **Physical Disk** Monitors hard disks with one or more partitions.
  - **Process** Monitors all processes running on a machine.
  - **Processor** Monitors each processor on the system.
  - **Server** Monitors bytes, sessions, certain system errors, pool nonpaged usage, and pool paged usage.
  - **System** Monitors the counters that affect all of the hardware and software running on the system.
  - **Thread** Monitors all threads running in the system.
- **Counter** A component within an object that represents data for a specific aspect of the system or service.
  - **Instance** A single occurrence of multiple performance objects of the same type on a machine. If a particular object has multiple instances, you can track the statistics for each instance by adding a counter for each. You can also add a counter to track all instances at once. An instantaneous counter, such as Process\ Thread Count, is an example of an instance. It displays the most recent count of the number of threads for a particular process. An instance can also be an average of the last two values for a process over a period of time between samples.

## Adding Counters

By default, System Monitor displays the system's current processor utilization as a line graph. You can add counters by clicking Add Counters to display the Add Counters dialog box (Figure 33-6) or by clicking the Data tab in the Properties dialog box. System Monitor compresses the data as necessary to fit the details pane, and you can display dozens of counters at a time, more than you can comfortably view on a single screen.

**Figure 33-6.** The Add Counters dialog box.

## Selecting Counters

In the Add Counters dialog box, you can select either the Use Local Computer Counters option or the Select Counters From Computer option. If you're monitoring the computer on which System Monitor is running, you'll want to select Use Local Computer Counters. If you want to monitor a different computer, select the Select Counters From Computer option, and then choose the name of the computer to be monitored from the list box.

In the Performance Object list box, specify an object to monitor. The Processor object is selected by default. For each object, you can choose to monitor all of the available counters or only those that you specify. To monitor all of the available counters for a particular object, select the All Counters option. To monitor only the counters you specify, select the Select Counters From List option. When you choose to select specific counters, you can obtain a description of any counter by selecting the name of the counter and then clicking Explain.

If you select a counter that has multiple instances, choose All Instances to monitor all instances of the selected counter, or choose Select Instances From List to specify the instances you want to monitor. If you monitor multiple instances of the same counter, you should be aware that the instance index number assigned to a particular instance might change over time. This possible change is a result of the instance starting and stopping and in the process being assigned a different instance index number.

## Matching Counters to Graph Lines

You can determine which counter matches a line on the graph in two ways. First, a color and bar thickness is assigned to each counter within the legend. If you aren't monitoring many counters, you can easily match the color to the counter. Second, when you double-click a line in the graph, the corresponding counter is selected in the legend located under the graph. If chart lines are close together, try to locate a position in the graph where they diverge; otherwise, System Monitor will have difficulty pinpointing the actual line you're interested in.

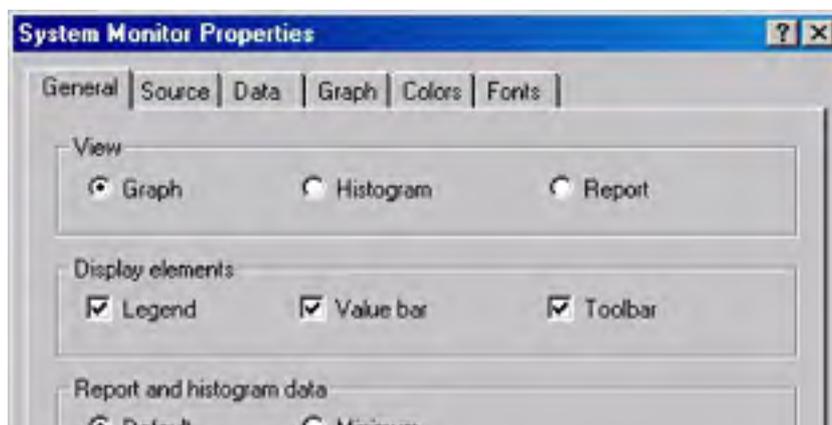

You can also highlight a chart line by clicking the counter you want to highlight and then pressing Ctrl+H.

## Deleting Counters

When you want to stop monitoring one or more counters, you have two options: you can delete only specific counters or you can delete all counters. To stop monitoring specific counters, open System Monitor, select the name of a counter in the legend in the System Monitor details pane, and click the Delete button on the toolbar. To delete all of the counters currently being monitored, click the New Counter Set button on the toolbar. You would do this if you wanted to start monitoring a new set of counters.

## Modifying the Display

You can change the way System Monitor displays information by using the System Monitor Properties dialog box (Figure 33-7). To access this dialog box, either click the Properties button on the toolbar or right-click in the details pane and choose Properties from the shortcut menu.

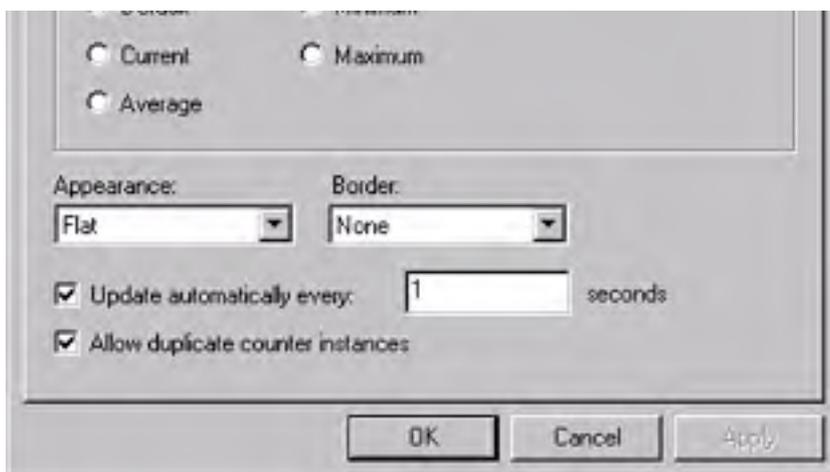

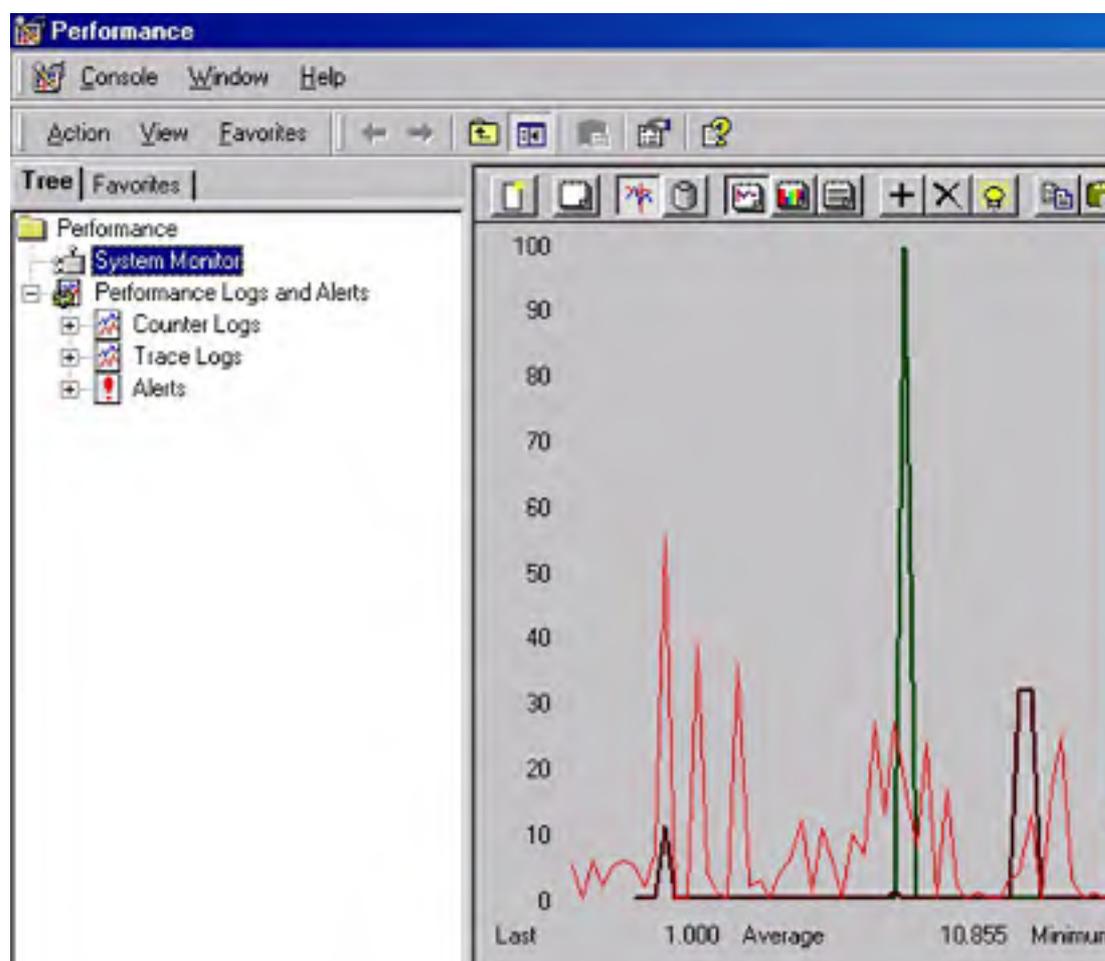

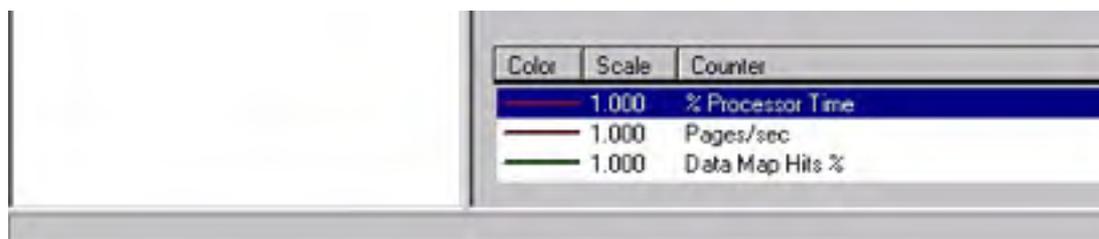

Figure 33-7. The System Monitor Properties dialog box.

## Choosing a View

In the General tab, you can choose whether to view the data in the form of a graph, a histogram, or a report:

- **Graph view** Graph view presents information in a traditional line graph format. Each of the counters and instances are displayed in a different color and line thickness, as shown in Figure 33-8. This view is the default, and it offers the greatest variety of options. For instance, you can highlight a particular counter by either clicking the counter name in the legend or double-clicking the data line in the graph and then clicking the Highlight button on the toolbar. A black line replaces the colored data line if the background color of the chart is white or a light color; for all other background colors, the line is white. If you would like to highlight another line instead, simply double-click the line. As long as the Highlight button is depressed, any line you click is highlighted on the screen.

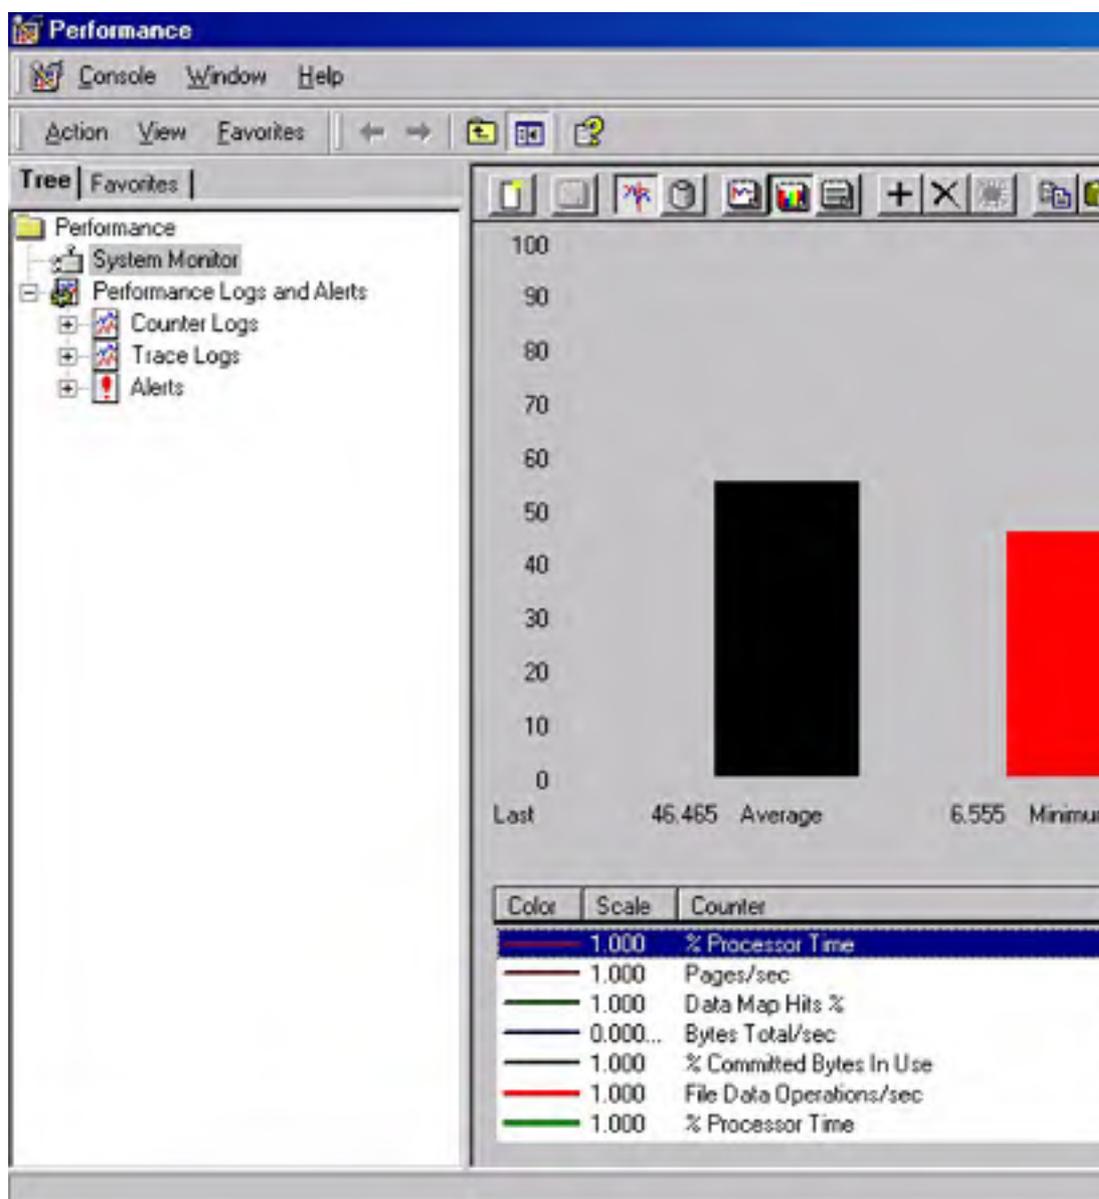

**Figure 33-8.** *Displaying system information in graph view.*

Although the graph view is the most versatile, you are better off using the histogram view or report view for tracking a large number of counters because the chart lines become increasingly difficult to view when a large number of counters are being monitored.

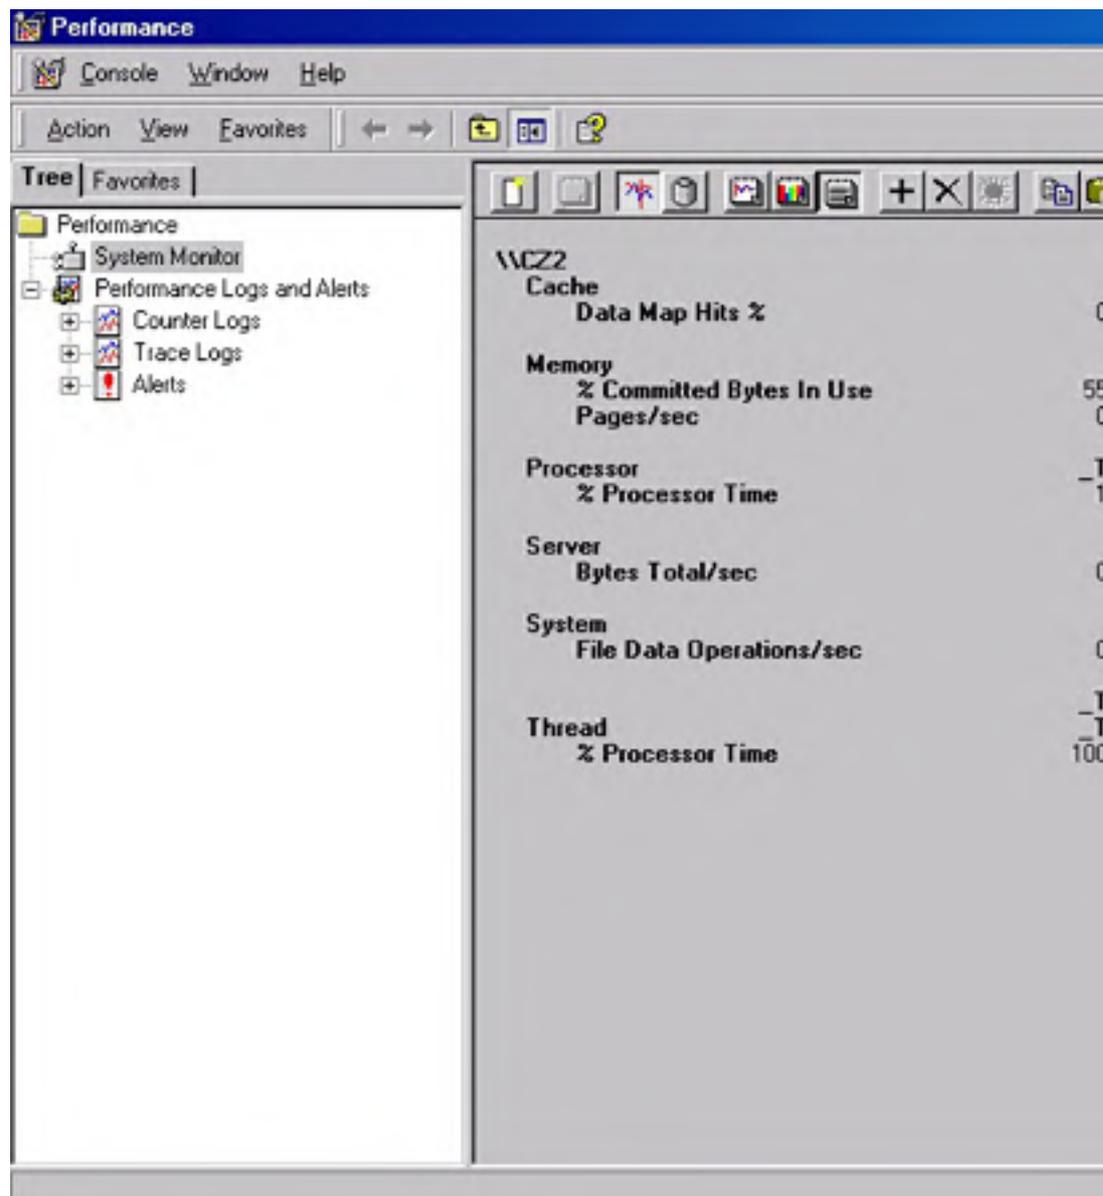

- **Histogram view** Histogram view presents information in a bar graph format, as shown in Figure 33-9. As in graph view, each of the counters and instances is presented in a different color. You can easily track up to 100 counters using this view because System Monitor adjusts the bars to fit the display.

**Figure 33-9.** *Displaying system information in histogram view.*

- **Report view** Report view presents the counter data in a report list format, as shown in

Figure 33-10. Objects are listed in alphabetical order, as are each of the chosen counters for each object. The data itself is displayed numerically. Each object displays the total percentage of processor time in use for the chosen counters. This view is best if you need to track a large number of counters.

**Figure 33-10.** Viewing system information in report view.

Depending on how you choose to view the data, these options in the Display Elements area might also be available:

- **Legend** Displays a legend at the bottom of the details pane that shows the data scale used for each counter, the counter name, the instance, the parent object (if applicable), the object the counter belongs to, the computer being monitored, and the color used to draw the line for the counter. The legend is available for the graph and histogram views. You need to display the legend to see the counter name associated with the data line.
- **Value Bar** Displays a value bar at the bottom of the details pane that provides a way to

highlight the values for a specific counter. Clicking a particular value in the legend or clicking directly on a data line displays statistics for the last, average, minimum, and maximum values recorded. The duration time is also displayed here. The values are calculated from the number of samples and time period displayed in the graph. The time period is reflected by the duration value rather than actual time elapsed since monitoring was started. The duration value is based on the update interval time and is calculated to show the total elapsed time displayed in the graph. This display element is available for the graph and histogram views and is helpful for monitoring a specific value that you want to keep a close watch on.

- **Toolbar** Displays the toolbar functions across the top of the details pane. It's advisable to have this option turned on because it's the only way you can perform certain functions.

## Choosing the Monitoring Time Interval

You can sample data for all three views at regular periodic intervals. To set this option, open the System Monitor Properties dialog box (by clicking the Properties button on the toolbar) and, in the General tab, select the Update Automatically Every *n* Seconds check box. The default interval is 1 second, but you might want to change this value to prevent a strain on your machine. Select the update interval that is best for capturing the type of activity you want to view.

## Selecting Additional Properties

You can add vertical and horizontal grid lines to the graph and histogram views by selecting their respective check boxes in the Graph tab of the System Monitor Properties dialog box. These elements are very helpful in quickly determining a counter's associated value.

You can also change the maximum and minimum vertical scale values in the Graph tab; the defaults are 100 for the maximum value and 0 for the minimum value. The highest value that you can specify is 999999999, and the lowest value is 0. Both of these values must be a positive integer. You need to determine the vertical scale range from the ranges of values for the counters you are monitoring.

You might need to adjust the counter scale settings for a specific counter to improve the visibility of its data within the graph. Counter scale settings for individual counters are adjusted in the Data tab of the System Monitor Properties dialog box. Counter scale values can range exponentially from 0.0000001 to 1000000.0. Adjusting the scale does not affect the statistics displayed in the value bar.

## Monitoring a Different Computer

By default, System Monitor displays information about the local system, but you can also configure it to monitor another computer on the network. It is also possible for you to monitor more than one computer at once in System Monitor. To do so, click Add Counters, select the Select Counters From Computer option, and then type the name of the computer to be monitored in the text box. You can choose and delete counters and modify the display in the same manner described in the previous sections.

You need administrative permissions on the other computer to monitor that computer through System Monitor. If you don't have administrative permissions, an error message is generated. The counter appears in the display, but no data or graph lines are associated with it. If a particular counter that you want to monitor does not appear in the counter list, it is likely that the service or feature providing the counter has not been installed or enabled on that computer.

## Performance Logs and Alerts

Performance Logs and Alerts expands the monitoring capabilities of System Monitor to include features for logging counter and trace data and for generating performance alerts. Using the capabilities of Performance Logs and Alerts has a number of advantages. Logged counter data information can be exported to spreadsheets or databases for analysis and report generation. The data can be stored in three formats: comma-separated format, tab-separated format, or a binary log-file format that can be used for logging instances that might have started after the log had already begun collecting data or for circular logging. In circular logging, new data is continuously logged into a single file, with the new data overwriting the old data.

Performance logging runs as a service. As a result, a user doesn't have to be logged on to the monitored computer for data collection to occur. You can manage multiple logging sessions from a single console window and view data as it is collected as well as after collection has stopped. Automatic log generation enables you to define parameters such as filename, file size, and start and stop time. An alert can be set on a counter to cause a specific action to occur, such as starting a specified program, sending a notification message, or starting a log when the value of a selected counter falls below or exceeds a specified setting.

### Counter Logs

A counter log collects data at a predefined interval. Counter logs are helpful for recording data about system services activities and hardware usage from the local machine or a remote machine. You can log data manually on demand or schedule logging to start and stop automatically. The system can also perform continuous logging, depending on the file size and duration limits you set. The logged data can be viewed through the System Monitor display or exported to spreadsheets or databases.

You can view the counters configured in the counter log dynamically through System Monitor by saving log settings such as counters as an HTML page. The resulting page hosts the System Monitor control through an ActiveX control that provides the interface for the monitoring user.

### Trace Logs

Rather than measure samples at a predefined interval, as counter logs do, a trace log monitors data continuously and waits for specific events, such as page faults, to occur. That data is then recorded into a trace log file. To interpret the trace log output, you need a parsing tool.

A parsing tool is software that reads the raw data and puts it into a form you can understand. Developers can create parsing tools by using the APIs provided at Microsoft's MSDN Online Library site at <http://msdn.microsoft.com/library/default.htm>.

## Creating Counter and Trace Logs

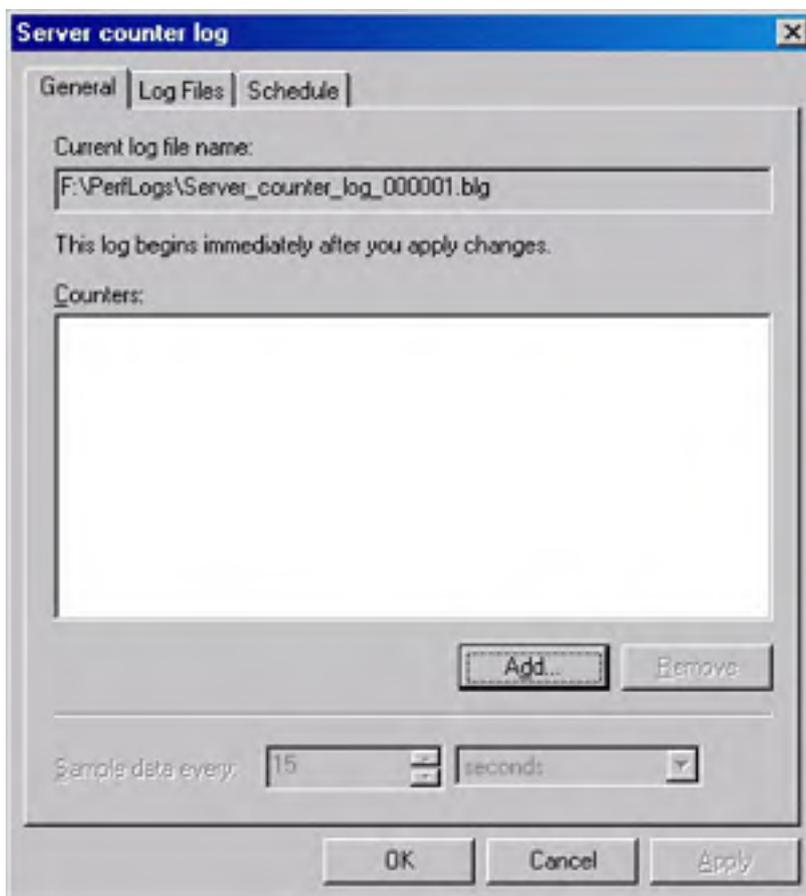

To create a counter log or a trace log, perform the following steps:

1. Open System Monitor, and double-click Performance Logs And Alerts.
2. Choose Counter Logs to create a counter log, or choose Trace Logs to create a trace log.
3. Right-click in a blank area of the details pane and choose New Log Settings. In the Name text box, enter the name of the counter or trace log you are creating and click OK. A Properties dialog box for configuring the counter or trace log you are creating is displayed.
4. Configure the counter or trace log to monitor your local or remote machine by choosing the proper counters for the resources to be monitored, selecting log file properties, and choosing the desired scheduling options. Any logs that already exist are listed in the details pane. A red icon indicates a log that is not running or that has been stopped; a green icon indicates a log that is running.

The sample data interval for counter logs is set in the General tab of the Properties dialog box for the log. For guidelines on setting time intervals, see the section entitled [Determining How Often to Monitor](#) later in this chapter.

## Adding Counters to Counter Logs

Counters are added in the General tab of a log's Properties dialog box (Figure 3311). When you create a counter log file, the Properties dialog box is displayed automatically. If you need to add counters later, you can display the Properties dialog box by right-clicking the name of the log file, choosing Properties from the shortcut menu, clicking Add in the General tab, and then choosing the desired counters. The procedure for selecting counters is identical to that described earlier in the section entitled [Selecting Counters](#).

**Figure 33-11.** *The General tab of a log's Properties dialog box.*

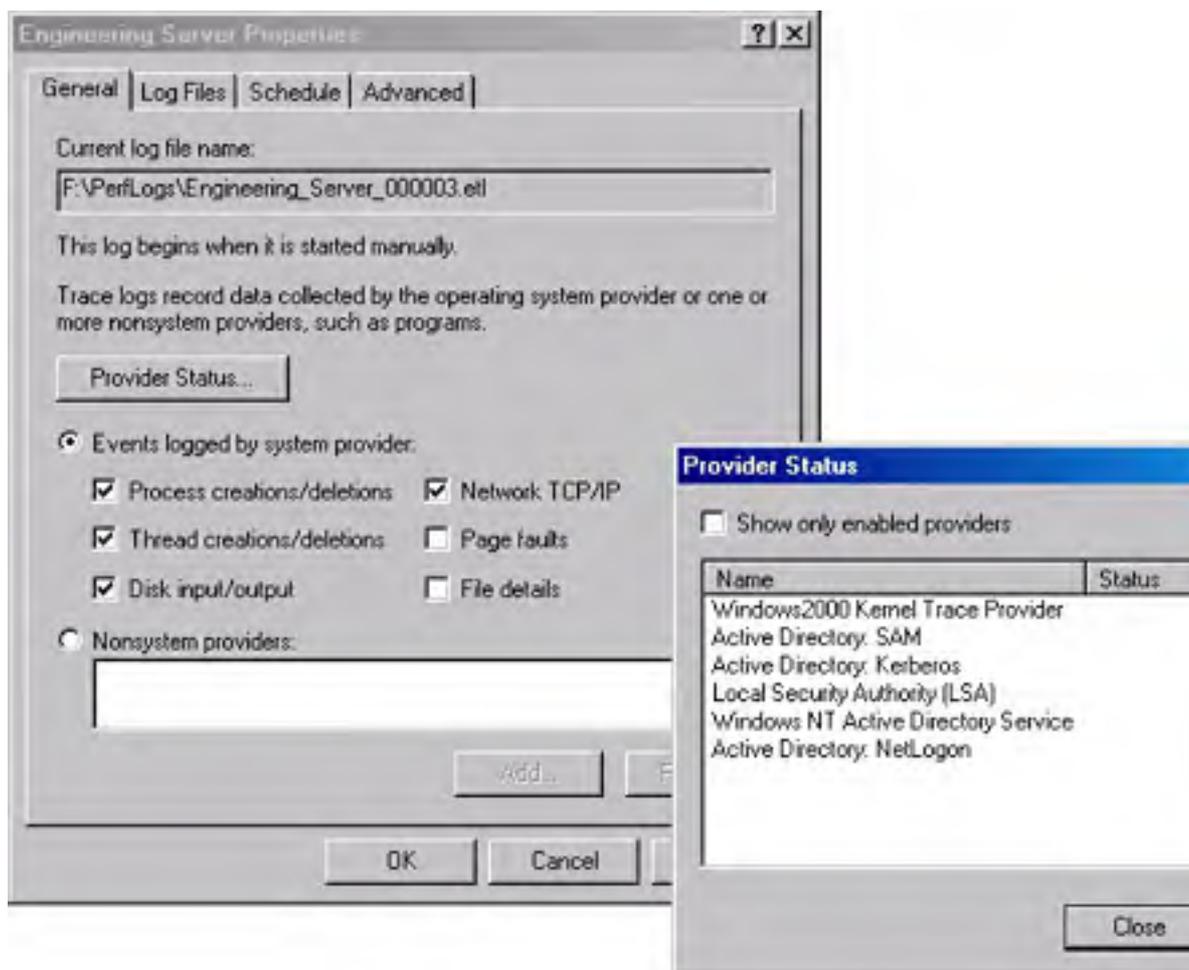

## **Saving Log and Alert File Settings**

To save the settings for a log or an alert file, right-click the name of the log or alert file in the details pane, and then choose Save Settings As from the shortcut menu. Enter the name you want to give to the log or alert file, and save it as an .HTM file. You can use the saved settings for a new log or alert by right-clicking in the details pane, choosing New Log Settings From, and then selecting the .HTM file containing the settings you want to reuse.

## **Selecting System and Nonsystem Providers for Trace Logs**

Events in trace logs are monitored not by counters but by providers. You can choose to log events by system or nonsystem providers. The default system provider, the Windows Kernel Trace Provider, monitors threads, processes, disk input/output, network TCP/IP, page faults, and file details. The system provider uses the most overhead to monitor events. Only one trace log at a time can be run using the system provider. If you attempt to run more than one, you receive an error message.

System and nonsystem providers are chosen in the General tab of the log's Properties dialog box (Figure 33-12). To view this dialog box, right-click the name of the trace log file and choose Properties from the shortcut menu. In the General tab, either select the Events Logged By System Provider option and then choose the events you want to monitor, or select the Nonsystem Providers option and then add the nonsystem providers of your choice by clicking Add.

**Figure 33-12.** Specifying events logged by the system provider.

It is important to remember that trace logging of page fault and file details generates a huge amount of data. Microsoft recommends that you limit trace logging using these fault options to a maximum of two hours; otherwise you might run out of disk space on your machine.

Choosing nonsystem providers to monitor the system incurs less overhead. With nonsystem providers, you can select the data providers of your choice. You cannot run concurrent multiple trace logs using the same nonsystem provider, but you can do so using different nonsystem providers. The nonsystem providers available in Windows 2000 are Active Directory: Kerberos, Active Directory: Net Logon, Active Directory: SAM, Local System Authority (LSA), and Windows NT Active Directory Service.

## Setting File Parameters for Counter and Trace Logs

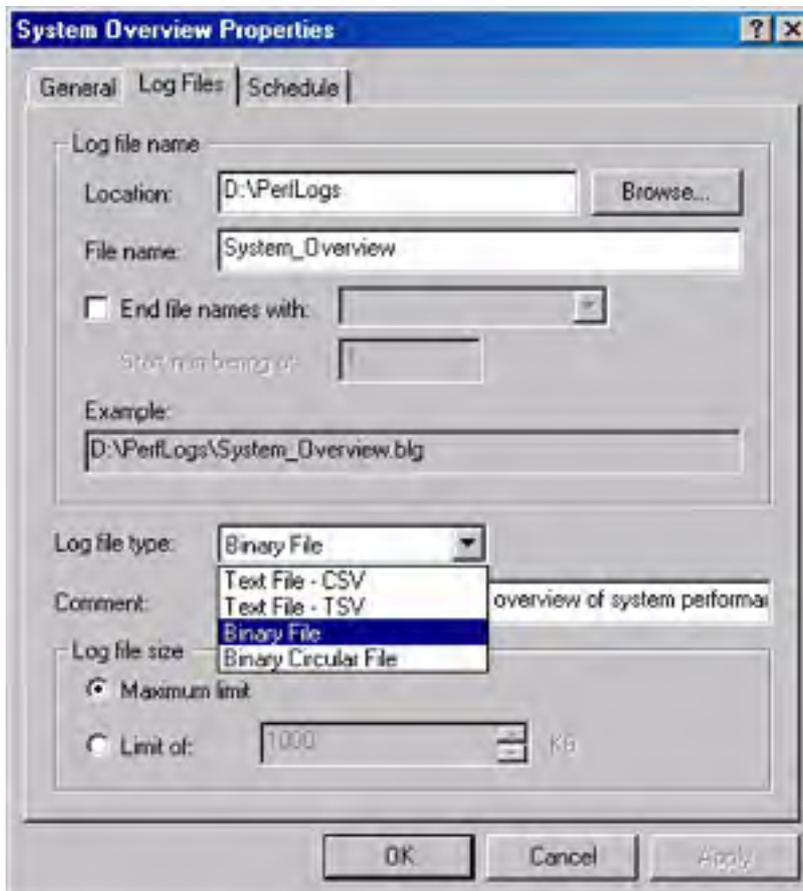

To set file parameters for counter and trace logs, follow these steps:

1. Double-click Performance Logs And Alerts in System Monitor.
2. Click Counter Logs to set file parameters for counter logs, or click Trace Logs to set file parameters for trace logs.
3. Double-click the name of the log for which you want to set the file parameters. A dialog box displaying the properties of the log appears.
4. Click the Log Files tab, and set the desired parameters for the log file. (The available parameters are described in the next section.)

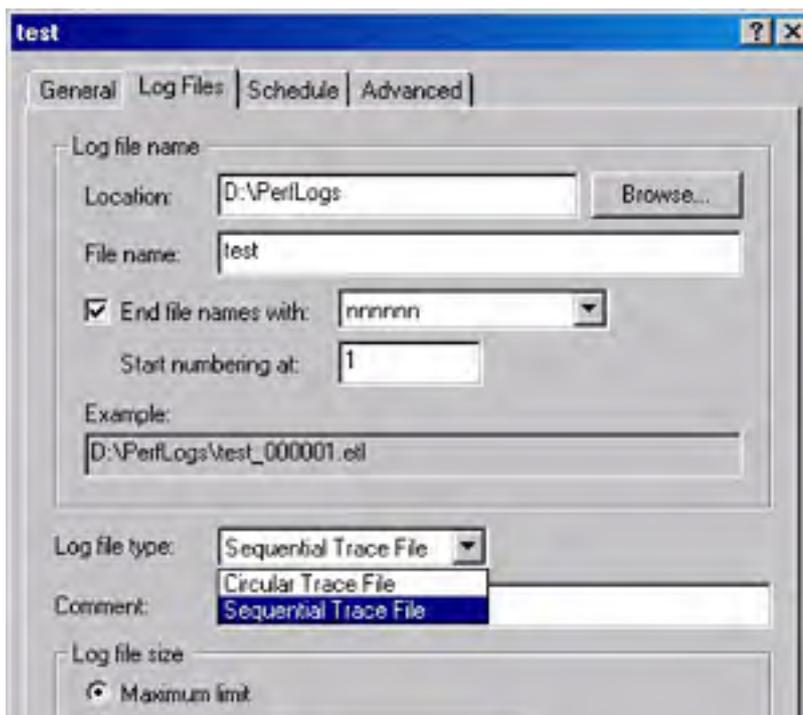

## Understanding the Log File Parameters

The Log Files tab of the Properties dialog box for a counter or trace log (Figures 33-13 and 33-14) allows you to set a number of file parameters. You can specify a folder other than the default chosen by Windows 2000 in the Location box. The default location is the PerfLogs folder at the root directory. You are also given the option of ending the filename with a set of sequential numbers or a date to keep track of multiple log files. This is helpful for log files that are automatically generated with the same filename.

**Figure 33-13.** The Log Files tab of a counter log's Properties dialog box.

**Figure 33-14.** The Log Files tab of a trace log's Properties dialog box.

A file size option is available with which you can either allow the log file to become as large as disk quotas or the operating system permits or limits the size to a specific number of kilobytes. Limit the size of a log file if you want to use one of the circular logging options. In conjunction with limiting the size of a log file, you can use the When The Log File Is Full option in the Schedule tab to run a command if you want a particular action to occur when the log file reaches its limit. You can choose from among four file types for a counter log:

- **Text File - CSV** This format is used to export data to a spreadsheet program. The data is stored as a comma-delimited log file that uses the file extension .CSV.
- **Text File - TSV** This format can also be used to export data to a spreadsheet program. The data is stored as a tab-delimited log file that uses the file extension .TSV.
- **Binary File** This format is used for intermittent instances (instances that stop and start after the log has been started). The data is stored as a sequential, binary-format log file that uses the file extension .BLG.
- **Binary Circular File** This format is used to record data continuously to the same log file, where the new records overwrite the previous ones. The data is stored in binary format as a circular file that uses the file extension .BLG.

Trace logs can be either of two file types:

- **Circular Trace File** This format is used to record data continuously to the same log file, where the new records overwrite the previous ones. The data is stored in a circular file that uses the file extension .ETL.
- **Sequential Trace File** This format is used to collect data until a user-defined limit is reached. Once the limit is reached, the current file is closed and a new one is started. The data is stored as a sequential file that uses the file extension .ETL.

The default file type for counter logs is Binary File (with the extension .BLG), and the default file type for trace logs is Sequential Trace File (with the extension .ETL).

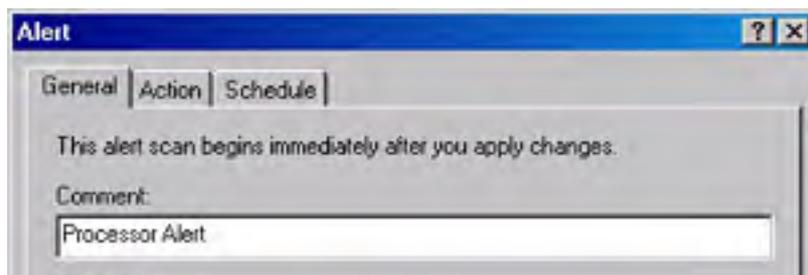

## Using Alerts

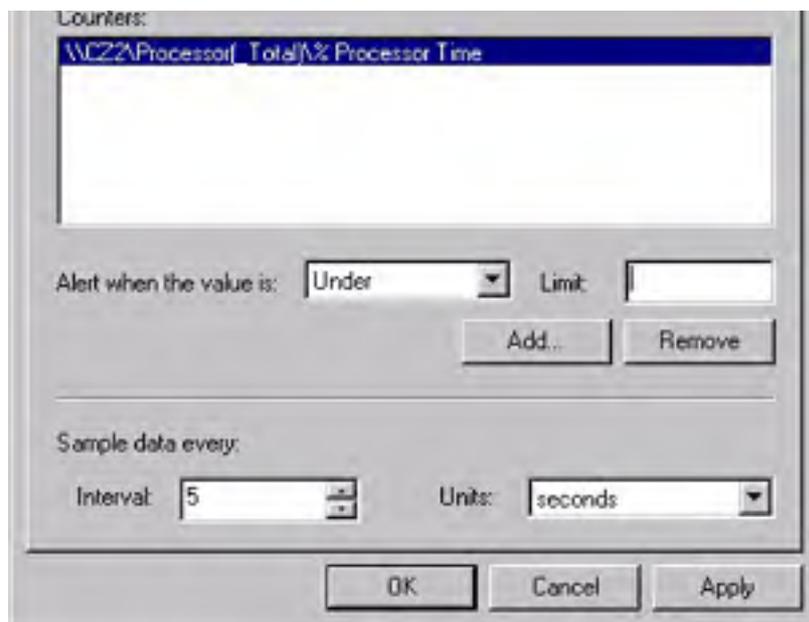

An alert notification is sent to the user by means of the Messenger service when a predefined counter value reaches, falls below, or rises above a defined threshold. The Messenger service must be running for alert notifications to be sent to the user.

### Creating an Alert

To create an alert, follow these steps:

1. Open System Monitor, and double-click Performance Logs And Alerts.
2. Click Alerts.
3. Right-click in a blank area of the details pane, and choose New Alert Settings. In the Name text box, enter the name of the alert you are creating, and click OK. A Properties dialog box for configuring the alert you are creating appears (Figure 33-15).

**Figure 33-15.** The Properties dialog box for an alert.

4. Configure the alert by specifying whether to monitor the local machine or a remote machine, choosing one or more counters, setting threshold values for the counters, selecting an action to perform when an alert is triggered, and choosing the desired scheduling options. These settings are described in the next section. Any alerts that already exist are listed in the details pane. A red icon indicates an alert that is not running or has been stopped; a green icon indicates an alert that is running.

## Configuring an Alert

For information on specifying a computer to monitor and on selecting counters for the alert, see the section entitled [Selecting Counters](#) earlier in this chapter.

You must choose threshold values for each counter on which you set an alert. This is done in the General tab of the Properties dialog box for the alert. When you create an alert, the Properties dialog box is displayed automatically. If you need to add counters at a later date, you can access the Properties dialog box by right-clicking the name of the alert file, choosing Properties from the shortcut menu, and clicking Add in the General tab.

You set thresholds to trigger an alert when the value of the counter falls either above or below a certain baseline for your organization. To establish a baseline, you must determine the level of system performance that is acceptable when your system is experiencing a typical workload and running all required services. You do this by reviewing logged data graphed by System Monitor or by exporting the data and generating reports for analysis.

In the Action tab of the Properties dialog box, you can specify actions that should occur when a threshold is exceeded. You have four available options:

- **Log An Entry In The Application Event Log** Causes the alert to log an entry that is visible to you in Event Viewer.
- **Send A Network Message To** Triggers the Messenger service to send an alert message to a specified computer.
- **Start Performance Data Log** Runs an existing counter log.
- **Run This Program** Specifies a command file and command-line arguments to run when an alert occurs.

## Permissions for Counter Logs, Trace Logs, and Alerts

To create or modify a log or alert, you must have Full Control permission for the registry entry KEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services\SysmonLog\LogQueries. Administrators are usually assigned this permission by default, and they can grant this permission to users in Regedt32.exe through the Security menu.

To run the Performance Logs and Alerts service, you must have permissions to configure or start services on the system. Administrators are usually assigned this permission by default, and they can grant this permission to users in the Group Policy snap-in. Furthermore, to log data for a remote computer, the Performance Logs and Alerts service is required to run under an account that has access to that remote system. The service runs in the background once a log or alert is configured and running.

### **Real World**

#### **Tuning and Testing Strategies**

Before starting System Monitor or Performance Logs and Alerts on the computer you are monitoring, do the following:

- Increase the paging file to the physical memory size plus 100 MB.
- Turn off any screen-saver programs.
- Shut down services that are not relevant or essential to monitoring the system.

Keep the following best practices in mind when preparing to tune your system:

- Set up Performance Logs and Alerts to monitor and report data on counters at a regular interval, such as every 10 to 15 minutes. It's a good practice to retain your logs for an extended period of time. You can store the data in a database and use it for trend analysis, performance assessment, and capacity planning.
- Make only one change at a time. Bottlenecks can be the fault of several components. Don't confuse the issue by making too many changes at once because that can make it impossible to assess the impact each change has on the system.
- Keep a record of each change you make, and repeat the monitoring process after every change. This practice is important because tuning changes can affect other resources and such records can help you to determine the effect of each change and whether additional changes are necessary.
- Do a comparison of programs that run over the network against those that run locally. This tells you whether network components might be playing a part in performance problems.
- Pay attention to event logs; certain performance problems generate output that you can view in Event Viewer.
- Under certain conditions, the performance tools increase overhead. If you find that this is a problem, you can reduce it as follows:
  - Be selective in the objects and counters you monitor. The more you choose, the higher the overhead.
  - Don't run System Monitor in graph view. This view incurs the highest overhead.
  - Specify sampling intervals of 3 seconds or more; anything less than 3 seconds is too frequent.
  - Run Performance Logs and Alerts instead of using a System Monitor graph.
  - Reduce the amount of disk space used by log files by extending the update interval and logging to a disk other than the one being monitored. Frequent logging places a greater demand on disk input and output.
- When logging data through Performance Logs and Alerts, you should exclude times that include start-up events. Start-up events tend to skew overall performance results because they show temporarily high values.
- When you save the performance tools settings to a file after you have completed the configuration, save the file under a name other than Perfmon.msc. Otherwise, you are permanently changing the configuration of the performance tools on the computer.

## Selecting a Monitoring Method

If you need to observe a system event as it's happening, use a graph in System Monitor. Graphs are helpful for real-time, short-term monitoring of a remote or local computer. Choose an update interval that best captures the data for the type of activity you are observing. Performance logs are better suited for long-term monitoring and record keeping. You can export logged data and use it to generate reports, and you can also view the information as graphs or histograms using System Monitor. Logging in this manner is also more practical when you need to monitor several computers at once.

## Determining How Often to Monitor

For routine logging of data logs, start out by setting the value in the Sample Data Every box to 15 minutes. To find this option, display the Properties dialog box of the specific counter log. You can adjust this interval to fit the type of data you are monitoring. If you have a slow memory leak, for example, you should use a longer time interval. Another consideration is the overall length of time that you monitor a system. If you are monitoring for less than 4 hours, a 15-minute interval is acceptable. If you are monitoring a system for 8 hours or more, don't set a time interval that is shorter than 5 minutes (300 seconds). Monitoring at a frequent rate causes the system to generate a lot of data, producing large log files. It also increases the overhead tremendously.

## Monitoring Memory Usage

If you are experiencing performance problems, the first step in examining the problem is usually to monitor memory usage, the most important factor in system performance. If you find that your system is paging frequently, you might have a memory shortage on your machine. Some paging is good because it helps to expand memory somewhat, but too much paging is a drain on system performance.

Paging is used to free memory for other uses by moving fixed-size blocks of data and code from RAM to your disk in units called pages.

Before you start to monitor memory usage, you should perform a few checks. For example, verify that your system has the recommended amount of memory for running the operating system as well as other applications and services. If you don't know what the memory requirements are for a process, you can discover its working set within System Monitor, shut the process down, and observe the effect on paging activity. The amount of memory that is freed when you terminate a process is the amount of memory the process was using.

A *working set* is the portion of physical memory allocated to each program running on the computer.

Excessive paging can result when Windows 2000 Setup configures your system with settings that optimize file sharing. In some cases, this can increase paging significantly because it causes the system to maintain a large system-cache working set. If you are not using the server for file sharing, you can reduce the amount of paging on your server by turning off the file-sharing settings. To do so, follow these steps:

1. On the Start menu, point to Settings and then choose Network And Dial-Up Connections.
2. Right-click Local Area Connection and choose Properties from the shortcut menu.
3. In the Components Checked Are Used By This Connection box, select File And Printer Sharing For Microsoft Networks and click Properties.
4. In the Server Optimization area, the Maximize Data Throughput For File Sharing option is selected by default. Select Maximize Data Throughput For Network Applications instead (Figure 33-16). This reduces paging activity on your system.

**Figure 33-16.** The File And Printer Sharing For Microsoft Networks Properties dialog box.

## Recommended Counters

Monitor memory counters for a low-memory condition. This section lists the minimum recommended counters for monitoring the server's memory component. To check for possible memory leaks or bottlenecks, monitor these counters:

- **Memory\ Pages/Sec** Displays the number of pages written to or read from disk to resolve hard page faults. A *hard page fault* occurs when a process requires code or data that must be retrieved from disk rather than from its working set or elsewhere in physical memory. If this value is above 20, you need to research paging activity and make adjustments as necessary. A high value for this counter might be more indicative of a paging problem than a memory problem.
- **Memory\ Committed Bytes** Displays the number of committed bytes of virtual memory on your system and is an instantaneous counter. Monitor this counter, along with Memory\ Available Bytes, over a period of time if you suspect a memory leak.
- **Memory\ Pool Nonpaged Bytes** Displays the number of bytes allocated to the nonpaged pool for objects that cannot be written to disk but must instead remain in physical memory as long as they are allocated. If this value is high, you need additional memory on your system. Use this counter in conjunction with Memory\ Pool Nonpaged Allocs if you suspect that a kernel-mode process is the cause of a memory leak.
- **Memory\ Pool Nonpaged Allocs** Shows the number of calls to allocated space in the nonpaged pool. Use this counter in conjunction with Memory\ Pool Nonpaged Bytes to determine whether you have a memory leak.
- **Server\ Bytes Total/Sec** Monitors the number of bytes the machine has received from and sent to the network. The value is indicative of how busy the server is. You need to add memory if you have a sustained, dramatic increase in this value.
- **Server\ Pool Paged Bytes** Monitors the number of bytes of pageable computer memory

currently in use by the system. You can use this information to determine values for the MaxPagedMemoryUsage entry in the Windows 2000 registry.

- **Server\ Pool Nonpaged Bytes** Monitors the number of bytes of non-pageable computer memory in use by the system. You can use this information to determine the values for the MaxNonpagedMemoryUsage entry in the Windows 2000 registry.

To monitor for a low memory condition, use these counters:

- **Memory\ Available Bytes** Windows 2000 uses free bytes to satisfy the memory requirements of programs. When free bytes fall into short supply, the shortage is replenished by taking memory from the working sets of less active programs. Subsequently, you will notice an increase in the working set value for one program and a steady decrease in the values of other programs. The result is an increase in paging that causes performance to suffer. To resolve this problem, you need to add memory to the machine.
- **Memory\ Cache Bytes** Monitors the number of bytes being used by the file system cache. Use this counter in conjunction with Memory\ Available Bytes. If the value for Memory\ Cache Bytes rises above 4 MB, you might need to add more memory to the machine.
- **Physical Disk\ % Disk Time and Physical Disk\ Avg. Disk Queue Length** These counters can indicate a memory shortage when used in conjunction with Memory\ Page Read/Sec. If an increase in queue length is not accompanied by a decrease in the Memory\ Page Read/Sec value, a shortage does exist.

To check for excessive paging, monitor these counters:

- **Paging File\ % Usage (all instances)** Paging files are shared by every process and are used to store pages of memory on your system. If you suspect that paging is to blame for your bottleneck, it is helpful to review this value, along with Memory\ Available Bytes and Memory\ Pages/Sec. The acceptable threshold for this value is 99 percent. Enlarge Pagefile.sys if the value increases to 100 percent.
- **Paging File\ % Usage Peak** If the value for this counter approaches the maximum paging file setting, the size of Pagefile.sys needs to be increased.
- **Physical Disk\ Avg. Disk Sec/Transfer and Memory\ Pages/Sec** The Physical Disk\ Avg. Disk Sec/Transfer counter displays the average disk transfer in seconds. The Memory\ Pages/Sec counter displays the number of pages written to or read from the disk when a process requires information that is no longer in its working set and must be retrieved from disk. To help determine whether your system is paging excessively, multiply the values of these two counters. If the result exceeds 0.1, paging is taking up more than 10 percent of disk access time. If this condition persists over a long period of time, you need additional memory.

## Tuning and Upgrading Tips for the Memory Component

If you are experiencing problems with memory, check the following possibilities:

- **Paging file** Make sure that the paging file is the correct size, and create multiple paging files to reduce excessive paging. You can also split the paging file between multiple physically separate disks (not multiple volumes on the same physical disk) of similar speeds to increase access time.

When the paging file reaches the maximum limit assigned to it, a warning is displayed and your system might halt.

- **Physical memory** Increase the physical memory above the required minimum.
- **Memory settings** Verify that memory settings are configured properly.
- **Memory-intensive programs** Run programs that are memory hogs when your system workload is lightest or on your highest performing computers.

## Monitoring Processor Activity

When monitoring processor usage, you need to consider the role of the computer and the work being done on it. High processor values could mean either that your machine is handling the workload in a very efficient manner or that it is struggling to keep up.

When a bottleneck occurs because a process's threads need more processor cycles than are available, long processor queues build up, causing the system response to suffer. The two common causes of processor bottleneck are excess demand placed on the processor by CPU-bound programs and excess interrupts generated by drivers or subsystem components, such as disk or network components.

### Minimum Recommended Counters

The following list shows the minimum recommended counters you should use to monitor the server's processor component for possible bottlenecks:

- **System\ Processor Queue Length (all instances)** Two or more items in the queue indicate a bottleneck. Because this is an instantaneous counter, the only way to get an accurate analysis is to observe the average value over several intervals.
- **Server Work Queues\ Queue Length** A queue length of greater than four over a sustained period of time indicates possible processor congestion.
- **Processor\ Interrupts/Sec** You can use this counter to determine whether interrupt activity is causing a bottleneck. If you find a dramatic increase in this counter value without a corresponding increase in system activity, a hardware problem is likely. To resolve this problem, you need to find the network adapter or other device that is causing the interrupts. Refer to the manufacturer's specifications for the acceptable processor threshold.
- **Processor\ % Interrupt Time** This counter displays the percentage of time the processor spends receiving and servicing hardware interrupts during the sample interval. This value gives you an indirect indication of the activities of devices that generate interrupts, such as disk drives, network adapters, and other peripheral devices. These devices interrupt the processor when they require attention or complete a task. Look for a dramatic increase in the value without a corresponding increase in system activity.

To monitor possible usage problems, use these counters:

- **Processor\ % Processor Time (all instances)** Use this counter to discover a process that is using more than 85 percent of processor time. You might need to install an additional processor or upgrade to a faster one.
- **Processor\ % User Time** Monitors the percentage of nonidle processor time that is spent in user mode. A high rate might indicate a need to upgrade or install additional processors. Use this counter in conjunction with Processor\ % Processor Time (all instances).
- **Processor\ % Privileged Time** Monitors the percentage of nonidle processor time designated for hardware-manipulating drivers and operating system components. A high rate might be attributed to a large number of interrupts being generated by a device that is failing. Use this counter in conjunction with Processor\ % Processor Time (all instances).

### Tuning and Upgrading Tips for the Processor Component

You can try the following solutions to resolve problems you are experiencing with the processor:

- **Upgrade the processor** Upgrade to a faster processor, replace a failing one, or add another processor to the machine, especially if you are running multithreaded programs.
- **Adjust the workload of the system** Distribute programs more efficiently among servers, or schedule programs to run at off-peak hours.
- **Manage processor affinity on multiprocessor computers** Managing the processor affinity with respect to interrupts and process threads can improve performance because it reduces the number of processor cache flushes during thread movement from one processor to another.

You set affinity for a particular process or program when you assign it to a single processor to improve its performance, at the expense of the other processors. Be forewarned that when you dedicate a process or program to a processor, your other program threads might not be permitted to migrate to the least busy processor. You can set affinity in Task Manager, and it is available only on multiprocessor systems.

## Monitoring Disk Activity

Monitoring disk usage helps you to balance the load of your network servers. When you are monitoring disk performance, log the performance data to another disk or computer to prevent it from skewing the data for the disk you are testing.

The operating system collects the Physical Disk counter data by using the `Diskperf -yd` command by default. This is not true of the Logical Disk counter data, however. To obtain performance counter data for logical drives, you must type `Diskperf -yv` at the command prompt. This command causes the driver used for collecting disk performance data to report data for logical drives. To obtain further information about the `Diskperf` command, type `diskperf -?` at a command prompt.

## Minimum Recommended Counters

The following list shows the minimum recommended counters you should use to monitor the server's disk performance for possible bottlenecks:

- **Physical Disk\ Current Disk Queue Length (all instances)** Monitors the number of system requests that are waiting for disk access. This number should remain steady at no more than 1.5 to 2 times the number of spindles that make up the physical disk. Most disks have one spindle. The exception is redundant array of independent disks (RAID) devices, which usually have more than one spindle. You need to observe this value over several intervals because it is an instantaneous counter.
- **Physical Disk\ % Disk Time** Indicates how busy your server's disk drives are by displaying the percentage of time that a drive is active. If the value of this counter rises to more than 90 percent or if you are using a RAID device, check the Physical Disk\ Current Disk Queue Length (all instances) counter to see how many disk requests are queued for disk access. RAID devices can cause the Physical Disk\ % Disk Time value to exceed 100 percent and thus give an incorrect reading.
- **Physical Disk\ Avg. Disk Sec/Transfer** Monitors the amount of time a disk takes to fulfill a request. A high value might indicate that the disk controller is continually trying to access the disk as a result of failures. For most systems, a value of 0.3 seconds or higher indicates a high average disk transfer time.

To monitor possible usage problems, use these counters:

- **Physical Disk\ Avg. Disk Bytes/Transfer** Monitors the average number of bytes that are transferred from or to a disk during read or write operations. A value less than 20 KB indicates that an application is accessing the disk drive inefficiently.
- **Physical Disk\ Disk Reads/Sec and Disk Writes/Sec** These counters can help you balance the workload of your network servers. Make sure that the specified transfer rate for your disk doesn't exceed the manufacturer's recommended specifications.

## Tuning and Upgrading Tips for Disk Activity

If you are experiencing problems with disk performance, try the following solutions:

- Install the latest driver software for your host adapters to improve the efficiency of disk access.
- Install additional disks, or upgrade your hard disk to a faster disk. Update the bus and the disk controller at the same time.
- On servers, create striped volumes on several physical disks to increase throughput.

- Distribute applications among your servers to help balance the workload.
- Optimize disk space by running Disk Defragmenter.
- Isolate tasks that use disk I/O heavily to separate disk controllers or physical disks to help balance the server's workload.

## Monitoring Network Activity

Monitoring the network consists of observing the use of server resources and measuring overall network traffic. Although you can do both with System Monitor, Network Monitor, discussed later in this chapter, gives you a more in-depth analysis of traffic.

Start monitoring your system by tracking the minimum recommended counters. Observe the resource usage on your system. Use the counters that correspond to the various layers of your network's configuration to concentrate on network-related resource usage. Abnormal network counter values are usually an indication of problems with a server's processor, memory, or hard disks. We recommend that you monitor network counters in conjunction with Memory\ Pages/Sec, Processor\ % Processor Time, and Physical Disk\ % Disk Time. For example, if Memory\ Pages/Sec increases dramatically, accompanied by a decrease in Memory\ Bytes Total/Sec handled by the server, the system is most likely running short of physical memory for network operations.

## Minimum Recommended Counters

The following list shows the minimum recommended counters you should use to monitor the network's performance for possible bottlenecks:

- **Server\ Pool Paged Peak** Indicates the amount of physical memory and the maximum paging file size. The acceptable threshold is the amount of physical RAM.

To monitor possible usage problems, use these counters:

- **Server\ Bytes Total/Sec** Indicates the number of bytes the server has sent to and received from the network. This value is helpful in providing an indication of how busy the server is. You might need to segment the network if the sum of the Bytes Total/Sec for all servers is close to equaling the maximum transfer rate of your network.
- **Server\ Work Item Shortages** Indicates the number of times no work items are available to service incoming requests. Consider tuning InitWorkItems or MaxWorkItems in the registry key HKEY\_LOCAL\_MACHINE\SYSTEM\CurrentControlSet\Services\LanmanServer if the value of this counter reaches or exceeds the threshold of 3.

## Tuning and Upgrading Tips for Network Activity

Try the following solutions if you are experiencing problems with network performance:

- To significantly increase performance, unbind infrequently used network adapters and upgrade each network adapter to a high-performance one.
- When you configure your network, make sure that the systems shared by the same group of people are on the same subnet.
- Install multiple network adapters to increase file-sharing throughput.
- Set the order in which the workstation and NetBIOS software bind to each protocol when you are using more than one protocol. Average connection time decreases when the protocol that is used most frequently is set to be first in the binding list.

## Using Network Monitor

You use Network Monitor to capture and display statistics about the frames that a server receives from the LAN. Network Monitor troubleshoots networking problems and helps you analyze network traffic. You can install Network Monitor only on a server.

Network Monitor consists of two components—Network Monitor itself and the Network Monitor driver—both of which must be installed on the server that is running Network Monitor so that you can capture frames. The Network Monitor driver enables Network Monitor to receive frames from the network adapter. The driver can be installed only on machines running Windows 2000 Server or Windows 2000 Professional.

The Systems Management Server (SMS) of Network Monitor 2.0 puts the network adapter in promiscuous mode, which means that the adapter reads all of the frames (packets) it receives over the network, instead of just the ones addressed to itself.

Network Monitor and the Network Monitor driver can be installed in one of two ways. You can install them both when you install the Windows 2000 Server operating system; or, at a later time, you can install Network Monitor by opening Add/Remove Programs in Control Panel and selecting Add/Remove Windows Components. You'll then need to install the Network Monitor driver separately by pointing to Network And Dial-up Connections on the Settings menu and then choosing Local Area Connection Properties.

A *frame* is a portion of information from the network data stream that has been divided into smaller pieces by the networking software and is sent out across the wire. Network Monitor makes it possible to capture frames directly from the network. It enables you to display, filter, save, and print the captured frames to help identify network traffic patterns and network problems. A frame contains the following items:

- The source address of the machine that sent the frame. The source address is a unique hexadecimal number that identifies the sending machine.
- The destination address of the machine that received the frame. The destination address is a unique hexadecimal number that identifies the receiving machine.
- The header information for the protocol that sent the frame.
- The actual data that was sent to the destination computer.

Network Monitor for Windows 2000 stores data captures to a temporary capture file. When you save the capture file, it is given the .CAP extension, and you can view the capture files within Network Monitor.

To isolate a specific subset of frames, you need to design a capture filter. The capture filter behaves like a database query used to isolate specific information. Frames can be filtered on the basis of several options that include protocols, protocol properties, and source and destination addresses. You can also set up a capture to respond to specific conditions by designing a capture trigger that is detected by Network Monitor.

## Viewing the Frame Viewer Window

Before you start capturing frames, you must choose the correct network interface. It is important to note that all network interfaces, including modems, are included in the network interface list. To specify the network interface, in the Capture window, choose Networks from the Capture menu.

To capture frames from the Capture window, you have three options: you can click the Start Capture button on the toolbar, choose Start from the Capture menu, or press the F10 function key. To examine the frames, you need to stop the capture of the current session in one of three ways: by selecting Stop And View from the Capture menu, by clicking the Stop Capture button on the toolbar, or by pressing the F11 function key. If you don't select Stop And View, you can view the Frame Viewer window by pressing the F12 function key.

The Frame Viewer window is used to view the contents of the captured frames (Figure 33-17). You can view captured information by choosing Stop And View from the Capture menu during data capture. You can zoom into a specific pane in the Frame Viewer window by selecting the pane and then choosing Zoom Pane from the Windows menu. This action places a check mark next to the Zoom option in the Windows menu.

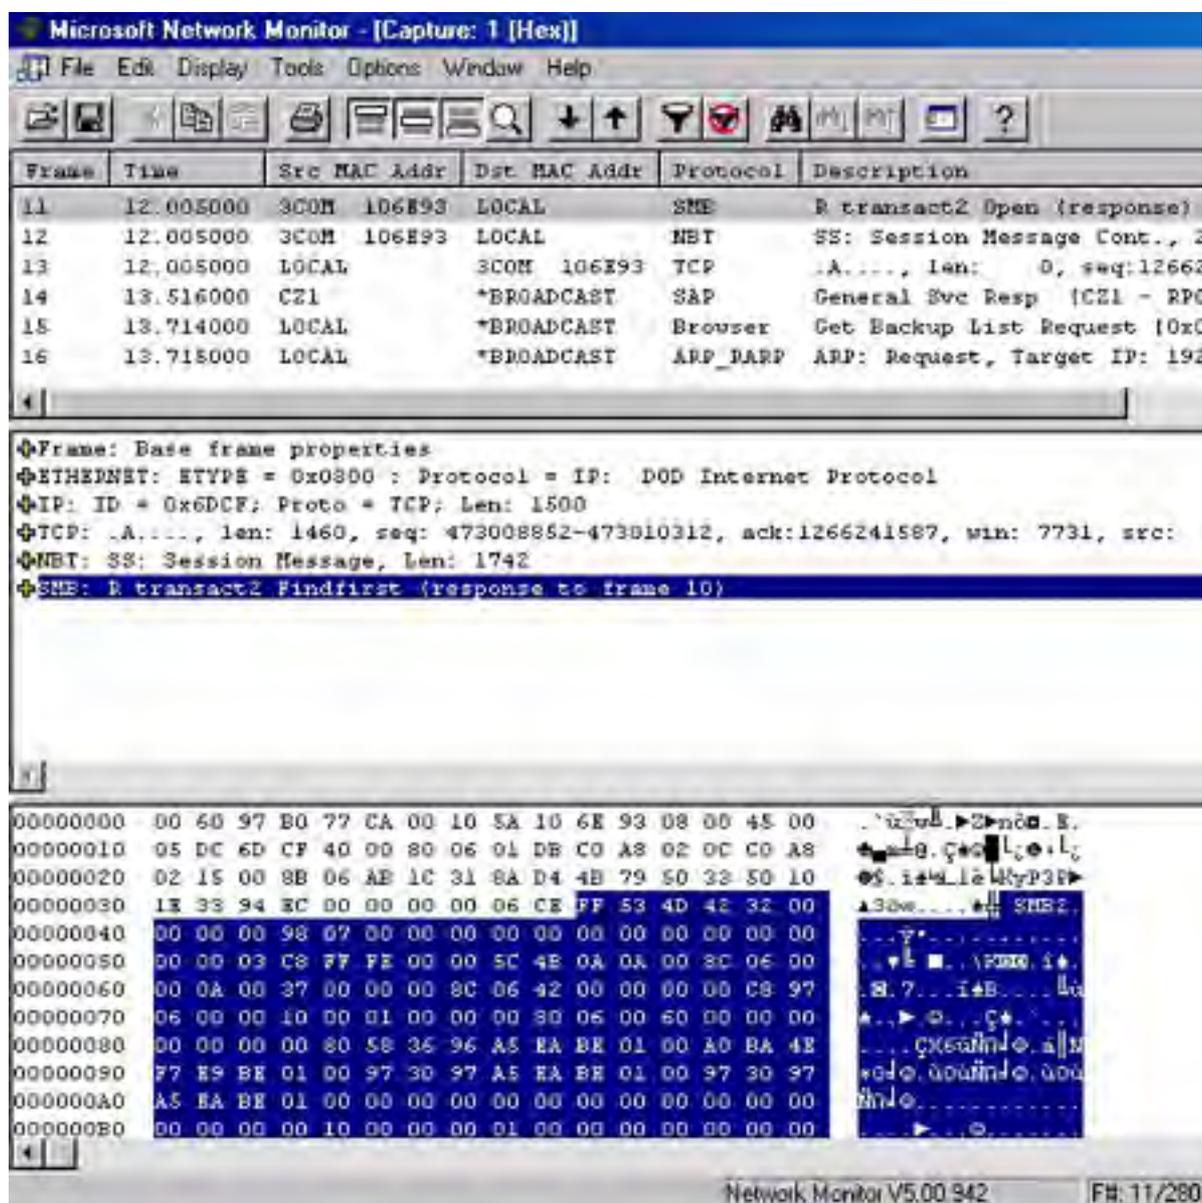

Figure 33-17. The Frame Viewer window.

The Frame Viewer window has three panes:

- The summary pane displays general information about the captured frames in the order in which they were captured.
- The detail pane displays the frames' contents, including the protocols used to send them.
- The hex pane displays the ASCII and hexadecimal representation of the data that is captured.

## Viewing the Capture Window

The statistics for the captured frames are displayed in the Capture window (Figure 33-18).

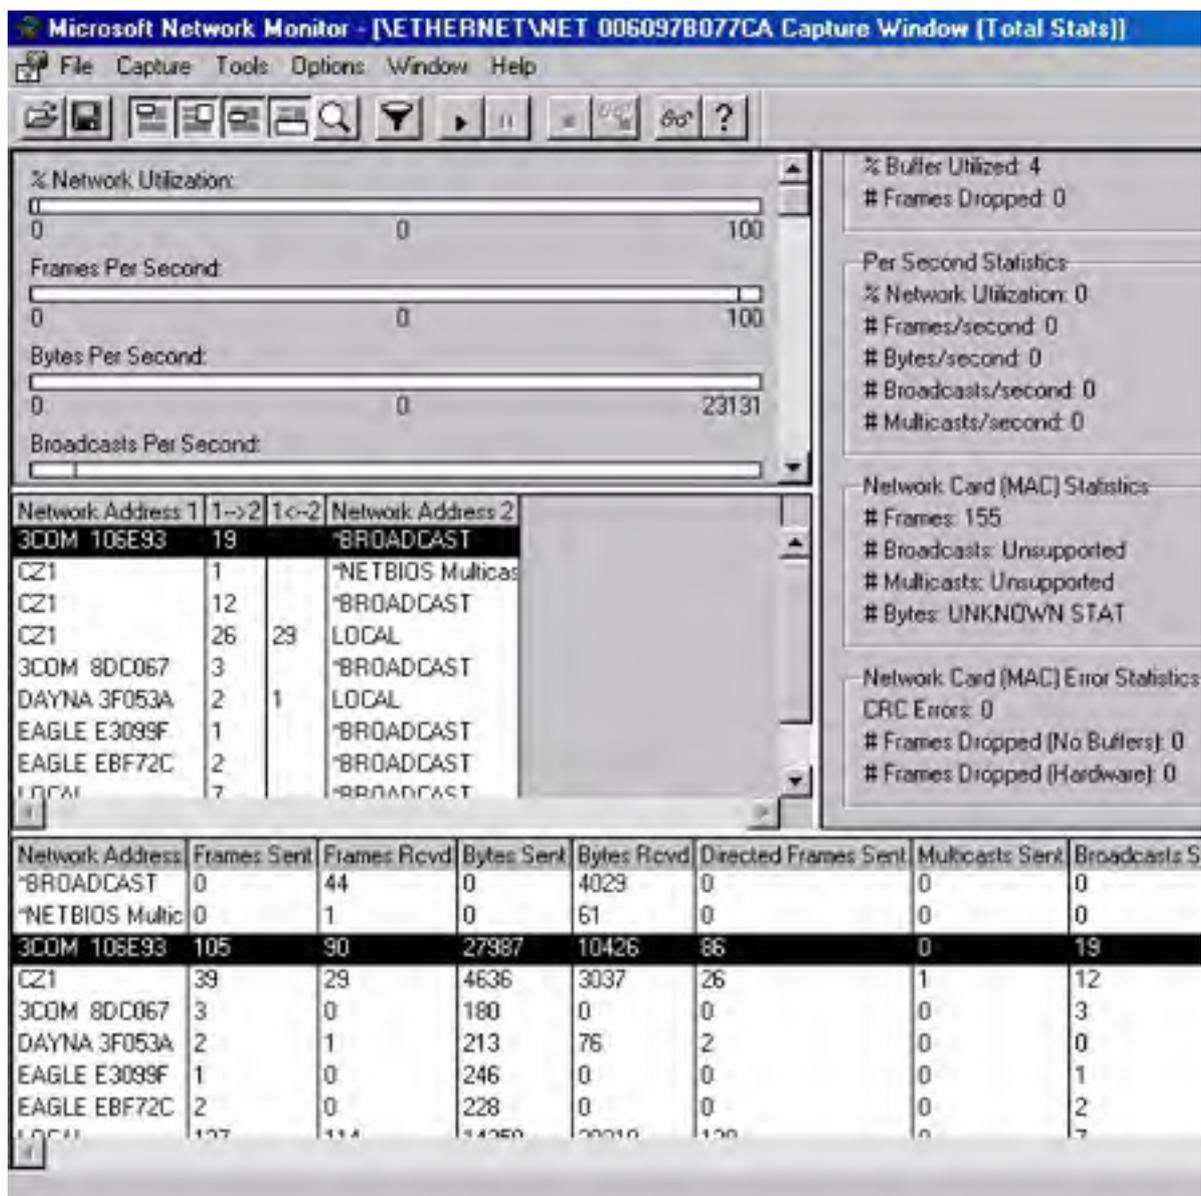

Figure 33-18. The Capture window.

The Capture window has four panes that display frame statistics:

- The graph pane (the upper left pane in Figure 33-18) graphically displays the total capture statistics of current network activity, such as percentage of available network resources in use by the current capture and the number of frames, bytes, broadcasts, and multicasts that the network transmits every second. This pane is displayed in the upper left corner of the Capture window by default.
- The session statistics pane (the middle left pane in the figure) displays statistics for current individual network sessions. Both participants in a session are identified, and information relating to the amount of information passed between them in either direction is displayed. The session statistics pane includes information such as the first participant's network address, labeled Network Address 1; the second participant's network address, labeled Network Address 2; the number of frames sent from the address listed as Network Address 1 to the address listed as Network Address 2, labeled 1->2; and the number of frames sent from the address listed as Network Address 2 to the address listed as Network Address 1, labeled 1<-2. Only the first 128 unique addresses are reflected in this pane, so it is best to design a capture filter if you need to capture statistics on a specific workstation. This pane is displayed in the center left section of the Capture window by default.

- The station statistics pane (the bottom pane in the figure) displays statistics about activities that occur from or to the local machine running Network Monitor. This pane is displayed at the bottom of the Capture window by default and includes the network address from which the frames were captured; the number of frames and bytes sent from the network address; the number of frames and bytes received by the network address; and the number of directed frames, multicasts, and broadcasts sent from the network address to other computers on the network. As with the session statistics pane, only the first 128 unique addresses are reflected in this pane.
- The total statistics pane (the right pane in the figure) summarizes statistics about overall network activity detected by Network Monitor from the time the current capture process began. Not all network adapter cards support all of the statistics displayed by this pane. The label for a statistic is replaced by the word "Unsupported" if the network adapter card doesn't support it. This pane is displayed in the upper right corner of the Capture window by default. The total statistics pane consists of five panels:
  - Network Statistics displays statistics about the total amount of traffic that has occurred since the current capture on Network Monitor began. These statistics include the total number of frames dropped and the total number of frames, broadcasts, multicasts, and bytes sent to the network. The network status is also displayed. The status is always Normal on an Ethernet network and reflects the status of the ring on a token ring network.
  - Captured Statistics displays statistics regarding the current capture that is running. These statistics include the total number of captured frames and bytes, the total number of frames and bytes in the temporary capture file, the percentage of allotted buffer space that is being utilized, the number of frames that were dropped by Network Monitor, and when the allotted buffer space was exceeded.
  - Per Second Statistics displays averages of current activity and is constantly updated to reflect per-second activity. All frames, even those excluded by a filter, are included in these statistics. The statistics displayed in this panel include the average percentage of network utilization and the average frames, bytes, broadcast messages, and multicast messages detected per second from the time the current capture process began.
  - Network Card (MAC) Statistics reflects the average activity detected by the network adapter from the time the current capture session began. These statistics include the total number of frames, broadcast frames, multicast frames, and bytes detected by the network adapter card.
  - Network Card (MAC) Error Statistics displays network adapter card errors that have occurred from the time the current capture session began. These statistics include the number of errors that occurred because the actual bytes received did not match the cyclical redundancy check (CRC) and the number of frames that were detected but dropped by the network adapter card, either because insufficient buffer space was available to Network Monitor or as a result of hardware constraints.

## Configuring and Customizing Network Monitor

You must be logged on as a user with administrative rights to run Network Monitor. You can customize Network Monitor in a number of ways to meet your needs, as described in this section.

### Modifying the Capture Buffer

The size of the capture buffer affects how much data is available for viewing in Network Monitor. If you set the buffer to 1 MB, Network Monitor will store only the last 1 MB of data.

To adjust the size of the capture buffer in Network Monitor, choose Buffer Settings from the Capture menu. You can adjust the Buffer Size (MB) or Frame Size (Bytes) options in the Capture Buffer Settings dialog box (Figure 33-19). The buffer size or frame size can be reduced if you find that your system becomes low on resources while you are capturing data with Network Monitor. Make sure that your buffer setting does not exceed the amount of physical memory you have available on your system because memory swapping can cause frames to be dropped.

Figure 33-19. The Capture Buffer Settings dialog box.

### Displaying Address Names

To see address names instead of hexadecimal network addresses in Network Monitor, choose Show Address Names from the Options menu. A check mark appears next to Show Address Names when this option is active. This option is very helpful to the administrator because it causes Network Monitor to replace the hexadecimal network addresses of the computers from which the frames have been captured with their user-designated machine names.

### Creating an Address Database

You might often need to capture frames that originated with or were sent to specific computers. To do this, you must know the addresses of the computers on the network. You can find the IP address of a computer in one of two ways: using the Ping command or using the mechanism that Network Monitor provides for associating the addresses of the network computers with their user-defined names. If you use the mechanism provided by Network Monitor, you can save the information to an address database once the association is made and later use the database to design display or capture filters.

To create an address database, choose Find All Names from the Display menu in the Frame Viewer window. The system might take a few minutes to process the information from the current frames. To display the addresses, choose Addresses from the Display menu of the Frame Viewer window (Figure 33-20). Save the database to a file if you want to use the addresses to design filters in the future.

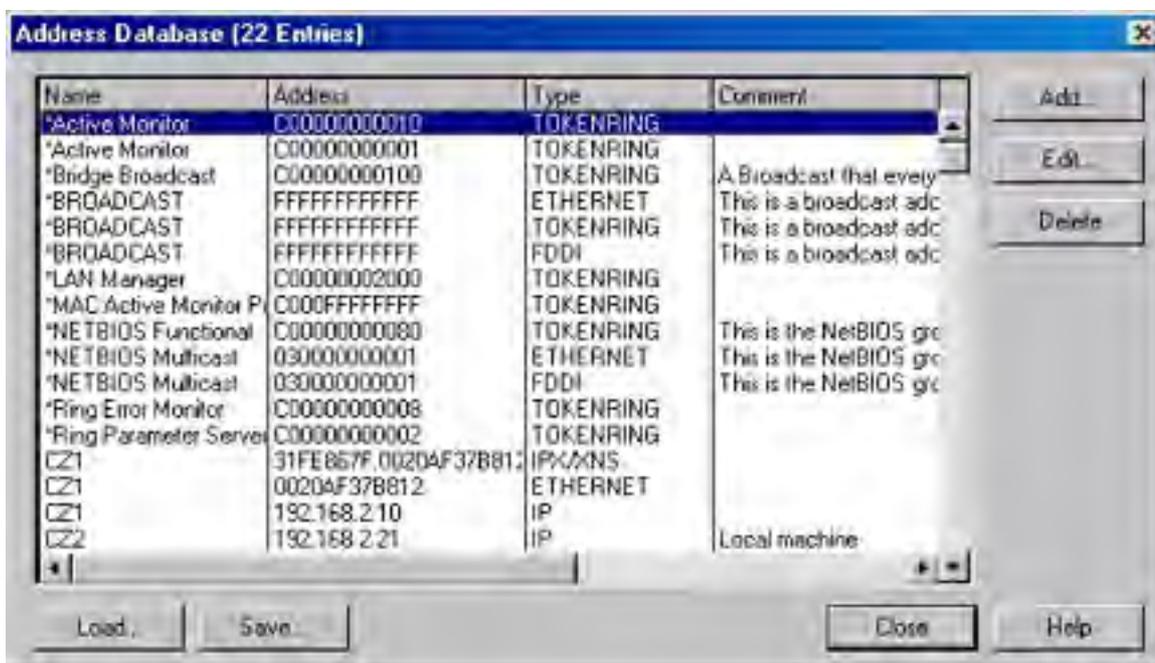

Figure 33-20. The Address Database dialog box.

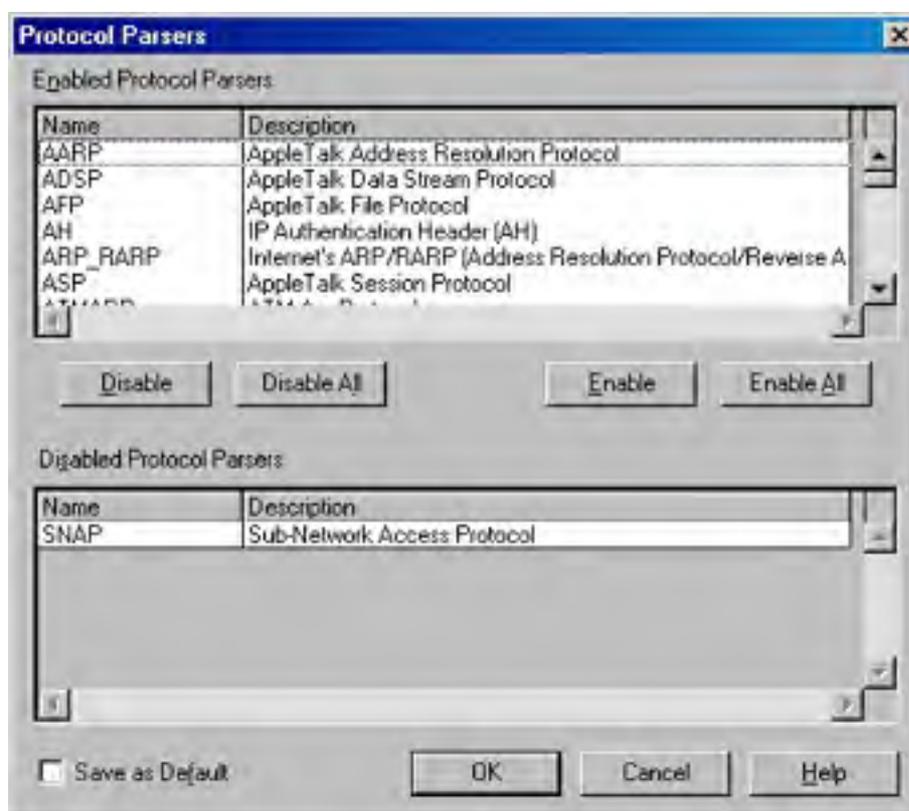

### Displaying Adapter Card Vendor Names

To replace the hexadecimal computer addresses with the names of the vendors of the adapter cards on the computers from which frames have been captured, in Network Monitor, choose Show Vendor Names from the Options menu. When this option is active, a check mark appears next to it.

## Adding a Protocol Parser

Network Monitor uses programs called protocol parsers to separate protocol information into smaller pieces to be able to act on the information. Each parser can parse one protocol or family of protocols. Parser DLLs from Network Monitor 1.2 can be added to Network Monitor 2.0. To add a protocol parser, take the following steps:

1. While Network Monitor is not running, copy the parser file to the `%SystemRoot%\System32\Netmon\Parsers` folder. The parser file should have a .DLL extension.
2. In the `%SystemRoot%\System32\Netmon` folder, find the Parser.ini file and open it. Enter the information about the parser you are adding in this file.
3. Start Network Monitor, close any open Frame Viewer windows, and then choose Default Parsers from the Options menu.
4. A window warning about disabling protocols through this option appears. Click Yes to continue.
5. The currently enabled protocols are listed under Enabled Protocol Parsers in the Protocol Parsers dialog box (Figure 33-21). All of the parsers present in your `%SystemRoot%\System32\Netmon\Parsers` subfolder are enabled by default.

**Figure 33-21.** The Protocol Parsers dialog box.

6. The name of the parser you just added to the `%SystemRoot%\System32\Netmon\Parsers` folder appears under Disabled Protocol Parsers. Select the name, and then click Enable. The name of the protocol should move to the Enabled Protocol Parsers box.
7. If you want the new parser to be included in the default configuration, select the Save As Default check box.

It is important to verify that the parser is working correctly. If the parser is handling frames properly, the Protocol column of the summary pane in the Frame Viewer window lists the protocol.

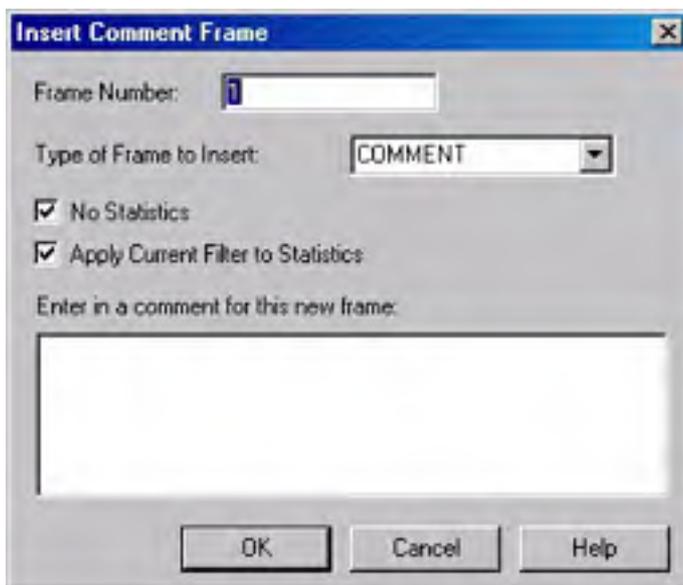

## Adding a Comment Frame to a Capture

A comment frame is a very useful tool that you can use to add comments or other information to a capture file within the Network Monitor Frame Viewer. For example, you can use comment frames to mark the beginning and ending points for a group of packets. The Trail protocol is contained in the comment frame and includes such information as the bandwidth and the number of frames consumed.

To add a comment frame, choose Insert Comment Frame from the Tools menu, or right-click the Frame column at the point where you want to insert the comment frame and choose Insert Comment from the shortcut menu. The Insert Comment Frame dialog box appears (Figure 33-22). The options in this dialog box are as follows:

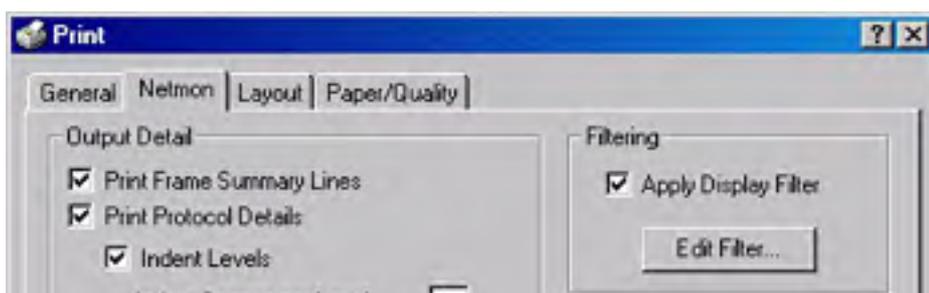

- **Frame Number** The frame position where Network Monitor places the comment frame within the capture. The default frame number is the current location.
- **Type Of Frame To Insert** The Comment or Bookmark protocol parser used to process the comment frame after the Trail protocol runs. The default parser is Comment.
- **No Statistics** Disables statistical generation for the comment frame. This check box is selected by default.
- **Apply Current Filter To Statistics** Calculates statistics using the current display filter. This check box is selected by default.
- **Enter In A Comment For This New Frame** Indicates the comment text that you want to attach to the frame by using the protocol parser chosen in Type Of Frame To Insert.

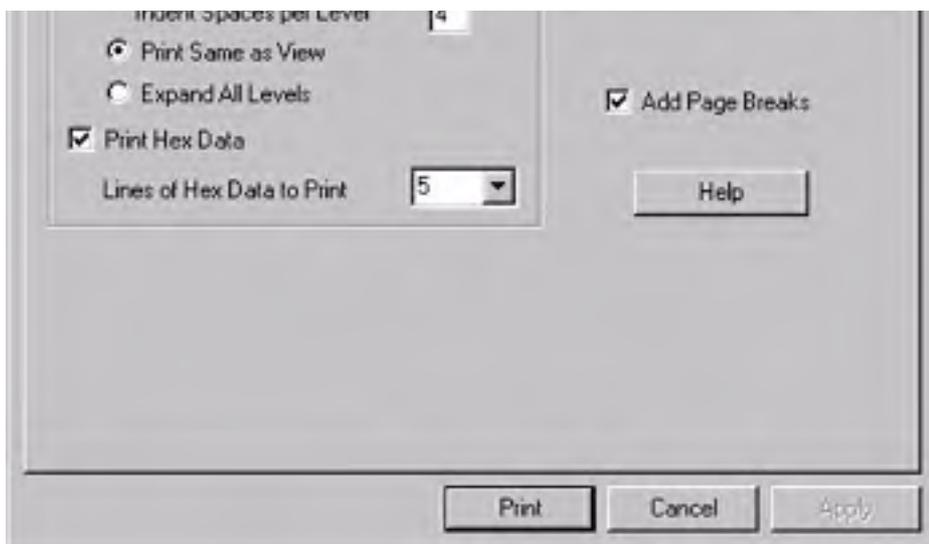

**Figure 33-22.** The Insert Comment Frame dialog box.

## Printing Captured Frames

To print captured frames, choose Print from the File menu in the Frame Viewer window. Select the desired output options in the Netmon tab in the Print dialog box (Figure 33-23). The Output Detail area enables you to specify the amount of detail you want to print for each of the frames. The choices presented to you include Print Frame Summary Lines, Print Protocol Details, and Print Hex Data. You can also set filters and add page breaks to the output.

**Figure 33-23.** The Netmon tab of the Print dialog box.

## Capturing Network Data

To begin the process of capturing frames, you must open the Capture window of Network Monitor and choose Start from the Capture menu. Network Monitor then begins to capture frames sent from the local machine or sent to the local machine from the network data stream and copies those frames to a temporary capture file. To halt the data capture temporarily, choose Pause from the Capture menu. To stop the capture and display the captured frames, you must choose Stop And View from the Capture menu. This displays the Frame Viewer window so that you can examine the contents of the captured frames. Network Monitor displays the session statistics for only the first 100 unique network sessions. To view information for the next 100 unique network sessions, you must choose Clear Statistics from the Capture menu.

## Designing a Capture Filter

A capture filter must be designed when Network Monitor is not running and no frames are being captured. You specify capture criteria to identify frames you want captured on the network. To design a capture filter, choose Filter from the Capture menu of the Capture window. You specify criteria to be used in the design of a capture filter expression through capture filter protocols, address pairs, and data pattern matches.

## Specifying Capture Filter Protocols

You use filter protocols when you want to capture frames sent using a specific protocol. To design filter protocols, choose Filter from the Capture menu in the Capture window. Double-click the default line SAP/ETYPE = Any SAP Or Any ETYPE in the decision tree. As you disable protocols, the information in this line changes to reflect those changes. For example, if you disable the AppleTalk Address Resolution Protocol (ARP), the line changes to SAP/ETYPE = Other SAPs Or Other ETYPES Or NOT AppleTalk ARP. You enable and disable protocols for use in the capture filter in the Capture Filter SAPs And ETYPES dialog box. The default is to enable all of the protocols.

## Specifying Address Pairs

You designate address pairs to capture only traffic sent to and from the specified computers or to exclude traffic between the specified computers. (One of the computers in an address pair must be the computer running Network Monitor.) You can specify up to three address pairs.

To designate address pairs, choose Filter from the Capture menu in the Capture window. Double-click the AND (Address Pairs) line in the decision tree, and specify address pair properties in the Address Expression dialog box. When an address pair is added, it is displayed under the AND (Address Pairs) line in the decision tree. You can edit or delete an address pair at any time by selecting the address pair name and then choosing Edit or Delete from the Capture Filter dialog box. You specify address pair properties in the following manner:

1. Choose whether to include or exclude capture data that travels between the members of the address pair you want to create.

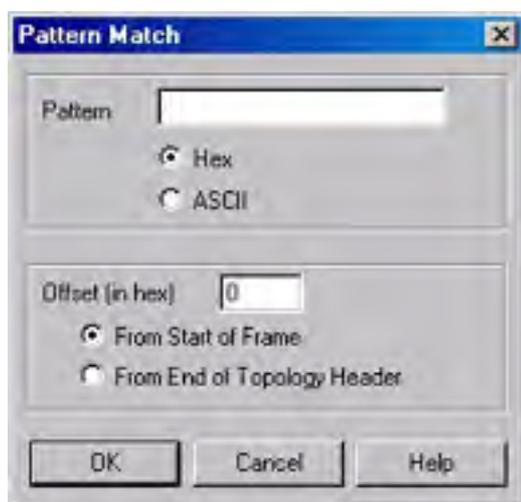

2. Choose the first address from the Station 1 list box and the second address from the Station 2 list box. Which address becomes the originating address and which becomes the destination address depends on the arrow you select in the Direction list box.
3. Choose one of the three arrows from the Direction list box to indicate the direction of the traffic between the two addresses:
  - <—> This arrow specifies capturing frames that travel in either direction between the Station 1 and Station 2 computers. This arrow is the default.
  - —> This arrow captures frames that travel from Station 1 to Station 2.
  - <— This arrow captures frames that travel from Station 2 to Station 1.
4. You can modify the existing address database by clicking Edit Addresses and then adding, editing, or deleting information.

Broadcast and Multicast are always destination addresses.

## Defining Pattern Matches

Pattern matches enable you to capture frames that consist of a specific pattern at a specified offset. You can define up to four pattern matches.

To specify data pattern matches, choose Filter from the Capture menu in the Capture window. Double-click the AND (Pattern Matches) line in the decision tree, and specify data pattern match properties in the Pattern Match dialog box (Figure 33-24). When you add a pattern match, it is displayed under the AND (Pattern Matches) line in the decision tree. You can edit or delete the pattern matches at any time by selecting the data pattern match name and then choosing Edit or Delete from the Capture Filter dialog box.

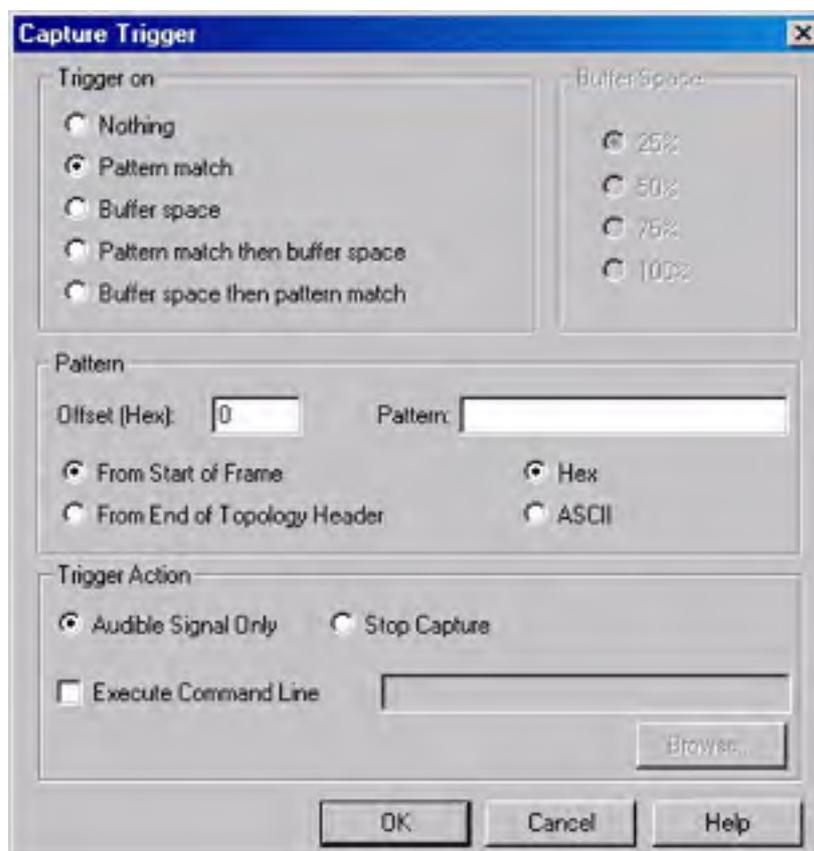

**Figure 33-24.** *The Pattern Match dialog box.*

To define pattern matches, enter the hexadecimal or ASCII data pattern that you want the captured frames to match. Then, in the Offset box, enter the hexadecimal number that specifies the byte where the pattern begins. Network Monitor interprets the number depending on whether you specify the From Start Of Frame option or the From End Of Topology Header option. The topology header is the section of the frame that is added by the network topology to identify the network type. Information such as the source and destination address of the frame is included in the topology header. For example, 14 bytes are added to the frame at the Ethernet layer for an Ethernet network. The number of topology header bytes varies in a token ring environment.

## Setting a Capture Trigger

A capture trigger is used to set conditions that, when met, initiate an action. For example, you can set a trigger to stop data capture and cause a program or command file to execute when certain criteria are met. To set a capture trigger, follow these steps:

1. Launch Network Monitor from the Administrative Tools folder and choose the area to monitor.
2. Choose Trigger from the Capture menu to open the Capture Trigger dialog box (Figure 33-25).

**Figure 33-25.** The Capture Trigger dialog box.

3. Choose from the options in the Trigger On area:
  - **Pattern Match** When a specified hexadecimal or ASCII pattern match occurs, the trigger is engaged.
  - **Buffer Space** When a capture fills a specified percentage of the capture buffer, the trigger is engaged.
  - **Pattern Match Then Buffer Space** Causes Network Monitor to monitor the buffer space after the specified data pattern match occurs and then to engage the trigger function when both of the specified conditions exist.
  - **Buffer Space Then Pattern Match** Causes Network Monitor to detect when a capture has filled the specified percentage of buffer space and then to perform the trigger action when the specified data pattern match is detected.

If you choose the Pattern Match Then Buffer Space option and set Buffer Space to 100 percent, the frame that has the data pattern match is overwritten by Network Monitor, because Network Monitor doesn't start counting the buffer space until after the pattern match has been found.

4. In the Trigger Action area, choose the action you want to have occur when the trigger criteria are met:
  - **Audible Signal Only** When the trigger condition is met, the computer beeps and continues to capture frames. This is the default option.
  - **Stop Capture** When the trigger condition is met, the capture process ends.
  - **Execute Command Line** Enabling this check box causes a command line to

execute or a file to open when the trigger condition is met. The command can be up to 259 characters.

5. Click OK when you're finished.

## Designing a Display Filter

A display filter acts on information that has already been captured and behaves in much the same way as a database query because it is used to specify the types of captured data you want to examine. You can indicate how much of the captured data you want displayed in the Frame Viewer window or what types of displayed data you want to save to a file, such as protocols and computer addresses.

The Display Filter dialog box helps you make changes to the display filter decision tree for the Frame Viewer window. The expression option is added to the display filter decision tree when you click OK. There are two default branches on the decision tree: the Protocol branch, which lists the protocols you want to display, and the Computer Address Pairs branch, which lists the computer address pairs you want to display. The sections that follow describe the various options available in the Display Filter dialog box.

## Adding an Expression

The Expression option is found in the Add group of the Display Filter dialog box and is used to write or edit an expression to specify the protocols, protocol properties, and computer address pairs you want to display. Only one expression at a time can be added in the Expression dialog box. If you click the Protocol tab or the Property tab before you have saved the specified expression to the decision tree by clicking OK, you lose the expression. You can specify options for three categories, each of which is represented by a tab:

- **Address tab** The Address tab, shown in Figure 33-26, is used to specify an address that you want to find or to add or edit an address expression within a display filter decision tree. You can also display this tab by double-clicking the default ANY line in the decision tree. Refer to the section entitled [Specifying Address Pairs](#) earlier in this chapter for information on how to design address pairs.

Broadcast, Functional, and Multicast should be specified only as destination addresses. You filter out all frames if Broadcast or Multicast is used in the construction of an expression because they are always destination addresses.

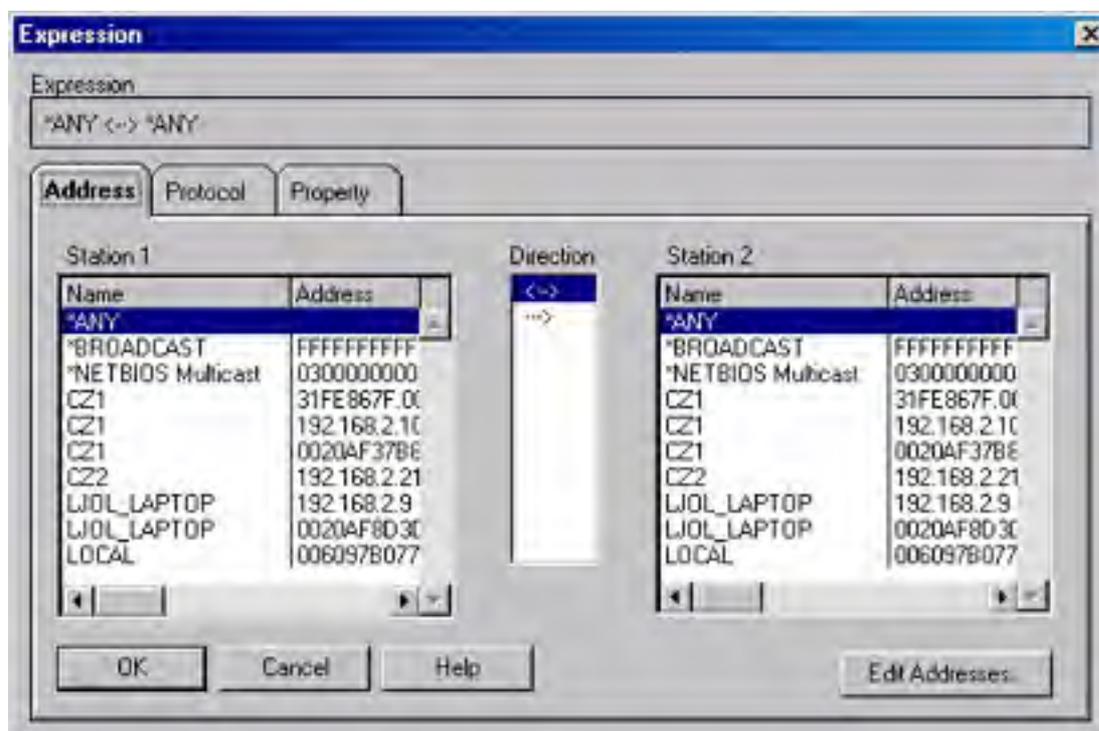

Figure 33-26. The Address tab of the Expression dialog box.

- **Protocol tab** This tab, shown in Figure 33-27, is used to specify protocols you want to display in Frame Viewer or to specify protocols in the display filter decision tree. The Enabled Protocols and Disabled Protocols list boxes display the protocol names. You choose the protocols you want displayed by clicking the Disable, Enable, Disable All, and Enable All buttons. You can also see this tab by double-clicking the default Protocol line in the decision tree. The default is to enable all protocols.

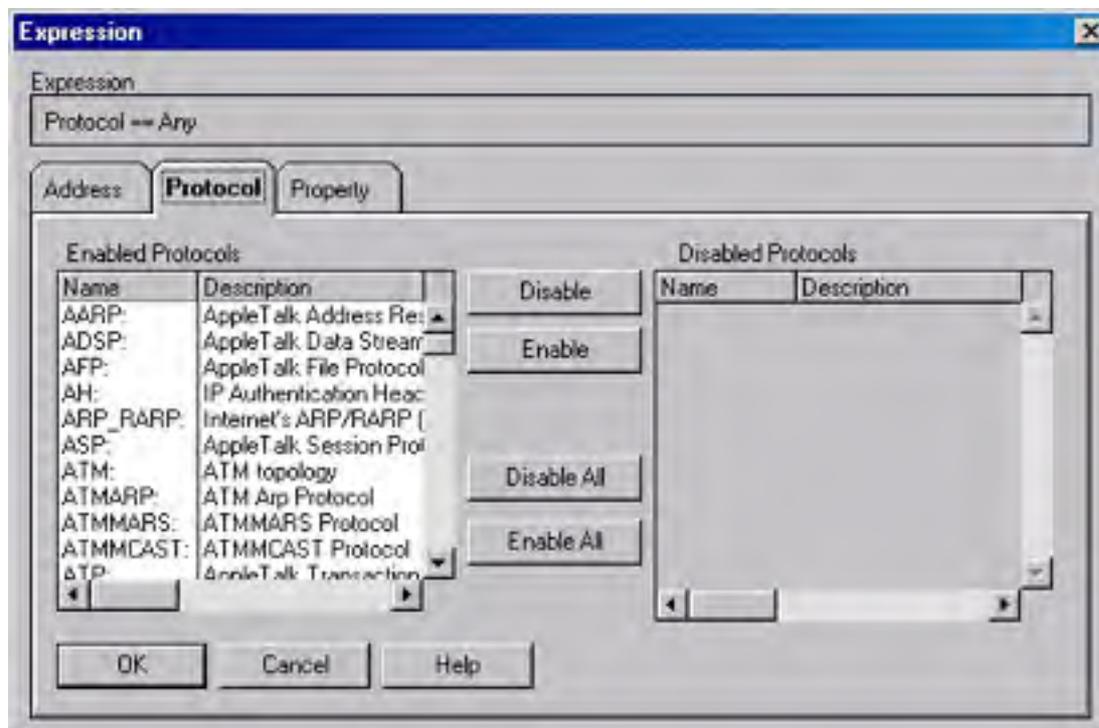

Figure 33-27. The Protocol tab of the Expression dialog box.

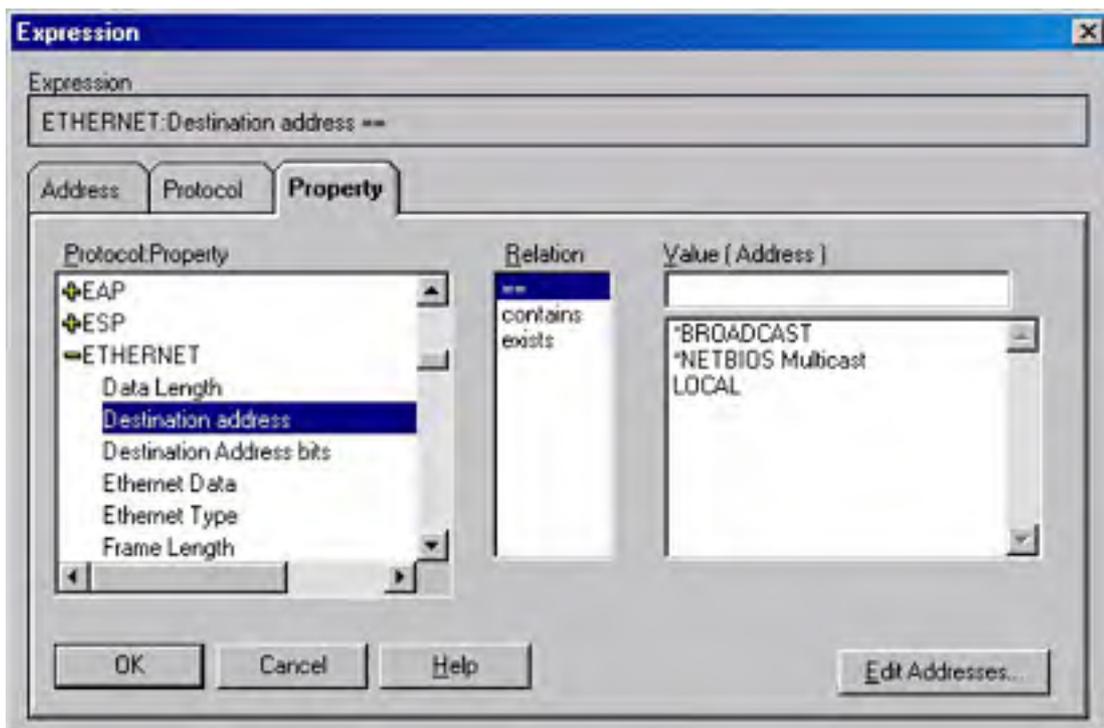

- **Property tab** This tab, shown in Figure 33-28, specifies the protocol properties you want to find or allows you to add or edit a protocol property expression within the display filter decision tree. Follow these steps to design protocol properties:
  1. Choose the desired properties from the Protocol:Property box. If a plus sign appears next to a protocol name, you can expand the protocol to choose a property from its list.
  2. Choose a relational operator from the Relation list box. A relational operator is used to specify the connection between the protocol property and its possible values.
  3. Type the value that you want to use as a comparison to the selected property into the Value (Address) box.

### Inserting Operators

The Insert group box defines logical operators for the decision tree. The operators available to you are And, Or, and Not. Using them, you can specify up to 4000 decision tree operators.

### Editing Expressions/Changing Operators

Edit Expression is used to edit an operator expression listed in the decision tree. It is not intended to edit address pairs, protocols, or protocol property expressions that are defined with the Add Expression option. The Edit Expression button changes to read Change Operator if you have an operator selected on the decision tree. This option allows you to toggle through the operator values.

**Figure 33-28.** The Property tab of the Expression dialog box.

The Hex Offset box appears for some properties. This box is used to specify the number of hex digits from the beginning of the frame to the point where you want to look for the specified property.

### Deleting Criteria

The Delete group box deletes decision criteria from the decision tree. The options available here are to delete a specific line, a specific branch, or the entire decision tree.

## **Summary**

Windows 2000 Server is equipped with tools for monitoring your network, finding problems, and fine-tuning performance. Although some of the processes might appear daunting, they can be approached gradually and adopted as needed. The next chapter discusses how to prepare and implement a plan for recovering from the inevitable failure of hardware.

# Chapter 34

## **Disaster Planning**

Smart bicycle riders wear helmets even though they ride carefully and certainly don't plan a headfirst landing. Schools and businesses have fire drills even though the vast majority of buildings never burn down. Similarly, system administrators sincerely hope never to need their verified backups and emergency repair disks. Nevertheless, we keep them because there are only two types of networks: those that have experienced disaster and those that haven't yet.

Disaster can take many forms, from the self-inflicted pain of a user or administrator doing something really, really unwise to the uncontrollable, unpreventable results of a natural disaster such as a flood or earthquake. In any case, your competence as a system administrator will be judged by how well you were prepared for the disaster and how well you and your team responded to it and recovered from it.

This chapter covers emergency preparedness. It discusses creating a disaster recovery plan, with standardized procedures to follow in the event of a catastrophe. It also describes how to prepare for a disaster, including how to make an emergency repair disk, how to make Microsoft Windows 2000 setup disks, how to make a boot disk, how to install the Recovery Console, how to specify recovery options in Windows 2000, and how to create an external recovery drive.

## Planning for Disaster

Some people seem to operate on the assumption that if they don't think about a disaster, one won't happen. This is similar to the idea that if you don't write a will, you'll never die—and just about as realistic. No system administrators should feel comfortable about their network's degree of preparedness without a clear disaster recovery plan that has been thoroughly tested. Even then, it's wise to always look for ways to improve the plan.

Planning for disaster or emergencies is not a single step, but an iterative, ongoing process. Systems are not mountains, but rivers, constantly moving and changing, and your disaster recovery plan needs to change as your environment changes. To put together a good disaster recovery plan, one you can bet your business on, you need to follow these steps:

1. Identify the risks.
2. Identify the resources.
3. Develop the responses.
4. Test the responses.
5. Iterate.

### Identify the Risks

The first step in creating a disaster recovery plan is to identify the risks to your business and the costs associated with those risks. The risks vary from the simple deletion of a critical file to the total destruction of your place of business and its computers. To properly prepare for a disaster, you need to perform a realistic assessment of the risks, the potential costs and consequences of each disaster scenario, and the likelihood of any given disaster scenario.

Identifying risks is not a job for only one person. As with all of the tasks associated with a disaster recovery plan, all concerned parties must participate. There are two important reasons for this: you want to make sure that you have commitment and buy-in from the parties concerned, and you also want to make sure you don't miss anything important.

No matter how carefully and thoroughly you try to identify the risks, you'll miss at least one. You should always account for that missing risk by including an "unknown risk" item in your list. Treat it just like any other risk: identify the resources available to address it and develop countermeasures to take should it occur. The difference with this risk, of course, is that your resources and countermeasures are somewhat more generic, and you can't really test your response to the risk, because you don't yet know what it is.

Start by trying to list all of the possible ways that your system could fail. If you have a team of people responsible for supporting the network, solicit everyone's help in the process. The more people involved in the brainstorming, the more ideas you'll get and the more prevention and recovery procedures you can develop and practice.

Next, look at all of the ways that some external event could affect your system. The team of people responsible for identifying possible external problems is probably similar to a team looking at internal failures, but with some important differences. In a large industrial plant, for example, when you start to look at external failures and disasters, you'll want to involve the security and facilities groups, because they will need to understand your needs as well as provide input on how well the plant is protected from these disasters.

An important part of this risk assessment phase is to understand and quantify just how likely a particular risk is. If you're located in a flood plain, for example, you're much more likely to think flood insurance is a good investment.

### Identify the Resources

Once you've identified the risks to your network, you need to identify what your resources are to address those risks. These resources can be internal or external, people or systems, hardware or software.

When you're identifying the resources available to deal with a specific risk, be as complete as you can, but also be specific. Identifying everyone in the IT group as a resource to solve a crashed server might look good, but realistically only one or two key people are likely to actually rebuild the server. Make sure you identify those key people for each risk, as well as what more general secondary resources they have to call on. So, for example, the primary resources available to recover a crashed Microsoft Exchange server might consist of one or two staff members who can recover the failed hardware and another one or two staff members who can restore the software and database. General secondary resources would include everyone in the IT group as well as the hardware vendor and Microsoft Premier Support.

An important step in identifying resources in your disaster recovery plan is to specify both the first-line responsibility *and* the back-end or supervisory responsibility. Make sure everyone knows who to go to when the problem is more than they can handle or when they need additional resources. Also, clearly define when they should do that. The best disaster recovery plans include clear, unambiguous escalation policies. This takes the burden off individuals to decide when and who to notify and makes it simply part of the procedure.

## Develop the Responses

An old but relevant adage comes to mind when discussing disaster recovery scenarios: when you're up to your elbows in alligators, it's difficult to remember that your original objective was to drain the swamp. This is another way of saying that people lose track of what's important when they are overloaded by too many problems that require immediate attention. To ensure that your swamp is drained and your network gets back online, you need to take those carefully researched risks and resources and develop a disaster recovery plan. There are two important parts of any good disaster recovery plan:

- Standard operating procedures (SOPs)
- Standard escalation procedures (SEPs)

Making sure these procedures are in place and clearly understood by all before a disaster strikes puts you in a far better position to recover gracefully and with a minimum of lost productivity and data.

## Standard Operating Procedures

Emergencies bring out both the best and worst in people. If you're prepared for the emergency, you can be one of those who come out smelling like a rose, but if you're not prepared and let yourself get flustered or lose track of what you're trying to accomplish, you can make the whole situation worse than it needs to be.

Although no one is ever as prepared for a system emergency as they'd like to be, careful planning and preparation can give you an edge in recovering expeditiously and with a minimal loss of data. It is much easier to deal with the situation calmly when you know you've prepared for this problem and you have a well-organized, tested standard operating procedure to follow.

Because the very nature of emergencies is that you can't predict exactly which one is going to strike, you need to plan and prepare for as many possibilities as you can. The time to decide how to recover from a disaster is *before* the disaster happens, not in the middle of it when users are screaming and bosses are standing around looking serious and concerned.

Your risk assessment phase involved identifying as many possible disaster scenarios as you could, and in your resource assessment phase you identified the resources that are available and responsible for each of those risks. Now you need to write up SOPs for recovering the system from each of the scenarios. Even the most level-headed system administrator can get flustered when the system has crashed, users are calling every 10 seconds to see what the problem is, the boss is asking every 5 minutes when you'll have it fixed, and your server won't boot.

Reduce your stress and prevent mistakes by planning for disasters before they occur. Practice recovering from each of your disaster scenarios. Write down each of the steps, and work through questionable or unclear areas until you can identify exactly what it takes to recover from the problem. This is like a fire drill, and you should do it for the same reasons—not because a fire is inevitable, but because fires do happen, and the statistics demonstrate irrefutably that those who have prepared for a fire and practiced what to do in a fire are far more likely to survive it.

Your job as a system administrator is to prepare for disasters and practice what to do in those disasters, not because you expect the disaster, but because if you do have one, you want to be the hero, not the goat. After all, it isn't often that the system administrator gets to be a hero, so be ready when your time comes.

The first step in developing any SOP is to outline the overall steps you want to accomplish. Keep it general at this point—you're looking for the big picture here. Again, you want everyone to be involved in the process. What you're really trying to do is make sure you don't forget any critical steps, and that's much easier when you get the overall plan down first. There will be plenty of opportunity later to cover the specific details.

Once you have a broad, high-level outline for a given procedure, the people you identified as the actual resources during the resource assessment phase should start to flesh in the outline. You don't need every detail at this point, but you should get down to at least a level below the original outline. This will help you identify missing resources that are important to a timely resolution of the problem. Again, don't get too bogged down in the details at this point. You're not actually writing the SOP, just trying to make sure that you've identified all of its pieces.

When you feel confident that the outline is ready, get the larger group back together again. Go over the procedure and smooth out the rough edges, refining the outline and *listening* to make sure you haven't missed anything critical. When everyone agrees that the outline is complete, you're ready to add the final details to it.

The people who are responsible for each procedure should now work through all of the details of the disaster recovery plan and document the steps thoroughly. They should keep in mind that the people who actually perform the recovery might not be who they expect. It's great to have an SOP for recovering from a failed router, but if the only person who understands the procedure is the network engineer, and she's on vacation in Bora Bora that week, your disaster recovery plan has a big hole in it.

When you create the documentation, write down everything. What seems obvious to you now, while you're devising the procedure, will not seem at all obvious in six months or a year when you suddenly have to use it under stress.

### **Real World**

#### **Multiple Copies, Multiple Locations**

It's tempting to centralize your SOPs into a single, easily accessible database. You should do that, making sure everyone understands how to use it. But you'll also want to have alternative locations and formats for your procedures. Not only do you not want to keep them in a single database, you also don't want to have only an electronic version. Always maintain hard copy versions as well. Every good server room should have a large binder, prominently visible and clearly identified, that contains all of the SOPs. Each responsible person should also have one or more copies of at least the procedures he or she is either a resource for or likely to become a resource for. We like to keep copies of all our procedures in several places so that we can get at them no matter what the source of the emergency or where we happen to be when one of our pagers goes off.

Once you have created the SOPs, your job has only begun. You need to keep them up to date and make sure that they don't become stale. It's no good having an SOP to recover your ISDN connection to a branch office when you ripped the ISDN line out a year ago and put in a DSL line with three times the bandwidth at half the cost.

You also need to make sure that all of your copies of an SOP are updated. Electronic ones should probably be stored in a replicated database. However, hard copy documents are notoriously tricky to maintain. One way to do so is to make yet another SOP that details who updates what SOPs and who gets fresh copies whenever a change is made. Then put a version control system into place and make sure everyone understands his or her role in the process.

### **Standard Escalation Procedures**

No matter how carefully you've identified potential risks, and how detailed your procedures to recover from them, you're still likely to have situations you didn't anticipate. An important part of any disaster recovery plan is a standardized escalation procedure. Not only should each individual SOP have its own procedure-specific SEP, but you should also have an overall escalation procedure that covers everything you haven't thought of—because it is certain that you haven't thought of everything.

An escalation procedure has two functions—resource escalation and notification escalation. Both have the same purpose: to make sure that everyone who needs to know about the problem is up to date and involved as appropriate, and to keep the overall noise level down so that the work of resolving the problem can go forward as quickly as possible.

The *resource escalation procedure* details the resources that are available to the people who are trying to recover from the current disaster, so that they don't have to try to guess who (or what) the appropriate resource might be when they run into something they can't handle or something doesn't go as it is supposed to. This helps them stay calm and focused. They know that if they run into a problem, they aren't on their own, and they know exactly who to call when they do need help.

The *notification escalation procedure* details who is to be notified of serious problems. Even more important, it should provide specifics regarding *when* notification is to be made. If your print server crashes but comes right back up, you might want to send only a general message to the users of that particular server letting them know what happened. However, if your mail server has been down for more than half an hour, a lot of folks are going to be concerned. The SEP for that mail server should detail who needs to be notified if the server is unavailable for longer than some specified time, and it should probably detail what happens and who gets notified when it's still down some significant amount of time after that.

This notification has two purposes: to make sure that the necessary resources are made available as required and to keep everyone informed and aware of the situation. If you let people know that you've had a server hardware failure and that the vendor has been called and will be on site within an hour, you'll cut down the number of phone calls exponentially, freeing you to do whatever you need to do to ensure that you're ready when the vendor arrives.

## Test the Responses

A disaster recovery plan is nice to have, but it really isn't worth a whole lot until it has actually been tested. Needless to say, the time to test the plan is at your convenience and under controlled conditions, rather than in the midst of an actual disaster. It's a nuisance to discover that your detailed disaster recovery plan has a fatal flaw in it when you're testing it under controlled conditions. It's a bit more than a nuisance to discover it when every second counts.

You won't be able to test all aspects of all disaster recovery plans. Few organizations have the resources to create fully realistic simulated natural disasters and test their response to each of them under controlled conditions. Nevertheless, there are things you can do to test your response plans. The details of how you test them depend on your environment, but they should include as realistic a test as feasible and should, as much as possible, cover all aspects of the response plan.

The other reason to test the disaster recovery plan is that it provides a valuable training ground. If you've identified primary and backup resources, as you should, chances are that the people you've identified as backup resources are not as skilled or knowledgeable in a particular area as the primary resource. Testing the procedures gives you a chance to train the backup resources at the same time.

You should also consider using the testing to cross-train people who are not necessarily in the primary response group. Not only will they get valuable training, but you'll also create a knowledgeable pool of people who might not be directly needed when the procedure has to be used for real, but who can act as key communicators with the rest of the community.

## Iterate

When you finish a particular disaster recovery plan, you may think your job is done, but in fact your work is just beginning. Standardizing a process is actually just the first step. You also need to improve it.

You should make a regular, scheduled practice of pulling out your disaster recovery plan with your group and making sure it's up to date. Use the occasion to actually look at it and see how you can improve on it. Take the opportunity to examine your environment. What's changed since you last looked at the plan? What servers have been retired, and what new ones have been added? What software is different? Are all of the people on your notification and escalation lists still working at the company, in the same roles? Are the phone numbers up to date?

Another way to iterate your disaster recovery plan is to use every disaster as a learning experience. Once the disaster or emergency is over, get everyone together as soon as possible to talk about what happened. Find out what they think worked and what didn't in the plan. Actively solicit suggestions for how the process could be improved. Then make the changes and test them. You'll not only improve your responsiveness to this particular type of disaster, but you'll improve your overall responsiveness by getting people involved in the process and enabling them to be part of the solution.

## Preparing for a Disaster

As Ben Franklin was known to say, "Failure to prepare is preparing to fail." This is truer than ever with modern operating systems, and although Windows 2000 includes a number of exceptionally useful recovery modes and tools, you still need to prepare for potential problems. Some of these techniques are covered in detail in other chapters and are discussed here only briefly, whereas others are covered here at length.

## Setting Up a Fault-Tolerant System

A fault-tolerant system is one that is prepared to continue operating in the event of key component failures. This technique is very useful for servers running critical applications. Here are a few of the many ways to ensure fault tolerance in a system:

- Use one or more RAID arrays for system and data storage, protecting you from hard disk failure. If a hard disk in the array fails, only that disk needs to be replaced—and no data is lost. See [Chapter 15](#) for information on using Windows 2000 to implement software RAID.
- Use multiple SCSI adapters to provide redundancy if a SCSI controller fails.
- Use an uninterruptible power supply (UPS) to allow the server to shut down gracefully in the event of a power failure.
- Use multiple network cards to provide redundancy in case a network card fails.
- Use multiples of everything that is likely to fail, including power supplies and so on.

## Backing Up the System

Back up the system and system state regularly using a good Windows 2000 backup program. If a hard disk fails and must be replaced and you're not using some sort of RAID array, the data and system can be restored from backup. (If you lose the system entirely, you'll need to install Windows 2000 on it before restoring the original system.) See [Chapter 35](#) for details on using the Windows 2000 backup program.

## Creating Emergency Repair Disks

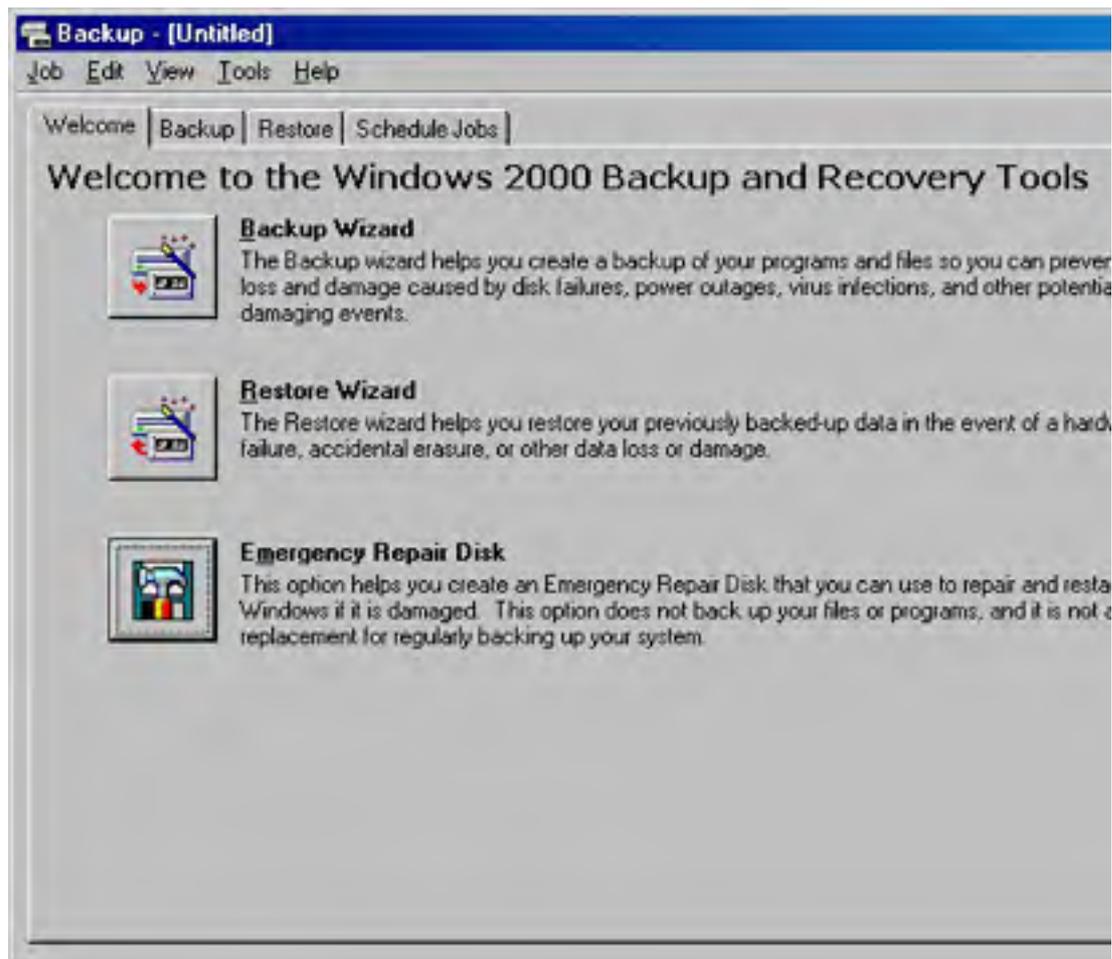

Windows 2000, like Microsoft Windows NT, can create an emergency repair disk (ERD) to help rescue the system in the event of a disaster. The ERD contains important information that can be used to fix system files, the boot sector, and the startup environment. The ERD is easy to make, and it is *very* useful in the event of a disaster.

In Windows 2000, you might have noticed that you didn't get prompted to create an emergency repair disk during installation, as you do during Windows NT setup. In fact, the entire procedure has changed. Now, to create an emergency repair disk, you run Windows 2000's Backup program.

To make a fresh emergency repair disk, you need a floppy that you don't mind being formatted. Always use a freshly formatted floppy to create an ERD. It's also a good idea to have a backup of your ERD, so always keep at least one generation back. We also like to keep an original ERD created immediately after the installation process as a kind of ultimate fallback position. To make an ERD, follow these steps:

1. Open the Windows 2000 Backup program from the Start menu by pointing to Programs, Accessories, and System Tools and then choosing Backup.

2. Click Emergency Repair Disk, as shown in Figure 34-1.

**Figure 34-1.** *The Windows 2000 Backup window.*

3. Select the check box in the Emergency Repair Diskette dialog box if you want to back up the system registry to the repair folder on the hard disk, for use if the registry becomes corrupt.
4. Insert a blank floppy disk in drive A, and click OK.

The emergency repair disk is not bootable; it must be used in conjunction with the Windows 2000 setup disks.

### **Real World**

#### **Using the Emergency Repair Disk Effectively**

What, exactly, is on the emergency repair disk? Well, certainly not all the stuff that used to be there in Windows NT. Instead of trying to fit all of the files necessary to recover your system onto a single floppy, a task that had become more than a little problematic, Windows 2000 now copies only the MS-DOS subsystem initialization files, Autoexec.nt and Config.nt, as well as a single file, Setup.log, which points to the location of the repair files on your server.

Unfortunately, with this change, it's a little more difficult to maintain multiple generations of repair information. Get in the habit of saving a copy of the %Windir%\Repair directory to a secondary or even tertiary location before updating the emergency repair disk. This gives you a fallback should you inadvertently update the information before you're sure it's stable. If you need to go back to earlier information, just copy it back into the %Windir%\Repair directory (probably by using the Recovery Console, discussed later in this chapter and in [Chapter 38](#)).

Whenever you make a major change to your system, it's a good idea to make a fresh copy of the ERD *before* you make the change. This gives you a fallback position if something goes wrong. If something doesn't work right, you can quickly restore the previous configuration. Once you've confirmed that the new configuration is stable and working, then and only then should you update your ERD for that server. Before you make a new emergency repair disk, copy the entire `%Windir%\Repair` directory tree to your failsafe location. At worst, you can recover from that failsafe location.

What constitutes a major change? Adding, removing, or otherwise modifying the hard disks or their partitions, formats, configurations, and so on, for one. Any time you make a change to the hard disk configuration, you'll definitely want to make a fresh ERD just before you make the change. Another major change would be the addition of a new component to the server, such as adding Microsoft Exchange Server or Microsoft SQL Server. Any changes made from Control Panel are candidates for redoing the ERD as well.

## Creating Windows 2000 Setup Disks

Windows 2000 includes a set of four disks that can be used to boot the computer if you cannot boot from the hard disk. If the system supports booting from a CD-ROM using the El Torito standard, you can boot from the Windows 2000 CD-ROM. Otherwise, you need these disks to boot the system in the case of an emergency.

If you have lost the original disks or need to create another set, you can do so. You need four 1.44-MB floppy disks. It would be really handy to use a single Zip disk instead, but booting from a Zip disk is not supported. (OK, if your Zip drive is drive A you *can* use your Zip drive, but you'll still need four disks—they'll just be mostly empty.) Follow these steps to create new setup disks:

1. Insert the Windows 2000 CD-ROM for which you want to create setup disks. Note that setup disks are specific to each version of Windows 2000—that is, Windows 2000 Professional and Windows 2000 Server use different setup disks.
2. Insert a blank, 1.44-MB floppy disk in drive A of the computer.
3. At a command prompt or in the Run dialog box, type the command `d:\bootdisk\makeboot a;`, replacing `d` with the CD-ROM drive letter.

## Creating a Boot Disk

We know; you're thinking that you just did this, but there is yet another floppy disk you can create for safety and recovery convenience. It's a plain old boot disk. Although a Windows 2000 boot disk doesn't get you to a command prompt, as a Windows 95 or Windows 98 boot disk does, it does permit you to boot the system under the following circumstances (provided that your actual Windows 2000 installation isn't damaged in any other way):

- Corrupted boot sector
- Corrupted master boot record (MBR)
- Virus infections of the MBR
- Missing or corrupt Ntldr or Ntdetect.com files
- Incorrect Ntbootdd.sys driver

The boot disk can also be used to boot from the shadow drive of a broken mirror set, although you might need to edit the Boot.ini file on the boot disk.

### Real World

#### Why MS-DOS Boot Disks Won't Help

More than one person new to Windows 2000 has accidentally deleted or corrupted a key file required to boot the system and tried to recover by digging out an old MS-DOS boot floppy. Alas, it doesn't work.

The files you need to get your hard drive back to booting condition aren't even on an MS-DOS floppy. When you install Windows 2000, it modifies the system's boot sector to look for and run a file called Ntldr. When you format a floppy under MS-DOS, even when you make it a system disk, this file doesn't get created, because MS-DOS doesn't know anything about Windows 2000.

As such, a boot disk is occasionally useful, and because it's easy to make and floppy disks grow on trees (although these trees are rarely seen outside of the Microsoft campus), you might as well make one. The boot disk is *not* generic for every Windows 2000 machine. However, if you have a standard configuration across several machines, this disk will work for all of the machines that use the same partition and disk controller as their Windows 2000 boot partition. Follow these steps to create a boot disk:

1. Insert the first Windows 2000 setup disk into the floppy drive.

If you're currently using a Windows 2000 computer, you can simply format a disk using Windows 2000's Format utility and then proceed to step 6.

2. At a command prompt, type the command `diskcopy a: a:`.
3. Follow the directions on the screen to make a copy of the first setup disk.
4. Delete all files on the new disk by entering `del *.*` at the `a:` command prompt.
5. Copy the Ntdetect.com and Ntldr files from the \i386 folder on the Windows 2000 CD-ROM to the floppy disk.
6. Rename Ntldr to Setupldr.bin.
7. Create a Boot.ini file, or copy the file from the boot drive to the floppy disk.
8. If you're using a SCSI system, copy the device driver for the SCSI controller to the floppy disk, and rename it Ntbootdd.sys.

To find out what drive file you're using for the SCSI adapter, launch the Computer Management snap-in from the Administrative Tools folder on the Programs menu. Then click Device Manager in the console tree, select the SCSI adapter, and click the Properties toolbar button. Click the Driver tab, and then click Driver Details. The driver file is listed in the Driver File Details dialog box.

## Real World

### ARC Naming Conventions

Understanding how the hard disks and partitions are named on your system is not a trivial task, unfortunately. To provide a uniform naming convention across multiple platforms, Microsoft uses a fairly arcane designation for all of the disks and partitions on your computer. Called ARC—short for Advanced RISC Computing—this is a generic naming convention that can be used in the same way for both Intel-based and RISC-based computers.

The convention describes the adapter type and number, the disk number, the rdisk number, and finally the partition number. The format is as follows:

`<adaptertype>(x)disk(y)rdisk(z)partition(n)`

where `<adaptertype>` can be either `scsi`, `multi`, or `signature`. Use `multi` for all non-SCSI adapters and for SCSI adapters that use a BIOS—as most adapters used with Intel-based processors do. The `(x)` is the adapter number, starting at zero. If `<adaptertype>` is `signature`, `(x)` is an 8-character drive signature.

The value for `(y)` is the SCSI ID of the disk for SCSI adapters. For `multi` this is always zero. The number for `(z)` is zero for `scsi`, and it the ordinal number of the disk for `multi`, starting with zero. Finally, the partition number `(n)` is the number of the partition on the target

disk. Here the partitions start at one, with zero reserved for unused space.

## Installing the Recovery Console

One of the most useful new recovery features in Windows 2000 is the Recovery Console. This is basically an enhanced, NTFS-enabled, secure command prompt that can be used to copy files, start and stop services, and perform other recovery actions if you can't boot the system using Windows 2000's new safe mode. The Recovery Console is always available for use through the four Windows 2000 setup disks or the CD-ROM; however, you can also install it as an option on the Boot menu for use in those instances when you can't boot using Windows 2000 safe mode. You'll still need to use the boot disk if you can't get to the Boot menu or if the Recovery Console is damaged. To install the Recovery Console, follow these steps:

1. While in Windows 2000, Windows NT, Windows 95, or Windows 98, insert the Windows 2000 CD-ROM.
2. Close the Autorun dialog box.
3. At a command prompt or in the Run dialog box, type the command `d:\i386\winnt32 /cmdcons`, replacing `d` with the drive letter of the Windows 2000 CD-ROM or network share.
4. Click Yes to install the Recovery Console, as shown in Figure 34-2.

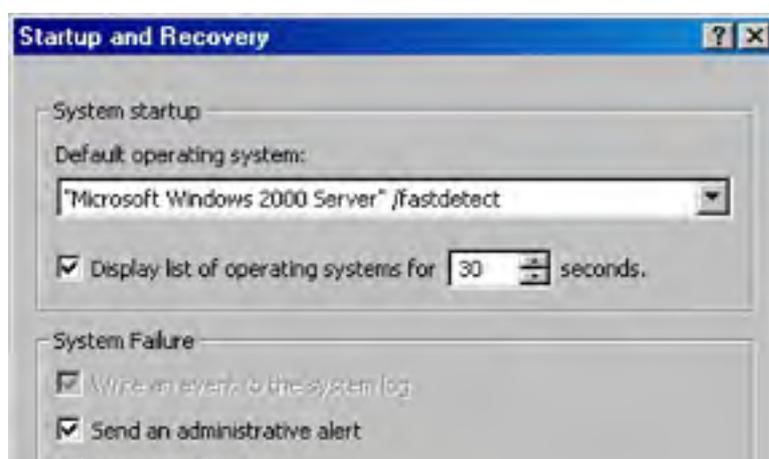

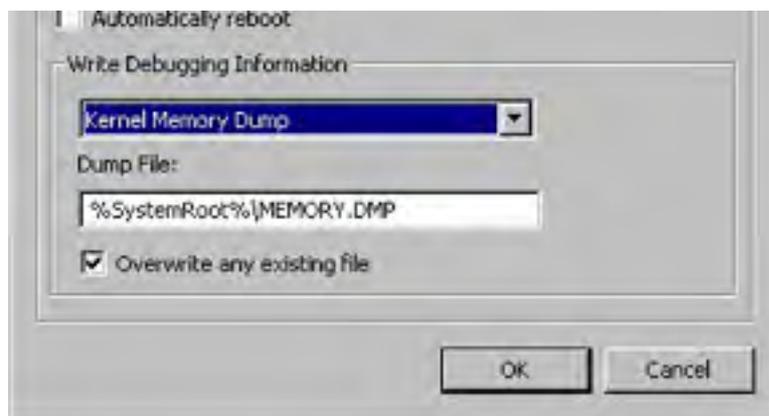

Figure 34-2. The Windows 2000 Setup window.

## Specifying Recovery Options

You can specify how you want Windows 2000 to deal with system crashes by changing a few options in the System tool in Control Panel. To do so, follow these steps:

1. Open the System tool from Control Panel, and click the Advanced tab.
2. Click Startup And Recovery to display the Startup And Recovery dialog box, shown in Figure 34-3.

**Figure 34-3.** *The Startup And Recovery dialog box.*

3. Select the operating system you want to have boot by default from the Default Operating System list box.
4. If you want to boot the default operating system automatically, without waiting, clear the Display List Of Operating Systems check box. Otherwise, specify how long you want to display a list of options in the box provided.
5. Select the Write An Event To The System Log check box, if available, to record an entry in the event log when the system experiences a crash.
6. Select the Send An Administrative Alert check box to send an alert to administrators over the network when the system crashes.
7. Select the Automatically Reboot option to instruct Windows 2000 to reboot the system in the event of a crash. Otherwise the system remains at a blue screen until an administrator manually reboots it.
8. Select how much debugging information you want to record from the Write Debugging Information list box. Note that if you have a large amount of RAM you need a lot of disk space if you want to use the Kernel Memory Dump option.
9. Enter the filename for the dump file in the Dump File text box, and select the Overwrite Any Existing File check box to maintain only a single dump file.

## Creating and Using a Recovery Drive

An excellent way to recycle an old, small drive that's not good for much else is to use it as an external recovery drive. This drive needs to be only about 700 MB at minimum. The recovery drive can even be used for several servers if you set it up as a portable device. Using a recovery drive in this way offers a somewhat cheaper alternative to mirroring the drive.

To create the recovery drive, perform a minimal install of Windows 2000 Server on the drive, configuring your swap file to be on that drive. Make sure that the installation includes the tape driver you will be using for tape backup. Create a bootable Windows 2000 floppy disk, following the procedure outlined earlier in the section entitled [Creating a Boot Disk](#), and edit the Boot.ini file on it to point to the SCSI address of the recovery drive.

When a system failure occurs, simply cable the recovery drive to the server and boot from the boot disk that points to the recovery drive. If the recovery drive has sufficient user accounts and software to keep your system running, you can run off the recovery drive until you can schedule a full-scale repair or replacement of the failed drive. When you are able to take the system down and replace the failed drive, all you need to do is restore your backup tape to it and restart the server. You can even do the restore in the background while you continue to run off the recovery drive if necessary.

## **Summary**

Assume that disaster will eventually occur, and plan accordingly. Create standardized recovery procedures and keep them up to date. When there's a lot of turmoil, as always happens in the case of a major failure, people forget important steps and can make poor decisions. Standardized procedures provide a course of action without the need for on-the-spot decisions. The next chapter describes how to use the Windows 2000 Backup utility.

# Chapter 35

## **Using Backup**

Backing up the data on your network is essential, and Microsoft Windows 2000 adds a new wrinkle to an already complicated problem with the need to back up the Active Directory service. Fortunately, the operating system includes the Windows 2000 Backup utility licensed from Veritas Software that, although it doesn't include all of the bells and whistles of the third-party network backup products, at least gets the job done in a reasonably efficient manner. You can use Windows 2000 Backup to protect the Windows 2000 system on which it runs and to back up other systems accessible by way of the network. This chapter examines the capabilities and limitations of Windows 2000 Backup and describes some basic strategies you can use to protect your network against data loss related to hardware failure, virus attack, or accidental file deletion.

## Selecting a Backup Medium

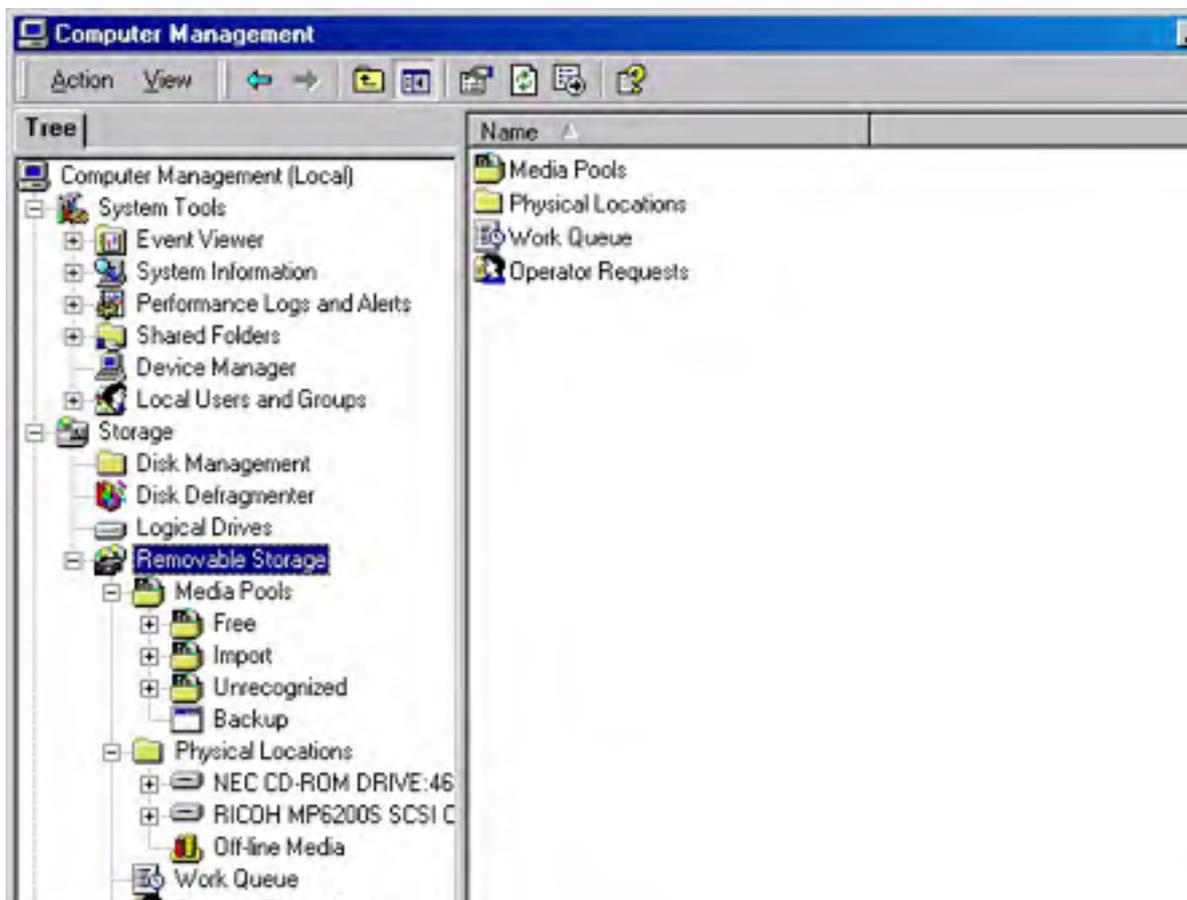

The first decision you must make when planning a backup strategy is where you intend to store your data. Windows 2000 Backup supports magnetic tape, the traditional backup medium, but it can also archive your data to a backup file that you can store on any device addressable by the Windows 2000 file systems, including cartridge drives (such as Iomega Zip and Jaz drives), floppy disks, and even recordable CD-ROMs. For more extensive archiving, Windows 2000 Backup also supports the use of *media pools*—that is, libraries of disks or tapes that you access through a jukebox or autochanger. The medium you choose should depend on your budget, the amount of data you have to back up, and how much time you have available for creating the backup.

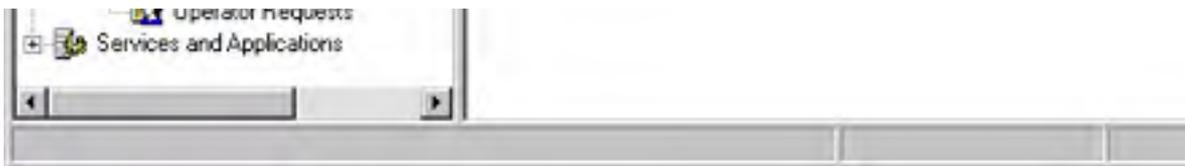

Estimating the cost of a backup storage medium isn't simply a matter of pricing tape drives and disk drives. The cost of the recording medium is also an important consideration. For example, a magneto optical drive like the Jaz that holds 2 GB might seem like a bargain, but the cartridge it uses can cost as much as \$100, or 5 cents per megabyte. In contrast, you can find recordable CD-ROMs (CD-Rs) for less than 25 cents a CD, at a cost per megabyte of about 3 hundredths of a cent. Tape media prices per megabyte tend to fall somewhere between these two extremes. Remember, too, that a CD-R or cartridge drive solution is useful for other storage besides backups, whereas a tape drive can be used for nothing else.

## Using Removable Storage

When you install a tape, CD-ROM, cartridge drive, or autochanger in Windows 2000 using the Add New Hardware Wizard, the drive falls under the control of the Removable Storage service. The Windows 2000 Backup utility relies on this service to provide basic media-handling functions. When you mount, dismount, or eject a disk or tape, the Removable Storage service, not Windows 2000 Backup, manages the device.

The Removable Storage service has its own user interface, separate from Windows 2000 Backup, in the Computer Management snap-in for the Microsoft Management Console (MMC), as shown in Figure 35-1. You use this tool when you need to send commands directly to a tape drive or other device, such as when you want to eject, format, or retension a tape.

**Figure 35-1.** *The Removable Storage service on the Computer Management snap-in.*

## Backing Up to Files

As an alternative to backing up using a device registered in the Removable Storage service, you can also back up system data to a file. Windows 2000 Backup can create the file on any writable storage device addressable by using a standard drive letter, such as a hard disk, cartridge, or floppy disk drive. By default, the backup file has a .BKF extension, but you can name the file anything you want and store it on any supported device.

## Using CD-ROMs

Because of their extremely low media cost, recordable CD-ROMs can be an excellent storage medium for system backups. Two types of writable CD-ROMs are commonly used: *CD-Rs*, which are WORM (write once, read many) devices, and *CD-RWs*, which you can write to many times. Using CD-Rs for backups might seem wasteful because you can fill them only once, but blank disks are cheap enough to make this feasible. As an added benefit, you get a permanent archive of your system, eliminating the need to develop a media rotation system and keep track of how many times you have used a particular tape or cartridge.

Windows 2000 Backup doesn't provide direct support for WORM devices like recordable CD-ROMs. You must use third-party backup software to use CD-R devices. CD-RW devices can be used like a standard removable disk drive if you have the appropriate packet-writing software installed (such as Roxio's DirectCD).

## Developing a Backup Strategy

To effectively back up a network, you must plan your approach to this complex task. Network backups are more complicated than simply putting a tape in the drive and starting up the software. Your backup strategy should address all of the following questions:

- How much data do you have to back up?
- How much time do you have to perform backups?
- How often should you back up the data?
- Who is going to be responsible for seeing that backups are completed?
- How many tapes (or other media) do you plan to use?
- How often will you overwrite your tapes?

For maximum security, assign the Backup and Restore permissions to different users.

## The Backup Window

The concept of the backup window should determine which devices you purchase for backing up your network and which types of backups you'll perform. The *backup window* is the amount of time you have available to perform backups of your data. You should compare the length of your backup window with the amount of data you have to back up to determine the optimum backup rate for your network. If, for example, your organization works overlapping shifts, leaving only a few hours of network time during which to perform backups, you might have to purchase faster equipment or run several devices in parallel to back up all of your data in the time allotted.

## Backup Types

Part of creating a strategy to fit your available backup window involves selecting the type of backups you'll perform. Windows 2000 Backup supports five types of backup jobs that specify how much of your data is backed up during each job. By selecting the appropriate job type, you can minimize the number of tapes (or other media) and the amount of time required to perform your backups without compromising the safety of your data.

Most of these backup types depend on the archive attribute to determine when the files on a given disk have changed and must be backed up again. The archive attribute in Windows 2000 is the same as that in MS-DOS, no matter which file system you're using. The attribute is a single bit included in the directory entry for each file, which the backup software can set or clear as needed.

Typically, a backup program clears the archive attributes for all of the files it backs up during a particular job. When you modify a file later, the system automatically sets the attribute as it writes to the disk. This enables the backup software to examine the archive attributes during the next job and back up only the files for which the attribute is set—that is, the files that have changed since the last backup. The backup types described in the following sections are variations on this technique.

### Normal Backup

A *normal backup*, in Windows 2000 parlance, is a full backup of all of the files and directories you select in the Windows 2000 Backup software. As part of the job, the program clears the archive attribute on each file. This type of job is the baseline for future jobs that back up only the modified files.

### Incremental Backup

During an *incremental backup*, the program examines the archive attributes and backs up only the files that have changed since the last normal or incremental backup. As with a normal backup, this type of job also clears the archive attribute on each file it copies. Incremental backups use the minimum amount of tape and also save time by not copying all of the files that remain unchanged during every job. However, performing a restore is inconvenient.

For example, if you perform a normal backup on Monday and incremental backups on Tuesday through Friday, you must restore from all five of these tapes in the order in which they were written to ensure that you have the most current version of every file. If a particular file is updated daily, Windows 2000 Backup overwrites it with a newer version during the restoration of each tape. However, if you restore only the Monday and Friday tapes, because they represent the last normal backup and the most recent incremental backup, you lose the most current versions of files that were modified on Tuesday through Thursday, but not on Friday.

## Differential Backup

A *differential backup* is identical to an incremental backup except that the program doesn't clear the archive attributes for the files that it copies to tape. This means that during each differential backup you are copying every file that has changed since the last normal or incremental backup. Thus, after a normal backup on Monday, a differential backup on Tuesday copies all of the files that have changed (just like an incremental job). However, the differential backups performed on Wednesday through Friday copy all of the files changed since Monday's normal backup. In other words, some redundancy of data is likely during this kind of job because a file modified only once on Tuesday is copied during each day's differential backups.

This type of job requires more tape than using incremental jobs, and more time as well, but the advantage is that when you perform a restore, you need only the tapes containing the last normal backup and the most recent differential. Thus, if you have to rebuild a system on Saturday, you need restore only the normal backup from the previous Monday and the most recent differential backup from Friday.

A network backup strategy typically uses incremental or differential backups in addition to normal jobs, but not both. If you're faced with a lot of data to back up and a limited backup window, incremental backups are faster and more economical. However, if you have to perform frequent restores, differential backups make the process far easier.

## Daily Backup

A *daily backup* copies only the files that have changed on the day that the backup job is performed, disregarding the current state of the archive attribute. This type of job also doesn't clear the archive attributes of the files it copies as it runs. Daily jobs are useful when you want to perform an extra backup on a given day without disturbing an established backup strategy by modifying the archive attributes.

## Copy Backup

A *copy backup* job is the equivalent of a normal backup, except that the program doesn't clear the archive attributes of the files it writes to the tape or other backup medium. You can use a copy backup job to perform an extra full backup without disturbing the archive attributes used by an established backup strategy.

## Media Rotation

A *media rotation scheme* dictates how many tapes (or other media) you use for your backups. In most cases, you'll want to keep copies of your backups for a while in case you need to perform a restore from them, but eventually, they become obsolete and you can reuse the tapes. For example, a small network might use a total of five tapes to perform a full backup each weekday and reuse the same tapes each week. In contrast, a large, security-conscious organization might use new tapes for every backup and permanently archive all of the used ones. Most media rotation schemes fall somewhere between these two extremes.

One popular rotation scheme is known as the grandfather-father-son method because it uses three "generations" of tapes representing monthly, weekly, and daily backups, respectively. In this rotation scheme, you perform a full backup every month and retain the tape for a year (preferably off-site); this is the "grandfather." You also perform a full backup every week and retain the tape for a month; this is the "father." The "son" backups are performed daily and retained for a week. The daily jobs can be either full, incremental, or differential backups.

The point of a media rotation scheme is to ensure that you always have a current copy of your data on tape and to reuse the tapes in an even and organized manner. Be sure to label your tapes carefully and store them in a safe place, away from magnetic fields and other adverse environments. We also strongly recommend that you store a copy of your backups off-site, such as in a safety deposit box or other fireproof vault, so that in the event of a true disaster such as a fire, your data is protected.

Some of the third-party network backup products can automatically implement a customizable rotation scheme by tracking the tapes, the number of times they're used, and the names that you should put on the labels. These programs also tell you which tape to put in the drive each day and let you know which tapes you must use to restore particular files. Unfortunately, Windows 2000 Backup lacks this feature.

## Backing Up Data

The Windows 2000 Backup program provides several methods that you can use to create and execute backup jobs. When you launch Windows 2000 Backup for the first time—by clicking Start, pointing to Programs, choosing Accessories, choosing System Tools, and then choosing Backup—you see the Welcome tab shown in Figure 35-2, from which you can choose a wizard to help you create a backup or restore job. To bypass the hand-holding provided by the wizard, you can also create a backup job by clicking the Backup tab in this dialog box and accessing the backup interface directly.

**Figure 35-2.** *The Welcome tab of Windows 2000 Backup.*

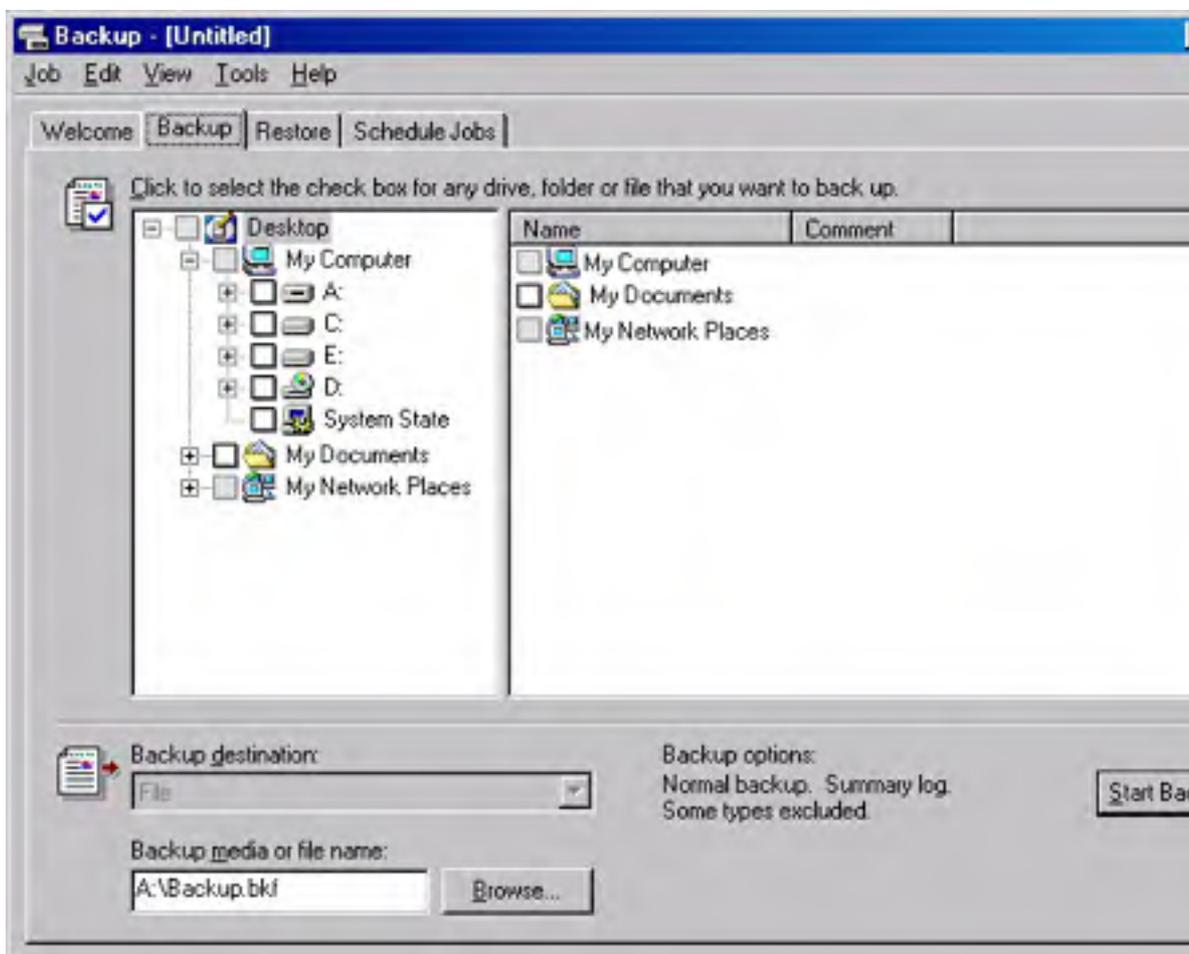

In addition to wizards and the GUI, you can execute Windows 2000 Backup jobs from the command line by running the executable program Ntbackup.exe with the appropriate parameters. See the section entitled [Executing Jobs from the Command Line](#) later in this chapter for more information.

The following sections examine the various methods for creating a backup job. Regardless of the particular method you use, creating any backup job involves the following basic steps:

- Select the drives, directories, and files you want to back up.
- Specify the storage medium that will be the destination for the backup.
- Configure backup options like backup type, logging, and file exclusions.
- Specify when the backup is to occur.

### Using the Windows 2000 Backup Tab

The Backup tab of the Windows 2000 Backup program (Figure 35-3) is where you select the files and directories to be backed up and choose their destination. You use a Microsoft Windows Explorer-like hierarchical display to browse local and network drives and make selections with the check boxes. You can select entire drives or individual files and directories for backup. The System State item backs up the registry and the Active Directory database on the local machine, as well as other system elements required in a disaster recovery situation. See the section entitled [Backing Up the System State](#), later in this chapter, for more information on the system state and disaster recovery.

**Figure 35-3.** The Backup tab of Windows 2000 Backup.

### Creating Selection Scripts

Once you've selected the files and directories to back up, you can create a selection script that contains the job configuration you created. After choosing Save Selections from the Job menu, you specify a filename with a .BKS extension for the selection script and the directory where the program should create it. You can use selection scripts to create an identical backup job during a subsequent session by loading the selection script from the Job menu. When you do this, the same system elements you selected before creating the script are selected again. You can then run the job as is or make additional selections. You can also use the script to execute the job from the Ntbackup.exe command line.

### Accessing Files and Folders for Backup

To back up any files and folders, the account used to run the job must have the appropriate permissions granting access to those files and folders. A user who is a member of the local Backup Operators group or Administrators group is automatically granted permission to back up any and all files and folders on the local machine. Members of the domain Backup Operators group and Administrators group can back up all files and folders on any computer in the domain, as well as any computer in a domain with which a two-way trust relationship exists.

A user who isn't a member of any of these groups must either be the owner or have the Read, Read and Execute, Modify, or Full Control permission for each of the files and folders to be backed up. Disk quota restrictions can also limit a user's ability to back up systems.

## Selecting the Storage Medium

After you specify what you want to back up, you must tell the program where to write the data. By default, Windows 2000 Backup provides the File option only in the Backup Destination field. If you've installed a tape drive or other device so that it is managed by the Removable Storage service, that device is also provided as a destination option. After you make a selection, you use the Backup Media field or the File Name field to specify a tape or disk name or the path and filename the program should use to create a backup file.

When you select a tape or other removable storage drive, the Backup Media field enables you to select it by the name that you've already created with Windows 2000 Backup or to select New Media, which enables you to specify a name for a new blank device.

## Configuring Backup Options

At this point, you can click Start Backup to trigger the backup job using the parameters specified in the Backup tab of the Backup window, or you can further configure the job by choosing Options from the Tools menu. In the General tab of the Options dialog box, you can specify whether the program should use certain media-handling features and, most importantly, select whether the program should verify the data on the tape after completing the backup job. A verification pass compares the data that has been written to the tape or other medium with the original copy on the hard disks to ensure that the data has been written properly. Although the verification process considerably lengthens the time required to run the job, it's a good precaution to take, especially when you're working with a newly installed drive.

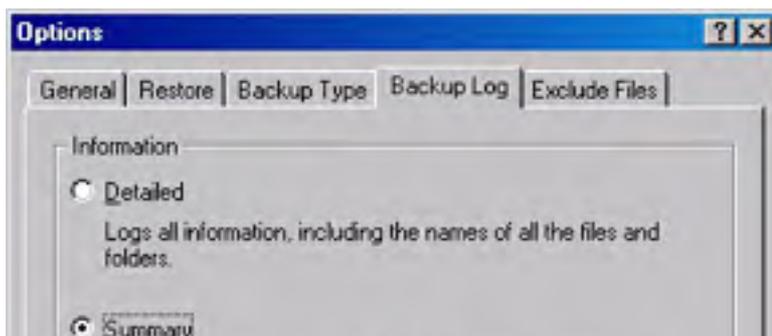

Although verifying the backup data written to any tape is a wise precaution to take, it isn't foolproof. Many times a backup job has seemed to complete successfully and has even been verified, but the data can't be restored for one reason or another. The *only* absolutely reliable method for ensuring that the data you've backed up has actually been written to the tape is to perform test restores.

In the Backup Type tab of the Options dialog box, you select the type of job that you want to run (either normal, incremental, differential, copy, or daily, as described in the section entitled [Backup Types](#), earlier in this chapter). The default is to run a normal backup, which might be undesirable if you're in the midst of a backup sequence that relies on the archive attributes to determine which files the program should copy to the tape.

You'll be prompted to specify values for the Backup options when you run a backup job using either the Start Backup button or the Windows 2000 Backup Wizard. The settings that you specify for these options now are the default values in the prompts generated later.

## Logging Backups

In the Backup Log tab of the Options dialog box (Figure 35-4), you can specify whether the program should keep a log of the activities that occur during the job and the level of detail in the log. Because a detailed log lists every file and directory copied during the job, the file can be quite long. If you want to review the job only to see that all of the procedures completed successfully, you can select the Summary option.

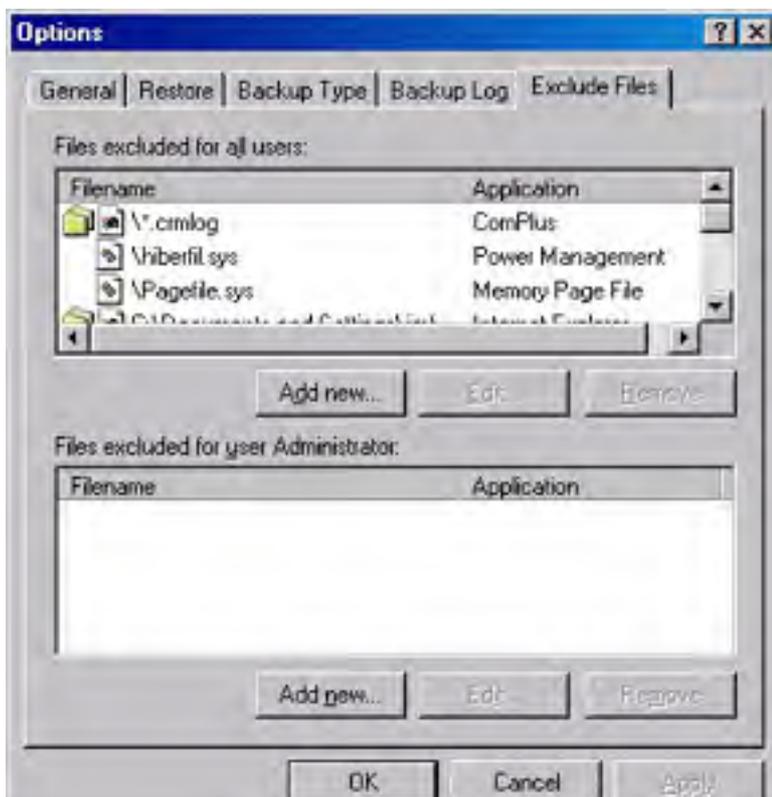

**Figure 35-4.** The Backup Log tab of the Options dialog box.

The backup logs are stored as ASCII files with a .LOG extension in a subfolder named Local Settings\Application Data\Microsoft\Windows NT\NTBackup\Data. This path is located in the Documents And Settings folder named for the user logged on while the backup is performed. You can view the logs with any text editor, but unfortunately, Windows 2000 Backup gives the files incremental names like Backup01.log and Backup02.log, making it difficult to locate the log for a particular job. To view a log by the job name, choose Report from the Backup program's Tools menu, select a particular job, and click View or Print. This displays or prints the log file using Notepad.

### Excluding Files

In the Exclude Files tab (Figure 35-5), you can list specific files and directories that the program should skip during the backup process. By default, the list already contains the files that you never need to back up, like the Windows 2000 memory paging file (Pagefile.sys). You can add other items to the list as needed. The advantage of using the Files Excluded For All Users list instead of simply clearing specific files on the Backup tab is that you can use wildcards to skip files located anywhere in the job. For example, you can add the file mask Backup\*.wbk to the list to exclude all of Microsoft Word's automatically created document backup files, wherever they occur in the selected drives and directories.

**Figure 35-5.** *The Exclude Files tab of the Options dialog box.*

The Exclude Files tab contains two lists: one to exclude files owned by all users on the system and one to exclude only files owned by the user currently logged on. With this option, you can add the Backup\*.wbk file mask to the current-user-only list and safely skip your Word document backups without disturbing anyone else's.

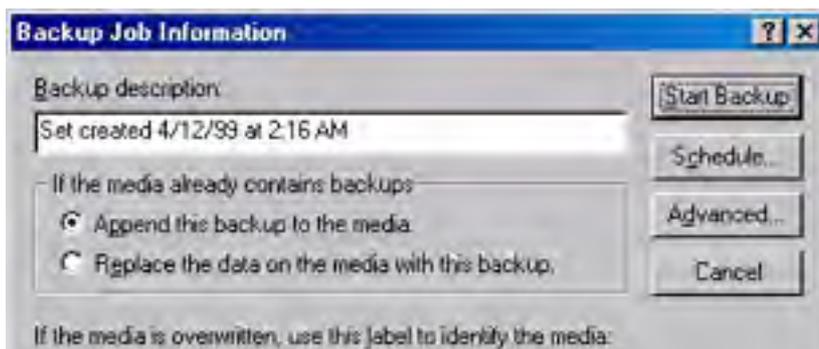

To add files to either list, click the appropriate Add New button and either select a registered file type or specify a custom file mask in the Add Excluded Files dialog box (Figure 35-6). You can also specify a particular path in which the files—selected either by file type or by file mask—are to be excluded. By default, the program excludes the files in the chosen folder and all of its subfolders, but you can limit the exclusion to the selected folder only by clearing the Applies To All Subfolders check box.

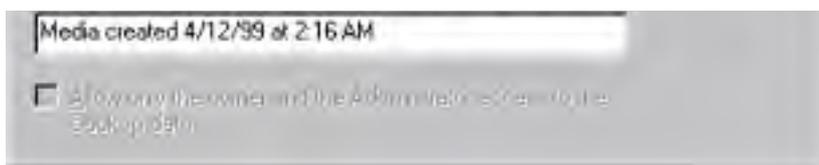

**Figure 35-6.** *The Add Excluded Files dialog box.*

## Running a Job

After you have configured the options for the job, you start it by clicking Start Backup in the Backup tab, which displays the Backup Job Information dialog box shown in Figure 35-7. The program prompts you to specify a descriptive name for the backup set and to decide whether the job should be appended to the selected tape (or other medium) or whether to overwrite any existing data. If you intend to overwrite the tape, you must specify a new name for it. If you choose to overwrite the tape, you can also control access to the data written to the tape by selecting a check box that permits only the owner of the job and members of the Administrators group to restore its files.

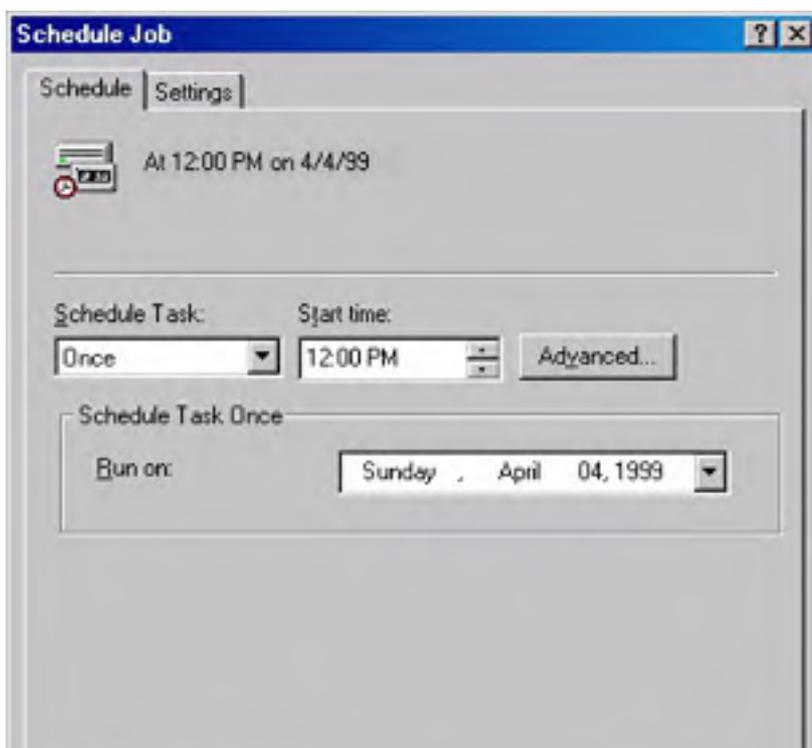

**Figure 35-7.** The Backup Job Information dialog box.

When you click Advanced in the Backup Job Information dialog box, the program prompts you for a backup type (with the value selected in the Backup Type tab of the Options dialog box as the default), and you must decide whether to enable the following options:

- **Back Up Data That Is In Remote Storage** When selected, this causes the program to back up the placeholder files referencing data that has been migrated to remote storage.
- **Verify Data After Backup** When selected, this causes the program to compare the data written to the tape with the original data. The default value is taken from the equivalent item in the General tab of the Options dialog box.
- **If Possible, Compress The Backup Data To Save Space** When selected, this activates the data compression capabilities built into the selected tape drive or other device. Windows 2000 Backup doesn't include any software-based compression capabilities; it facilitates only the use of your storage device's hardware-based compression. This option is enabled by default if the selected device has hardware-based compression capabilities and disabled if it doesn't.
- **Automatically Back Up System Protected Files With The System State** This option is enabled only if the System State object has been selected for backup. When this option is selected, all of the system files in the *%SystemRoot%* folder and any subfolders are backed up in addition to the files normally backed up for a system state backup.

## Scheduling a Job

At this point, you can start the backup job immediately by clicking Start Backup in the Backup Job Information dialog box, but to establish an organized backup strategy, you'll want to schedule your jobs to execute at specific intervals. When you click Schedule in the Backup Job Information dialog box, if the backup selections have not been saved, you are instructed to do so before you can schedule a backup. Otherwise, the program prompts you to specify the user name and password for the account that the system should use when running the job. The program then calls for you to specify a name for the job and displays the current date and time for the start date. To execute the job later, click Properties to display the Schedule Job dialog box shown in Figure 35-8.

**Figure 35-8.** *The Schedule Job dialog box.*

The Task Scheduler Service must be running in order to schedule backup operations.

Here you can specify whether the job is to be executed once at a certain time or repeated at regular intervals. The options available in the Schedule Task drop-down list are as follows:

- **Once** Executes the job once at a specific time on a specific date.
- **Daily** Executes the job at the specified time each day or, if you modify the value of the Schedule Task Daily selector, each specified number of days.
- **Weekly** Executes the job at the specified time on each of the specified days of the week or, if you modify the value of the Schedule Task Weekly selector, each specified number of weeks.
- **Monthly** Executes the job at the specified time once a month, based on either a selected date (such as the first of every month) or a day of the week (such as the first Monday of every month). By clicking Select Months, you can specify the months in which the job should run.
- **At System Startup** Executes the job the next time the system is started.
- **At Logon** Executes the job the next time the job owner logs on.
- **When Idle** Executes the job when the system has been idle for a specified number of minutes.

The scheduling capabilities of Windows 2000 Backup are quite comprehensive but not always intuitive. For example, you must select Weekly to run a daily job only on weekdays, and then select all of the days except Saturday and Sunday.

If you select the Show Multiple Schedules check box, the heading on the Schedule tab changes to a selector in which you can create and manage separate schedules for the same job. You can, for example, schedule a normal backup job to execute every weekday and create a separate event to execute the same job on the last Sunday of each month, to create an extra copy for off-site storage.

If you select Once, Daily, Weekly, or Monthly from the Schedule Task list, the Advanced button becomes available. Clicking this button opens the Advanced Schedule Options dialog box. In this dialog box, you can specify a date at which a repeating job should no longer be rescheduled and you can also configure a job to repeat continually after a specified interval has elapsed. You can use this feature to copy important and volatile data to a backup file every few minutes, as an extra precaution against data loss.

In the Settings tab of the Schedule Job dialog box, you can specify conditions under which the system is instructed not to run the job, such as when the computer has not been idle for a specified length of time or when it's running on battery power. You can also configure the job to terminate if it doesn't finish within a specified length of time.

After you've scheduled a job for later execution, you will see an icon representing it in the backup program's Schedule Jobs tab (Figure 35-9). You can modify the parameters for any scheduled job by clicking its icon to access its Scheduled Job Options dialog box.

Figure 35-9. The Schedule Jobs tab of Windows 2000 Backup.

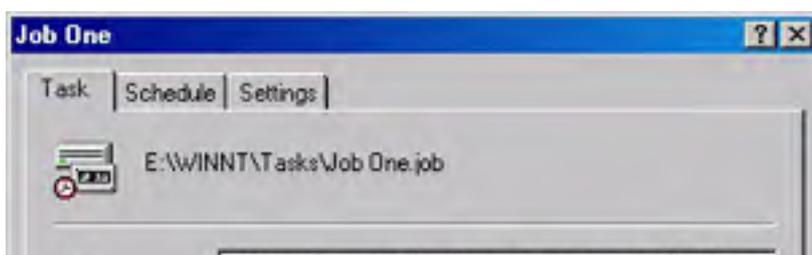

## Using the Windows 2000 Backup Wizard

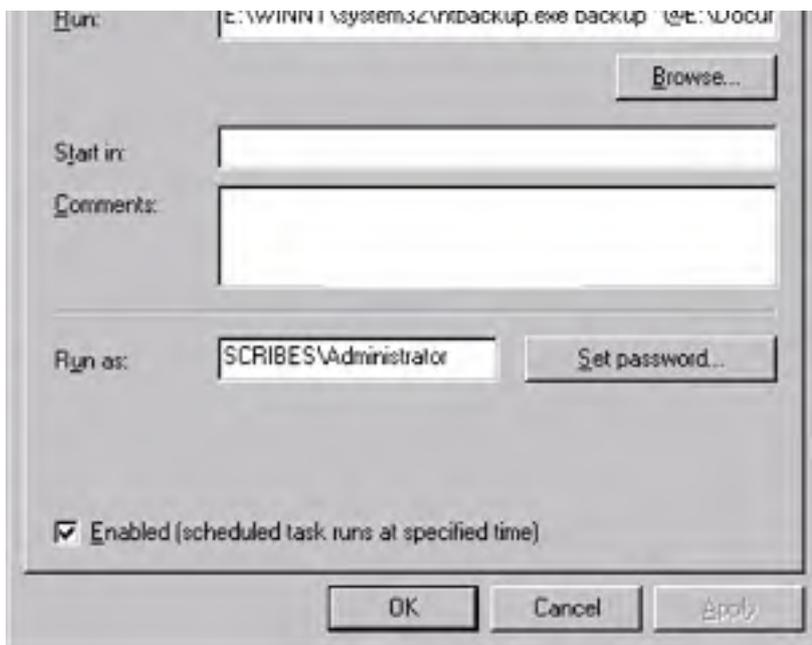

Windows 2000 Backup also includes a wizard that walks you through the process of configuring and creating a backup job. You can launch the wizard from the Windows 2000 Backup program's Welcome tab, by double-clicking a particular calendar date on the Schedule Jobs tab, or by clicking Add Job on the Schedule Jobs tab. If you have already selected drives, folders, or files to back up in the Backup tab, the program offers to use those selections in the wizard when you select a date.

The prompts presented by the wizard correspond to the options available in the program's regular GUI dialog boxes, reminding users of the program's capabilities and preventing them from inadvertently omitting an important option.

## Executing Jobs from the Command Line

In addition to creating backup jobs by using the GUI and the wizard, you can also execute jobs from the command line. In fact, when you schedule a job for later execution using the GUI or the Backup Wizard, the program actually uses the Windows 2000 Task Scheduler to launch the job with the command-line equivalents to the options you've chosen. When you open the Scheduled Tasks application in Control Panel and then double-click the name of the saved backup job, you can see the command line for your job in the Run field in the dialog box's Task tab (Figure 35-10).

**Figure 35-10.** The Task tab of the Job One dialog box.

The executable file for the Windows 2000 Backup program is still called Ntbackup.exe and is located in the `%SystemRoot%\System32` folder. The best application for this command-line capability is to execute selection scripts that you've previously created in the backup program's GUI interface from batch files or other scripts. The syntax for running Ntbackup.exe from the command line is as follows:

```
Ntbackup backup [systemstate] bksfilename|foldername /J "jobname"
[/P "poolname"] [/G "guidname"] [/T "tapename"] [/N "medianame"
[/F "backupfilename"] [/D "setdescription"] [/DS "servername"
[/IS "servername"] [/A] [/V:{yes|no}] [/R:{yes|no}] [/L:{f|s|n}]
[/M backuptype] [/RS:{yes|no}] [/HC:{on|off}]
```

- **backup** Specifies that the program will be performing a backup operation (even though *restore* is not a valid parameter on the command line).
- **systemstate** Specifies that the program should back up the system state in addition to the files and folders specified on the local computer's command line or in a selection script.
- ***bksfilename|foldername*** Specifies the name of a selection script file or the name of a folder that the program will back up (along with its subfolders).
- **/J "*jobname*"** Specifies a name for the backup job that the program will use to identify it in the log file.
- **/P "*poolname*"** Specifies the name of the media pool from which the program should take the tape (or other medium) to perform the backup. This option must not be used with the */A*, */G*, */F*, or */T* switch.
- **/G "*guidname*"** Specifies that the program perform the backup to a tape or other medium identified by the *guidname* variable. This option cannot be used with the */P* switch.
- **/T "*tapename*"** Specifies that the program perform the backup to a tape or other medium identified by the *tapename* variable. This option cannot be used with the */P* switch.
- **/N "*medianame*"** Specifies the new name for a tape or other medium that is being overwritten by the backup job. This option cannot be used with the */A* switch.
- **/F "*backupfilename*"** Specifies the name of the .BKF file to which the program should back up the selected files and folders. This option cannot be used with the */P*, */G*, or */T* switch.

- **/D "setdescription"** Specifies a descriptive label to be assigned to the backup set.
- **/DS "servername"** Causes the program to back up the directory service file for a specified Microsoft Exchange server.
- **/IS "servername"** Causes the program to back up the information store file for a specified Microsoft Exchange server.
- **/A** Causes the program to append the backup job to the tape or other medium specified by the /G or /T switch. This option cannot be used with the /P switch.
- **/V:{yes|no}** Specifies whether or not the program should verify the data after the backup is completed.
- **/R:{yes|no}** Specifies whether or not access to data on the tape or other medium should be restricted to the owner of the job and members of the Administrators group.
- **/L:{f|s|n}** Specifies the type of log that the program should keep while executing the backup job, where *f* = full, *s* = summary, and *n* = none.
- **/M *backuptype*** Specifies the type of backup to be performed, where *backuptype* is replaced by one of the following values: *normal*, *incremental*, *differential*, *copy*, or *daily*.
- **/RS:{yes|no}** Specifies whether or not the program should back up the Removable Storage database.
- **/HC:{on|off}** Specifies whether or not the program should activate the hardware compression capabilities of the tape drive.

The default states of the /V, /R, /L, /M, /RS, and /HC switches correspond to the current settings of the corresponding options in the backup program's GUI dialog boxes.

## Restoring Data

Of course, backups are useless unless you can restore files from them, and Windows 2000 Backup enables you to select individual files and directories for restoration or simply to restore the entire backup set to its original location. As with the program's backup function, you can create restore jobs using GUI screens or a wizard.

### Selecting Files to Be Restored

When you display the Restore tab in the Windows 2000 Backup program, you see a list of the media in the backup media pool and the backup files you've created. As part of each backup operation, Windows 2000 Backup creates a catalog of the backup set and stores it on the tape or other medium. (If a backup job spans two or more tapes, the backup set catalog is stored on the last tape.) The program accesses this catalog whenever you select a tape from the list for restoration.

After you insert the proper tape into the drive, the program reads the catalog and shows the contents of the tape in a hierarchical display just like that of the Backup tab (Figure 35-11). You can select drives, folders, and files to restore just as you selected them to be backed up.

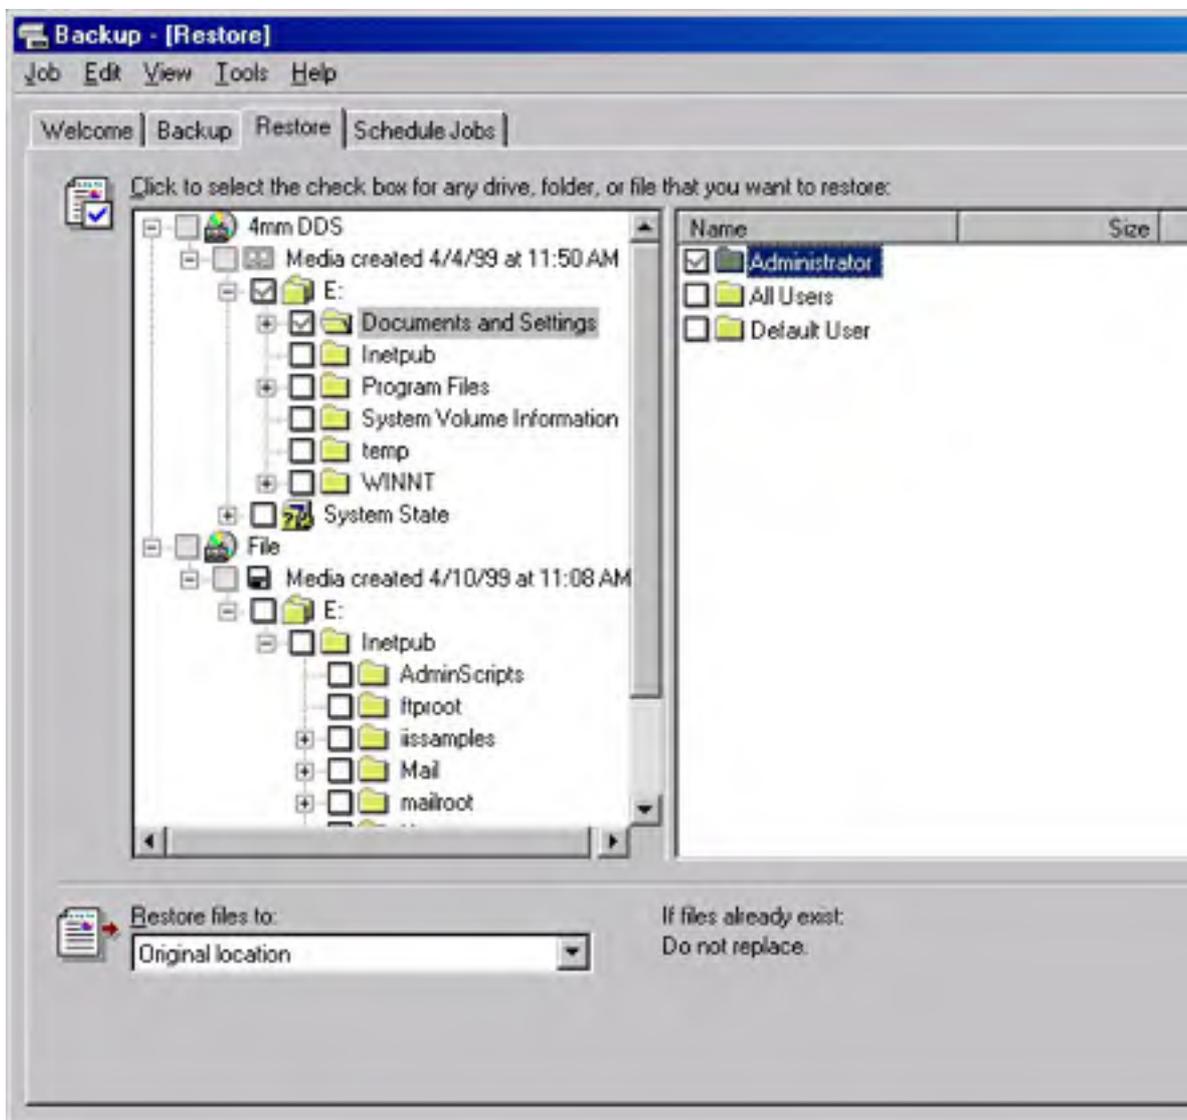

Figure 35-11. The Restore tab.

### Selecting Destinations for Restored Files

In a disaster recovery situation, you will probably want to restore an entire backup set to its original location, but in most cases, network administrators perform restores to retrieve a copy of a file or folder that a user has accidentally deleted or that has become corrupted somehow. When this is the case, you might not want to restore the files to their original location, and Windows 2000 Backup provides options that enable you to specify another location. The Restore Files To drop-down list box in the Restore tab provides the following options:

- **Original Location** Restores all of the selected files and folders to their original locations on local or network drives, preserving the original directory structure
- **Alternate Location** Restores all of the selected files and folders to a specified folder, preserving the directory structure of the restored material
- **Single Folder** Restores all of the selected files to a single specified folder, disregarding the original directory structure

If you elect to use the Single Folder option when performing a restore and you have files with identical names in the selected directories, the program uses the settings from the Restore tab in the Options dialog box to determine whether to overwrite the first files with subsequent, identically named files.

## Setting Restore Options

In the Restore tab of the Options dialog box, you specify how the backup program should behave when it encounters existing files with the same names during a restore operation. The following options are available:

- **Do Not Replace File On My Computer** Restores only the files that don't already exist on the destination disk
- **Replace The File On Disk Only If The File On Disk Is Older** Compares the dates of the identically named files and overwrites existing files on the destination disk only if the backed-up version is newer
- **Always Replace The File On My Computer** Restores all of the selected files to the destination disk, overwriting any existing files with identical names

When you click Start Restore, the Confirm Restore dialog box gives you the opportunity to click Advanced to configure the following advanced restore options before beginning the restore process:

- **Restore Security** Specifies whether the program should restore all of the security settings for each file and folder, including ownership, permissions, and audit entries. To restore the security settings, the destination for the restore job must be an NTFS drive (and the files and folders must have been backed up from an NTFS drive).
- **Restore Removable Storage Database** Specifies whether the program should restore the Removable Storage database to the `\%SystemRoot%\System32\Ntmsdata` folder, overwriting any existing Removable Storage database at that location.
- **Restore Junction Points, And Restore File And Folder Data Under Junction Points To The Original Location** Specifies whether the program should restore the junction points created with mounted drives as well as the data that the junction points reference. When this feature is disabled, Windows 2000 Backup restores the junction points themselves but doesn't necessarily restore the referenced data.
- **When Restoring Replicated Data Sets, Mark The Restored Data As The Primary Data For All Replicas** Specifies whether the program should restore file replication service (FRS) data so that it will be replicated to other servers. When this feature is disabled, Windows 2000 Backup restores the FRS data, but because of its age, it is likely to be overwritten later by data from the replicas on other servers.

Windows 2000 Backup can only execute restore jobs immediately. The program can't schedule restores for execution later.

## Planning for Disaster

A catastrophic server hard disk failure is every network administrator's worst nightmare, and many other disasters can result in the destruction of disks or even entire systems. Making sure that you have current backups of your disks is an essential part of any disaster recovery plan, as described in [Chapter 34](#), but other Windows 2000 system elements should also be protected. Windows 2000 Backup includes additional features that enable you to protect the entire system configuration and simplify the process of restoring the computer to its former state.

## Backing Up the System State

A separate entry called System State appears with the local drive letters under the My Computer heading in the Backup tab of Windows 2000 Backup. Selecting the System State entry causes the program to back up the components of the local system configuration that aren't directly accessible through the file system. These components include the following:

- Registry (on both servers and workstations)
- Class Registration database (on both servers and workstations)
- System boot files (on both servers and workstations)
- Certificate Services database (on certificate servers only)
- Active Directory (on domain controllers only)
- SYSVOL folder (on domain controllers only)

Backing up these components makes it possible for you to completely restore a system to a new disk without losing any of the domain and local user accounts or the rights and permissions associated with them. You can back up the system state only for the local machine, meaning that if you have multiple Windows 2000 systems on your network, you have to run the backup program on each computer to fully protect them. In most cases, however, only Windows 2000 servers contain system state information that is irreplaceable.

Because of dependencies between the system state elements, you can't back them up or restore them individually; you must treat them as a unified system element. However, you can restore the system state to an alternate location, in which case the program restores only the registry, SYSVOL, and system boot files.

Even if you can't back up the system state on remote systems, you can back up disks from those systems over the network. You can effectively protect all of your systems by first running a backup job on each Windows 2000 computer; this job saves only the system state to a file on the computer that has the tape drive (or other backup medium). Then, by backing up that entire machine to tape, along with the disks on the remote systems, you'll be protecting all of the disks as well as the system state for each machine.

## Handling Backup and Restore Problems

Backing up and restoring data in a network environment is a process that has always been subject to special problems and considerations. Windows 2000 Backup addresses some of these problems, as discussed in the following sections.

### Backing Up Exchange Servers

Because they can be constantly in use, mail servers like Microsoft Exchange have particularly difficult backup problems. Windows 2000 Backup includes a feature specifically designed to back up Exchange servers, which is available only when the program detects an Exchange module called Edbbcli.dll on the local system. When this module is present, a Microsoft Exchange item appears in the backup program's Tools menu, enabling you to specify the Universal Naming Convention (UNC) name of the Exchange server you want the program to access. Also, the expandable display in the Backup tab includes a Microsoft Exchange icon that you select to back up the mail server (Figure 35-12).

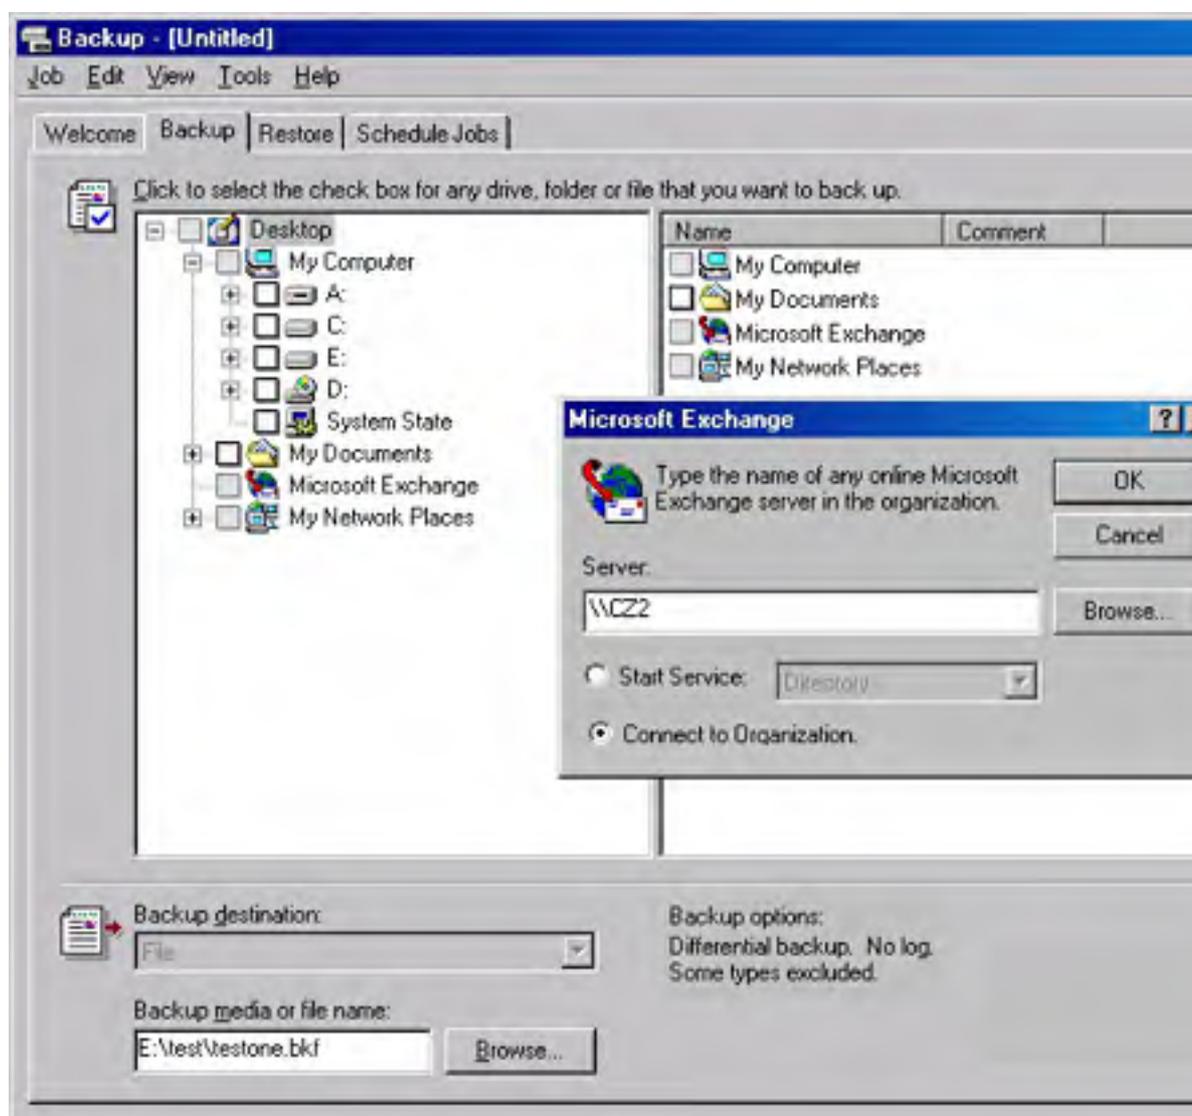

Figure 35-12. The Backup tab with the Microsoft Exchange dialog box displayed.

### Backing Up Encrypted Files

Encrypted files aren't stored any differently than unencrypted files by the Windows 2000 file systems; only their data format is different. Therefore, backing up encrypted files doesn't in any way compromise their security status. The files are copied to the tape or other medium in their encrypted form and restored the same way. The personnel responsible for backing up the files don't need to have access to the encryption codes, nor does access to the tape itself present a risk.

## Restoring the System State

Backing up the system state is as simple as selecting the appropriate box in the Backup tab, but restoring it is a bit trickier. The restoration process must not only overwrite vital system data that is currently in use, such as the registry, but it must also (in the case of a domain controller) restore the Active Directory database. This problem is particularly difficult because in a domain with multiple domain controllers, the replication system can overwrite the newly restored data because of its outdated update sequence numbers.

Therefore, to effectively restore the system state on a domain controller, you must perform two special procedures during the restoration process: start the computer in directory services restore mode and perform an authoritative restore of the Active Directory database.

You can restore the system state only on the local system. The Windows 2000 Backup program automatically determines the correct destination for the restored data, based on the location of the system root directory (typically C:\Winnt), and it overwrites the existing system state data on the computer.

## Directory Services Restore Mode

To restore Active Directory and the SYSVOL volume on a Windows 2000 domain controller, you must first reboot the system in directory services restore mode, a form of safe mode that ensures that the system is ready to have its Active Directory database overwritten. To do this, restart the system and press the F8 key when you see the Please Select The Operating System To Start message. From the Boot menu, choose Directory Services Restore Mode. After checking the system's local drives to ensure their integrity, Windows 2000 loads the operating system in a stand-alone server configuration with a set of generic drivers that permit safe-mode access to the operating system.

Because your domain controller system won't be functioning as a domain controller at this time, you might see error messages stating that Active Directory-dependent services have failed to load. This is to be expected. Because the machine isn't functioning as a domain controller, it isn't using the user and group objects associated with the domain. Instead, the system is using a small set of user and group accounts stored in the registry rather than in Active Directory. At this point, you can run Windows 2000 Backup and restore the system state.

## Authoritative Restore

When you restore the system state on a domain controller, the restored Active Directory objects have the same update sequence numbers as when they were backed up. These numbers are necessarily older than those currently in use in Active Directory and, as a result, they are considered to be outdated and overwritten during the next replication pass. To prevent this from happening, you must perform an authoritative restore of the Active Directory data stored as part of the system state on the backup medium. An authoritative restore is one that flags the restored Active Directory objects as authoritative, meaning that during the next replication event they overwrite the equivalent objects on the domain controllers containing the replicas.

To perform an authoritative restore, you must run the Windows 2000 Ntdsutil.exe program after you restore the system state and before you reboot the computer. Ntdsutil.exe modifies the update sequence numbers of the restored objects so that they appear to the replicas to contain the newest data available. During the next replication pass, the system uses the restored Active Directory database objects to overwrite the data on the domain's other controllers.

## Ntdsutil

The Ntdsutil.exe program is an interactive command-line utility copied to the %SystemRoot%\System32 folder by default during the operating system installation. You see a prompt labeled *ntdsutil:* when you run the executable file from the command line. The program uses a series of menus to navigate its various functions. Type a question mark (?) or *help* at any prompt to list the available commands and submenus for that prompt. To perform an authoritative restore, type *authoritative restore* at the ntdsutil prompt and then type *help* to display the

available commands, which are as follows:

- **Restore Database** Modifies the update sequence numbers of all Active Directory objects, making them authoritative for the entire domain
- **Restore Database Verinc %d** Authoritatively restores the entire database specified by the variable %d and overrides version increase
- **Restore Subtree %s** Modifies the update sequence numbers of Active Directory objects in the subtree specified by the %s variable, making them authoritative for the entire domain
- **Restore Subtree %s Verinc %d** Authoritatively restores the subtree specified by the variable %s and overrides version increase

Thus, to use the entire Active Directory database restored with the system state as authoritative information, you use the Restore Database command at the Ntdsutil.exe *authoritative restore:* prompt. The program opens the database and increases the version number of all the Active Directory objects by 100,000. Once the process is completed, you can exit the program by typing *quit* twice and restart the system in normal mode. When the computer is functioning as a domain controller again, it replicates its Active Directory database to all of the other controllers in the domain, and because the version numbers of its objects are substantially higher than those of the other replicas, the system copies the restored data to all of the replicas in the domain.

## Preserving NTFS Permissions

File system permissions are an essential element of any network storage policy, and for a backup program to function in a network environment, it must be able to save the permissions along with the files and restore them either to the same or a different location. However, the various file systems supported by Windows 2000 complicate this process considerably. The FAT file systems don't support permissions, and if you restore a backup of an NTFS drive to a FAT drive, those permissions are lost.

The introduction of NTFS 5 in Windows 2000 presents another significant incompatibility, and that is with NTFS drives created in Microsoft Windows NT 4. When you restore a backup of an NTFS 5 drive to a Windows NT 4 NTFS drive, you lose the following file system elements:

- Permissions
- Encrypting File System (EFS) settings
- Disk quota information
- Mounted drive information
- Remote storage information

The loss of these elements can compromise network security and make it impossible to access data that is encrypted or stored on another drive or medium. Restoring NTFS 5 data files to another file system can also cause you to lose data from embedded or linked documents and from alternate data storage formats such as those used by Services for Macintosh, disk image files, and custom file types created by certain non-Microsoft applications. You should always consider the file system used on your destination drive before you perform any NTFS restores.

## Third-Party Backup Utilities

The Windows NT backup utilities suffer from serious deficiencies in their tape drive support, scheduling capabilities, and other features. However, Windows 2000 has a backup program that provides all of the essential functions required by a network backup program and a few extras as well. (Of course, there's always room for improvement.)

One of the shortcomings of the Windows 2000 Backup program is that because the backup set catalogs are stored on the backup media themselves, you can't tell whether a particular file is on a tape without loading it so that the program can read the catalog. Some third-party backup products store the catalog information in a database on the local drive, enabling you to search for particular files (and even particular versions of files) to discover which tape you must use to restore them. This procedure can require a lot of extra disk space, but if you perform frequent restores, the sacrifice can be worthwhile.

Although Windows 2000 Backup supports backing up to CD-RW media (if you have packet-writing software such as Roxio's DirectCD installed), it doesn't support disk spanning (the ability to save the backup to multiple disks). This, combined with the lack of CD-R support (CD-R disks are much cheaper than CD-RW disks), makes the Windows 2000 Backup program less than useful when paired with CD burners. Fortunately, most third-party backup programs support both CD-R media and disk spanning, allowing you to back up to multiple CD media (although your patience might be taxed if backing up more than a couple of gigabytes).

Most third-party programs also simplify the process of creating a media rotation scheme by enabling you to specify the types of jobs you want to run each day and indicating when to run them. The program takes charge of the tape labeling by telling you which tape to insert each day and assigning it a new name. After overwriting each tape a specified number of times, the program advises you to retire it and add a new tape to the rotation. This also makes restoring to a specified file easier because the program can tell you by name exactly which tape you need to restore from.

Some network backup solutions also provide additional capabilities such as modules that enable you to back up certain types of files while they're in use or that allow you to back up workstations running non-Windows operating systems. Although third-party network backup solutions are no longer necessary, they can provide simplified backup administration and expanded capabilities.

## Summary

Once you've developed an adequate backup strategy and have configured the software to implement it, it's up to the administrator to see that it is carried out. Frequently, backups require no more attention than the insertion of a new tape into a drive, and yet even this simple task is often overlooked. Too many administrators learn about the importance of keeping current backups the hard way, through the irretrievable loss of important data. Those who find suitable employment afterward have usually learned their lesson, but it's always better if you can learn painful lessons without the pain. The next chapter focuses on the tools for building a Windows 2000 environment that is both fault-tolerant and available.

# Chapter 36

## **Planning Fault Tolerance and Avoidance**

Microsoft Windows 2000 Server, and especially Advanced Server with its clustering support, provides an excellent environment in which to build a truly fault-tolerant system. Of course, avoiding the faults in the first place is even better than handling them once they've happened, but the realistic system administrator knows that a problem will occur sooner or later, and he or she plans for it. [Chapter 34](#) covered disaster planning in depth, so you should refer to that chapter for information on how to prepare for major problems and how to build a full disaster recovery plan to quickly resolve them.

This chapter focuses primarily on the hardware and software tools that allow you to build a highly available and fault-tolerant Windows 2000 environment. Remember, however, that no matter what hardware and software you deploy, building and deploying for high availability and fault tolerance requires time, a clear understanding of the trade-offs required, and—most importantly—discipline. You'll need to make informed decisions about your real requirements and determine the resources available to meet those requirements. When planning for a highly available and fault-tolerant deployment, you should consider all points of failure and work to eliminate any single point of failure. Redundant power supplies, dual disk controllers, multiple network interface cards (multihoming), and fault-tolerant disk arrays (RAID) are all strategies that you can and should employ.

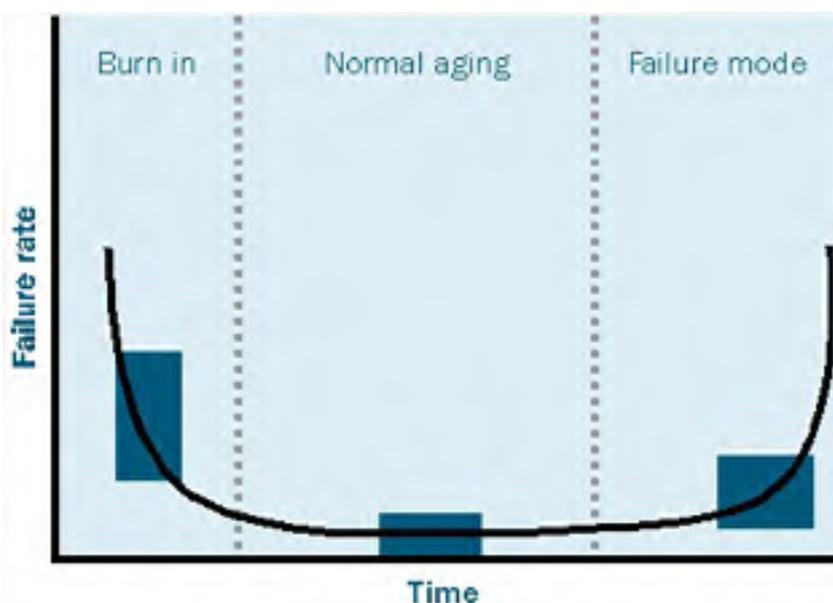

## Mean Time to Failure and Mean Time to Recover

The two most common metrics used to measure fault tolerance and avoidance are the following:

- **Mean time to failure (MTTF)** The mean time until the device will fail
- **Mean time to recover (MTTR)** The mean time it takes to recover once a failure has occurred

Although a great deal of time and energy is often spent trying to lower the MTTF, it's important to keep in mind that even if you have a finite failure rate, if your MTTR is zero or near zero, this may be indistinguishable from a system that hasn't failed. Downtime is generally measured as MTTR/MTTF, but because it can be prohibitively expensive to increase MTTF beyond a certain point, you should spend both time and resources on managing and reducing the MTTR for your most likely and costly points of failure.

Most modern electronic components have a distinctive "bathtub" curve that represents their failure characteristics, as shown in Figure 36-1. During the early life of the component (referred to as the burn-in phase), it's more likely to fail; once this initial phase is over, a component's overall failure rate remains quite low until it reaches the end of its useful life, when the failure rate increases again.

**Figure 36-1.** The normal statistical failure rates for mechanical and electronic components: a characteristic "bathtub" curve.

The typical commodity hard disk of 10 years ago had an MTTF on the order of three years. Today, a typical MTTF for a commodity hard disk is more likely to be 35 to 50 years! At least part of that difference is a direct result of counting only the portion of the curve in the normal aging section while taking externally caused failure out of the equation. So a hard disk that fails because of a power spike that wasn't properly filtered doesn't count against the MTTF of the disk, nor does a disk that fails in its first week or two. This may be nice for the disk manufacturer's statistics, but it doesn't do much for the system administrator whose system has crashed because of a disk failure. As you can see, it's important to look at the total picture and carefully evaluate all the factors and failure points on your system. Only by looking at the whole system, including the recovery procedures and methodology, can you build a truly fault-tolerant system.

## Protecting the Power Supply

The single biggest failure point for any network is its power supply. If you don't have power, you can't run your computers. It seems pretty obvious, and most of us slap an uninterruptible power supply (UPS) on the order when we're buying a new server or at least make sure that the current UPS can handle the extra load. However, this barely scratches the surface of what you can and should do to protect your network from power problems. You need to protect your network from four basic types of power problems:

- **Local power supply failure** Failure of the internal power supply on a server, router, or other network component
- **Voltage variations** Spikes, surges, sags, and longer term brownouts
- **Short-term power outages** External power failures lasting from fractions of a second to several minutes
- **Long-term power outages** External power failures lasting from several minutes to several hours or even days

Each type of power problem poses somewhat different risks to your network and will likely require somewhat different protection mechanisms. The possible threat that each one poses to your environment varies depending on the area in which you are located, the quality of power available to you, and the potential loss to your business if your computers are down.

### Local Power Supply Failure

The weakest links in all networks are the mechanical moving parts, and the mechanical moving parts most likely to fail are the internal power supplies on the servers and network components. All the power conditioning, uninterruptible power supplies, and external generators in the world won't help much if your server's power supply fails. Most servers these days either come with a redundant power supply or have the option of including one. Take the option! The extra cost associated with adding a redundant power supply to a server or critical piece of network hardware is usually far less than the cost of downtime should the power supply fail.

If your server, router, or other piece of network hardware doesn't have the option of a redundant power supply, order a spare power supply for it when you order the original hardware. Don't count on the hardware manufacturer's "4 hour response" time, especially when you consider the cost to your business even if they actually repair the equipment in 4 hours. If you have a spare power supply, you can quickly, and with minimal disruption, replace the failed power supply and return the equipment to full functionality. *Then* you can afford to wait patiently for the manufacturer's service response.

#### Real World

##### It's Only Useful If You Can Find It!

Having a good supply of critical spares is a great idea, but sometimes reality intrudes. Storage can be the weak link here. Most server rooms are not nearly as spacious as administrators would like them to be, and all too often the spare parts end up jammed into a bin with inadequate identification. If your network is down and you need a power supply to get it back up, you don't want to be pawing through a jumble of spare parts looking for the right power supply.

Make every effort to develop a single, central, secure location for all spare parts. Then make sure the manufacturer's part number is visible and clearly label the machine or machines each part is for. Finally, keep a master list of the spare parts you have and where they are located. It does you no good to have a spare power supply if you can't find it or don't know you have it.

Finally, practice replacing the power supplies of your critical hardware. Include well-illustrated and detailed instructions on how to replace the power supplies of your critical hardware as part of your disaster recovery standard operating procedures. If you can change the power supply in a very short time, the cost of having it fail diminishes significantly. If you have to wait for your original equipment supplier to get a replacement to you, even if you're on a 4-hour response service contract, the cost can be much higher than the cost of keeping a spare around.

## Voltage Variations

Even in areas with exceptionally clean power that is always available, the power that is supplied to your network inevitably fluctuates. Minor, short-term variations merely stress your electronic components, but major variations can literally fry them. You should never, ever simply plug your computer into an ordinary wall socket without providing some sort of protection against voltage variations. The following sections describe the types of variations and the best way to protect your equipment against them.

### Spikes

*Spikes* are large but short-lived increases in voltage. They can occur because of external factors, such as lightning striking a power line, or because of internal factors, such as a large motor starting. The most common causes of severe voltage spikes, however, are external and outside your control. The effects can be devastating. A nearby lightning strike can easily cause a spike of 1000 volts or more to be sent into equipment designed to run on 110 to 120 volts. Few, if any, electronic components are designed to withstand large voltage spikes of several thousand volts, and almost all will suffer damage if they're not protected from them.

Protection from spikes comes in many forms, from the \$19.95 power strip with built-in surge protection that you can buy at your local hardware store to complicated arrays of transformers and specialized sacrificial transistors that are designed to die so that others may live. Unfortunately, those \$19.95 power strips just aren't good enough. They *are* better than nothing, but barely, because they have a limited ability to withstand really large spikes.

More specialized (and more expensive, of course) surge protectors that are specifically designed to protect computer networks are available from various companies. They differ in their ability to protect against really large spikes and in their cost. There's a fairly direct correlation between the cost of these products and their rated capacity and speed of action within any company's range of products, but the cost for a given level of protection can differ significantly from company to company. As always, if the price sounds too good to be true, it is.

In general, these surge protectors are designed to work by sensing a large increase in voltage and creating an electrical path for that excessive voltage that doesn't allow it to get through to your server. In the most severe spikes, the surge protectors should destroy themselves before allowing the voltage to get through to your server. The effectiveness of these stand-alone surge protectors depends on the speed of response to a large voltage increase and the mechanism of failure when their capacity is exceeded.

Many of the newer UPSs also provide protection from spikes. They have built-in surge protectors, plus isolation circuitry that tends to buffer the effects of spikes. The effectiveness of the spike protection in a UPS is not directly related to its cost, however—the overall cost of the UPS is more a factor of its effectiveness as an alternative power source. Your responsibility is to read the fine print and understand the limitations of the surge protection a given UPS offers. Also remember that just as with simple surge protectors, large voltage spikes can cause the surge protection to self-destruct rather than allow the voltage through to your server. That's the good news; the bad news is that instead of having to replace just a surge protector, you're likely to have to repair or replace the UPS.

Finally, one other spike protection mechanism can be helpful—the constant voltage transformer. You're not likely to see one unless you're in a large industrial setting, but they are often considered to be a sufficient replacement for other forms of surge protection. Unfortunately, they're not really optimal for surge protection. They do filter some excess voltage, but a large spike is likely to find its way through. However, in combination with either a fully protected UPS or a good stand-alone surge protector, a constant voltage transformer can be quite effective. They also provide additional protection against other forms of voltage variation that surge protectors alone can't begin to manage.

### Surges

Voltage surges and spikes are often discussed interchangeably, but we'd like to make a distinction here. For our purposes, a *surge* lasts longer than most spikes and isn't nearly as large. Most surges

last a few hundred milliseconds and are rarely over 1000 volts. They can be caused by many of the same factors that cause voltage spikes.

Providing protection against surges is somewhat easier than protecting against large spikes. Most of the protection mechanisms just discussed also adequately handle surges. In addition, most constant voltage transformers are sufficient to handle surges and might even handle them better if the surge is so prolonged that it threatens to overheat and burn out a simple surge protector.

## Sags

Voltage *sags* are short-term reductions in the voltage delivered. They aren't complete voltage failures or power outages and are shorter than a full-scale brownout. Voltage sags can drop the voltage well below 100 volts on a 110- to 120-volt normal line and cause most servers to reboot if protection isn't provided.

Stand-alone surge protectors provide no defense against sags. You need a UPS or a very good constant voltage transformer to prevent damage from a voltage sag. Severe sags can overcome the rating of all but the best constant voltage transformers, so you generally shouldn't use constant voltage transformers as the sole protection against sags. A UPS, with its battery power supply, is an essential part of your protection from problems caused by voltage sag.

## Brownouts

A *brownout* is a planned, deliberate reduction in voltage from your electric utility company. Brownouts most often occur in the heat of the summer and are designed to protect the utility company from overloading. They are *not* designed to protect the consumer, however.

In general, a brownout reduces the available voltage by 5 to 20 percent from the normal value. A constant voltage transformer or a UPS provides excellent protection against brownouts, within limits. Prolonged brownouts might exceed your UPS's ability to maintain a charge at the same time that it is providing power at the correct voltage to your equipment. Monitor the health of your UPS carefully during a brownout, especially because the risk of a complete power outage increases if the power company's voltage reduction strategy proves insufficient.

The best protection against extended brownouts is a constant voltage transformer of sufficient rating to fully support your critical network devices and servers. This transformer takes the reduced voltage provided by your power company and increases it to the rated output voltage. A good constant voltage transformer can handle most brownouts for an extended time without problems, but you should still supplement the constant voltage transformer with a quality UPS and surge protection between the transformer and the server or network device. This extra protection is especially important while the power company is attempting to restore power to full voltage because during this period you run a higher risk of experiencing power and voltage fluctuations.

## Short-Term Power Outages

*Short-term power outages* last from a few milliseconds to a few minutes. They can be caused by either internal or external events, but you can rarely plan for them even if they are internal. A server that is unprotected from a short-term power outage will, at the minimum, reboot or, at the worst, fail catastrophically.

You can best protect against a short-term power outage by using a UPS in combination with high-quality spike protection. Be aware that many momentary interruptions of power are accompanied by large spikes when the power is restored. Further, a series of short-term power outages often occur consecutively, causing additional stress to electronic components.

## Long-Term Power Outages

*Long-term power outages*, lasting from an hour or so to several days, are usually accompanied by other, more serious problems. Long-term power outages can be caused by storms, earthquakes, fires, and the incompetence of electric power utilities, among other things. As such, long-term power outages should be part of an overall disaster recovery plan. (See [Chapter 34](#) for more on disaster planning.)

Protection against long-term power outages really becomes a decision about how long you want or need to function if all power is out. If you need to function long enough to be able to gracefully shut down your network, a simple UPS or a collection of them will be sufficient, assuming that you've sized the UPS correctly. However, if you need to be sure that you can maintain the full functionality of your Windows 2000 network during an extended power outage, you're going to need a combination of one or more UPSs and an auxiliary generator.

If your situation requires an auxiliary generator to supplement your UPSs, you should carefully plan your power strategy to ensure that you provide power to all of the equipment that the network will require in the event of a long-term power outage. Test your solution to make sure you didn't miss anything! Further, you should regularly test the effectiveness of your disaster recovery plans and make sure that all key personnel know how to start the auxiliary generator manually in the event it doesn't start automatically. Finally, you should have a regular preventive maintenance program in place that services and tests the generator and ensures that it is ready and functioning when you need it.

## Disk Arrays

The most common hardware malfunction is probably a hard disk failure. Even though hard disks have become more reliable over time, they are still subject to failure, especially during their first month or so of use. They are also vulnerable to both catastrophic and degenerative failures caused by power problems. Fortunately, disk arrays have become the norm for most servers, and good fault-tolerant RAID systems are available in Windows 2000 Server and RAID-specific hardware supported by Windows 2000.

The choice of software or hardware RAID, and the particulars of how you configure your RAID system, can significantly affect the cost of your servers. To make an informed choice for your environment and needs, you must understand the trade-offs and the differences in fault tolerance, speed, configurability, and so on.

### Hardware vs. Software

RAID can be implemented at the hardware level, using RAID controllers, or at the software level, either by the operating system or by a third-party add-on. Windows 2000 supports both hardware RAID and its own software RAID.

Hardware RAID implementations require specialized controllers and cost significantly more than an equal level of software RAID. But, for that extra price, you get a faster, more flexible, and more fault-tolerant RAID. When compared to the software RAID provided in Windows 2000 Server, a good hardware RAID controller supports more levels of RAID, on-the-fly reconfiguration of the arrays, hot-swap and hot-spare drives (discussed later in this chapter), and dedicated caching of both reads and writes.

The Windows 2000 Server software RAID requires that you convert your disks to dynamic disks. The disks will no longer be available to other operating systems, although this really shouldn't be a problem in a production environment. However, you should consider carefully whether you want to convert your boot disk to a dynamic disk. Dynamic disks can be more difficult to access if a problem occurs, and the Windows 2000 setup and installation program provides only limited support. For maximum fault tolerance, we recommend using hardware mirroring on your boot drive; if you do use software mirroring, make sure that you create the required fault-tolerant boot floppy disk and test it thoroughly before you need it. (See [Chapter 34](#).)

### RAID Levels for Fault Tolerance

Except for level 0, RAID is a mechanism for storing sufficient information on a group of hard disks such that even if one hard disk in the group fails, no information is lost. Some RAID arrangements go even further, providing protection in the event of multiple hard disk failures. The more common levels of RAID and their appropriateness in a fault-tolerant environment are shown in Table 35-1.

**Table 36-1.** RAID levels and their fault tolerance

Level	Number of Disks <sup>1</sup>	Speed	Fault Tolerance	Description
0	$N$	+++	- - -	Striping alone. Not fault-tolerant—it actually increases your risk of failure—but does provide for the fastest read and write performance.
1	$2N$	+	++	Mirror or duplex. Slightly faster read than single disk, but no gain during write operations. Failure of any single disk causes no loss in data and minimal performance hit.
3	$N+1$	++	+	Byte-level parity. Data is striped across multiple drives at the byte level with the parity information written to a single dedicated drive. Reads are much faster than with a single disk, but writes operate slightly slower than a single disk because parity information must be generated and written to a single disk. Failure of any single disk causes no loss of data but can cause a significant loss of performance.

4	$N+1$	++	+	Block-level parity with a dedicated parity disk. Similar to RAID-3 except that data is striped at the block level.
5	$N+1$	+	++	Interleaved block-level parity. Parity information is distributed across all drives. Reads are much faster than a single disk but writes are significantly slower. Failure of any single disk provides no loss of data but results in a major reduction in performance.
0+1 (also known as level 10)	$2N$	+++	++	Striped mirrored disks. Data is striped across multiple mirrored disks. Failure of any one disk causes no data loss and no speed loss. Failure of a second disk could result in data loss. Faster than a single disk for both reads and writes.
Other	Varies	+++	+++	Array of RAID arrays. Different hardware vendors have different proprietary names for this RAID concept. Excellent read and write performance. Failure of any one drive results in no loss of performance and continued redundancy.

When choosing the RAID level to use for a given application or server, consider the following factors:

- **Intended use** Will this application be primarily read intensive, such as file serving, or will it be predominantly write intensive, such as a transactional database?
- **Fault tolerance** How critical is this data, and how much can you afford to lose?
- **Availability** Does this server or application need to be available at all times, or can you afford to be able to reboot it or otherwise take it offline for brief periods?
- **Performance** Is this application or server heavily used, with large amounts of data being transferred to and from it, or is this server or application less I/O intensive?
- **Cost** Are you on a tight budget for this server or application, or is the cost of data loss or unavailability the primary driving factor?

You need to evaluate each of these factors when you decide which type of RAID to use for a server or portion of a server. No single answer fits all cases, but the final answer requires you to carefully weigh each of these factors and balance them against your situation and your needs. The following sections take a closer look at each factor and how it weighs in the overall decision-making process.

## Intended Use

The intended use, and the kind of disk access associated with that use, plays an important role in determining the best RAID level for your application. Think about how write intensive the application is and whether the manner in which the application uses the data is more sequential or random. Is your application a three-square-meals-a-day kind of application, with relatively large chunks of data being read or written at a time, or is it more of a grazer or nibbler, reading and writing little bits of data from all sorts of different places?

If your application is relatively write intensive, you'll want to avoid software RAID if possible and avoid RAID-5 if other considerations don't force you to use it. With RAID-5, any application that requires more than 50 percent writes to reads is likely to be at least somewhat slower, if not much slower, than it would be on a single disk. You can mitigate this to some extent by using more but smaller drives in your array and by using a hardware controller with a large cache to offload the parity processing as much as possible. RAID-1, in either a mirror or duplex configuration, provides a high degree of fault tolerance with no significant penalty during write operations—a good choice for the Windows 2000 system disk.

If your application is primarily read-intensive, and the data is stored and referenced sequentially, RAID-3 or RAID-4 might be a good choice. Because the data is striped across many drives, you have parallel access to it, improving your throughput. And because the parity information is stored on a single drive, rather than dispersed across the array, sequential read operations don't have to skip over the parity information and are therefore faster. However, write operations are substantially slower, and the single parity drive can become an I/O bottleneck.

If your application is primarily read intensive and not necessarily sequential, RAID-5 is an obvious choice. It provides a good balance of speed and fault tolerance, and the cost is substantially lower than the cost of RAID-1. Disk accesses are evenly distributed across multiple drives, and no one drive has the potential to be an I/O bottleneck. However, writes require calculation of the parity information and the extra write of that parity, slowing write operations down significantly.

If your application provides other mechanisms for data recovery or uses large amounts of temporary storage, which doesn't require fault tolerance, a simple RAID0, with no fault tolerance but fast reads and writes, is a possibility.

## **Fault Tolerance**

Carefully examine the fault tolerance of each of the possible RAID choices for your intended use. All RAID levels except RAID-0 provide some degree of fault tolerance, but the effect of a failure and the ability to recover from subsequent failures can be different.

If a drive in a RAID-1 mirror or duplex array fails, a full, complete, exact copy of the data remains. Access to your data or application is unimpeded, and performance degradation is minimal, although you do lose the benefit gained on read operations of being able to read from either disk. Until the failed disk is replaced, however, you have no fault tolerance on the remaining disk. Once you replace the failed disk, overall performance is significantly reduced while the new disk is initialized and the mirror rebuilt.

In a RAID-3 or RAID-4 array, if one of the data disks fails, a significant performance degradation occurs because the missing data needs to be reconstructed from the parity information. Also, you'll have no fault tolerance until the failed disk is replaced. If it is the parity disk that fails, you'll have no fault tolerance until it is replaced, but also no performance degradation. Once you replace the failed disk, overall performance is significantly reduced while the new disk is initialized and the parity information or data is rebuilt.

In a RAID-5 array, the loss of any disk results in a significant performance degradation, and your fault tolerance will be gone until you replace the failed disk. Once you replace the disk, you won't return to fault tolerance until the entire array has a chance to rebuild itself, and performance is seriously degraded during the rebuild process.

RAID systems that are arrays of arrays can provide for multiple failure tolerance. These arrays provide for multiple levels of redundancy and are appropriate for mission-critical applications that must be able to withstand the failure of more than one drive in an array.

### **Real World**

#### **Multiple Disk Controllers Provide Increased Fault Tolerance**

Spending the money for a hardware RAID system increases your overall fault tolerance, but it can still leave a single point of failure in your disk subsystem: the disk controller itself. Although failures of the disk controller are certainly less common, they do happen. Many hardware RAID systems are based on a single multiple-channel controller—certainly a better choice than those based on a single-channel controller, but an even better solution is a RAID system based on multiple identical controllers. In these systems, the failure of a single disk controller is not catastrophic but simply an annoyance. In RAID-1 this technique is known as duplexing, but it is also common with many of the proprietary arrays of arrays that are available from server vendors and in the third-party market.

## **Availability**

All levels of RAID, except RAID-0, provide higher availability than a single drive. However, if availability is expanded to also include the overall performance level during failure mode, some RAID levels provide definite advantages over others. Specifically, RAID-1, mirroring/duplexing, provides enhanced availability when compared to RAID levels 3, 4, and 5 during failure mode. There is minimal performance degradation when compared to a single disk if one half of a mirror fails, whereas a RAID-5 array has substantially compromised performance until the failed disk is replaced and the array is rebuilt.

In addition, RAID systems that are based on an array of arrays can provide higher availability than RAID levels 1 through 5. Running on multiple controllers, these arrays are able to tolerate the failure of more than one disk and the failure of one of the controllers, providing protection against the single point of failure inherent in any single-controller arrangement. RAID-1 that uses duplexed disks running on different controllers—as opposed to RAID-1 that uses mirroring on the same controller—also provides this additional protection and improved availability.

Hot-swap drives and hot-spare drives (discussed later in this chapter) can further improve availability in critical environments, especially hot-spare drives. By providing for automatic failover and rebuilding, they can reduce your exposure to catastrophic failure and provide for maximum availability.

## Performance

The relative performance of each RAID level depends on the intended use. The best compromise for many situations is arguably RAID-5, but you should be suspicious of that compromise if your application is fairly write intensive. Especially for relational database data and index files where the database is moderately or highly write intensive, the performance hit of using RAID-5 can be substantial. A better alternative is to use RAID-0+1 (also known as RAID-10 from some vendors).

Whatever level of RAID you choose for your particular application, it will benefit from using more small disks rather than a few large disks. The more drives contributing to the stripe of the array, the greater the benefit of parallel reading and writing you'll be able to realize—and your array's overall speed will improve.

## Cost

The delta in cost between RAID configurations is primarily the cost of drives, potentially including the cost of additional array enclosures because more drives are required for a particular level of RAID. RAID-1, either duplexing or mirroring, is the most expensive of the conventional RAID levels, because it requires at least 33 percent more raw disk space for a given amount of net storage space than other RAID levels.

Another consideration is that RAID levels that include mirroring/duplexing must use drives in pairs. Therefore, it's more difficult (and more expensive) to add on to an array if you need additional space on the array. A net 36-GB RAID-0+1 array, comprising four 18-GB drives, requires four more 18-GB drives to double in size, a somewhat daunting prospect if your array cabinet has bays for only six drives, for example. A net 36-GB RAID-5 array of three 18-GB drives, however, can be doubled in size simply by adding two more 18-GB drives, for a total of five drives.

## Hot-Swap and Hot-Spare Disk Systems

Hardware RAID systems can provide for both hot-swap and hot-spare capabilities. A *hot-swap* disk system allows failed hard disks to be removed and a replacement disk inserted into the array without powering down the system or rebooting the server. When the new drive is inserted, it is automatically recognized and either will be automatically configured into the array or can be manually configured into it. Additionally, many hot-swap RAID systems allow you to add hard disks into empty slots dynamically, automatically or manually increasing the size of the RAID volume on the fly without a reboot.

A *hot-spare* RAID configuration uses an additional, preconfigured disk or disks to automatically replace a failed disk. These systems usually don't support hot-swapped hard disks so that the failed disk can't be removed until the system can be powered down, but full fault tolerance is maintained by having the hot spare available.

## Distributed File System

The Distributed file system (Dfs) is primarily a method of simplifying the view that users have of the available storage on a network—but it is also, when configured appropriately, a highly fault-tolerant storage mechanism. By configuring your Dfs root on a Windows 2000 domain controller, you can create a fault-tolerant, replicated, distributed file system that gives you great flexibility while presenting your user community with a cohesive and easy-to-navigate network file system.

When you create a fault-tolerant Dfs root on a domain controller and replicate it and the links below it across multiple servers, you create a highly fault-tolerant file system that has the added benefit of distributing the load evenly across the replicated shares, giving you a substantial scalability improvement as well. See [Chapter 17](#) for more on setting up your Dfs and ensuring that replication works correctly.

## Clustering

Windows 2000 Advanced Server supports two different kinds of clustering, either of which can greatly improve your fault tolerance:

- For many TCP/IP-based applications, the Network Load Balancing service provides a simple, "shared nothing," fault-tolerant application server.
- Server clusters provide a highly available fault-tolerant environment that can run applications, provide network services, and distribute loads.

## Network Load Balancing

The Network Load Balancing service (called Windows Load Balancing Service in Microsoft Windows NT 4) allows TCP/IP-based applications to be spread dynamically across up to 32 servers. If a particular server fails, the load and connections to that server are dynamically balanced to the remaining servers, providing a highly fault-tolerant environment without the need for specialized, shared hardware. Individual servers within the cluster can have different hardware and capabilities, and the overall job of load balancing and failover happens automatically, with each server in the cluster running its own copy of Wlbs.exe, the Network Load Balancing service.

## Server Clusters

Server clusters, unlike network load balancing, depend on a shared resource between nodes of the cluster. This resource, which in Windows 2000 Advanced Server, as shipped, must be a shared disk resource, is generally a shared SCSI or Fibre Channel-attached disk array. Each server in the cluster is connected to the shared resource, and the common database that manages the clustering is stored on this shared disk resource.

Nodes in the cluster generally have identical hardware and identical capabilities, although it is technically possible to create a server cluster with dissimilar nodes. Microsoft Windows 2000 Advanced Server supports up to two node server clusters, whereas up to four nodes are supported in Datacenter Server.

Server clusters provide a highly fault-tolerant and configurable environment for mission-critical services and applications. Applications don't need to be specially written to be able to take advantage of the fault tolerance of a server cluster, although if the application is written to be clustering aware, it can take advantage of additional controls and features in a failover and fallback scenario.

## Summary

Building a highly available and fault-tolerant system requires you to carefully evaluate both your requirements and your resources to eliminate single points of failure within the system. You should evaluate each of the hardware subsystems within the overall system for fault tolerance, and ensure that recovery procedures are clearly understood and practiced to reduce recovery time in the event of a failure. Uninterruptible power supplies, RAID systems, distributed file systems, and clustering are all methods for improving fault tolerance. In the next chapter, we discuss the registry: what it is, how it's structured, and how to back it up and restore it.

# Chapter 37

## **Using the Registry**

The registry is a source of fear for many system administrators because it's the central repository of system configuration settings. Making mistakes while editing the registry can have undesirable consequences, but it's not so different from using a power saw, or an automobile, for that matter. All powerful tools cause negative consequences if misused. If you know what you're doing and take a few simple safety precautions, you can take advantage of a powerful tool—like the registry—without grief.

## Introducing the Registry

The registry is a binary database that organizes all of a system's configuration settings into a hierarchy. Applications, system components, device drivers, and the Microsoft Windows 2000 kernel all use the registry to store their own preferences, read them back again, and obtain information about the system's hardware configuration, the current user's preferences, and the default settings that should be used when no predefined settings exist (such as when a new user logs on to the machine for the first time).

## The Origins of the Registry

Back in the days of Microsoft Windows 3.1, applications and Windows stored their configuration information in .INI files. These files were simple to edit, which was both a blessing and a curse—users could easily make changes when needed, but they could also easily make changes when they *weren't* needed. The proliferation of Windows applications soon meant that machines were littered with dozens of .INI files, each with its own combination of settings—not all of which were documented or even understood by anyone other than the application programmers.

Windows NT 3.1 largely eliminated .INI files; it introduced the predecessor to what is now known as the Windows 2000 registry. The Windows NT 3.1 registry has some important features that have continued on more or less unchanged to Windows 2000:

- Registry data is organized by category, so settings that pertain to a single user (like your choice of default wallpaper) are kept separate from settings for other users or the system's own internal parameters. Each setting is stored as an independent piece of data.
- Registry data is stored in binary database files on disk; the only way to view or edit these files is to use special-purpose tools that call the registry access routines of the Win32 API.
- Each data item in the registry has a data type, like REG\_DWORD (a long integer) or REG\_SZ (an ASCII string). The system's registry editors enforce these data types, so you can't put a string where a number belongs. This restriction helps weed out one class of mistakes—well-intentioned but misinformed attempts to put a round peg into a square hole.
- Like every other object in the system, each registry item has an owner, and it can have its own independent set of security access control lists (ACLs) and auditing controls.
- With appropriate permissions, administrators or programs on one computer can connect to, read, and modify the registries of remote computers.

Some of these features made it into Windows 95, Windows 98, and Windows Me, which shares the organizing principles of the Windows NT family registry without its security or remote access features. The two operating system (OS) families use different internal formats for their registry databases even though their registries look similar to registry-editing tools; their files aren't interchangeable or interoperable.

Perhaps the most remarkable aspect of the Windows 2000 registry is how little it has changed from the Windows NT 4 version. The binary structures used to store the data remain the same, as do the structural underpinnings discussed later in this chapter.

## What Registry Data Is Used For

Now that you have a general understanding of what the registry's data is used for, it's time to get more specific. Registry data is used in six different areas:

- Registry data is used during setup, installation, configuration, and removal of the OS itself, of OS components like Internet Information Services (IIS) or Certificate Services, and of hardware devices. Any time you see an "Add/Remove Something-or-Other Wizard," you can bet that registry data is being used.
- At boot time the Windows 2000 recognizer (Ntdetect.com) and some associated code in the Windows 2000 kernel search for hardware devices and store their findings in a memory-based portion of the registry.

- The Windows 2000 kernel uses the information gathered at boot time to figure out which device drivers to load and in what order; it also stores information needed by those drivers in the registry.
- Device drivers use the data written by the recognizer and the kernel to configure themselves to work with the physical hardware in the machine.
- System tools and applications like control panels and some MMC snap-ins read and write configuration data in the registry.
- Applications can store their own settings in the registry; in addition, they can read (and possibly write) the data gathered by other software that uses the registry.

Note that during the boot, kernel, and device driver phases, the system can't use the disk—until the device drivers are loaded, the system can't "talk" to the disk. You'll learn how the system works around this seemingly severe limitation in the section entitled [Volatile Keys](#) later in the chapter.

## **Real World**

### **Being on Your Best Behavior**

Microsoft continually warns us that editing the registry is dangerous—is it really, or are they just covering themselves? The answer is somewhere between the two extremes. Because the registry is used by virtually every part of Windows 2000, and because most programmers are lazy when it comes time to write code to check the validity of values that come from the registry, making an improper or ill-advised registry change can certainly harm your machine. Having said that, however, if you're careful and attentive, you don't need to be afraid of the registry. A few simple rules will keep you out of trouble:

- Don't edit a part of the registry for fun. If you don't know how a certain change will affect your system, don't make it unless you can live with the consequences.
- Be careful about adding new values or keys. Software pays attention only to keys that have names it understands. Adding a new key or value in the hope that some component will recognize it and change its behavior is like adding a new switch labeled "Jet Boost" to your car's dashboard and expecting it to increase your car's speed. The exception to this rule is that Microsoft often uses code that can recognize hidden (or at least under documented) keys and change its behavior accordingly.
- Maintain a current backup of your system state.
- Use the Export Key and Import Key functions of Regedit.exe to backup keys before modifying them.

## Understanding the Registry's Structure

In a file system, the root objects are disks, which contain folders and files. A single folder can contain an arbitrary number of other folders and files; each folder or file has a name. By combining the names of the folders that enclose a file, we can construct a path that unambiguously names only one file on the disk, so that C:\Windows\Mapi32.dll and C:\Winnt\Mapi32.dll are completely separate files, for example.

The Windows 2000 registry is organized much like a file system, except that the vocabulary needed to describe it is somewhat different. At the root of the registry structure are the *root keys* (likened to a disk in a file system). Each root key contains several *subkeys* (folders); in turn, these subkeys contain other subkeys and *values* (the registry equivalent of files). Like files, each value has a name that must be unique in the subkey or folder that encloses it; each value also has an associated data type that governs what kind of data it can hold.

Any registry value can be identified by specifying its full path, starting at the root. For example, the path HKEY\_LOCAL\_MACHINE\SOFTWARE\Microsoft\Exchange\Security\ObscureWireDataFormat specifies a particular value in the Security subkey that belongs to Microsoft Exchange Server. Figure 37-1 shows an annotated section of the Windows 2000 registry so that you can identify the root keys, subkeys, and values in it.

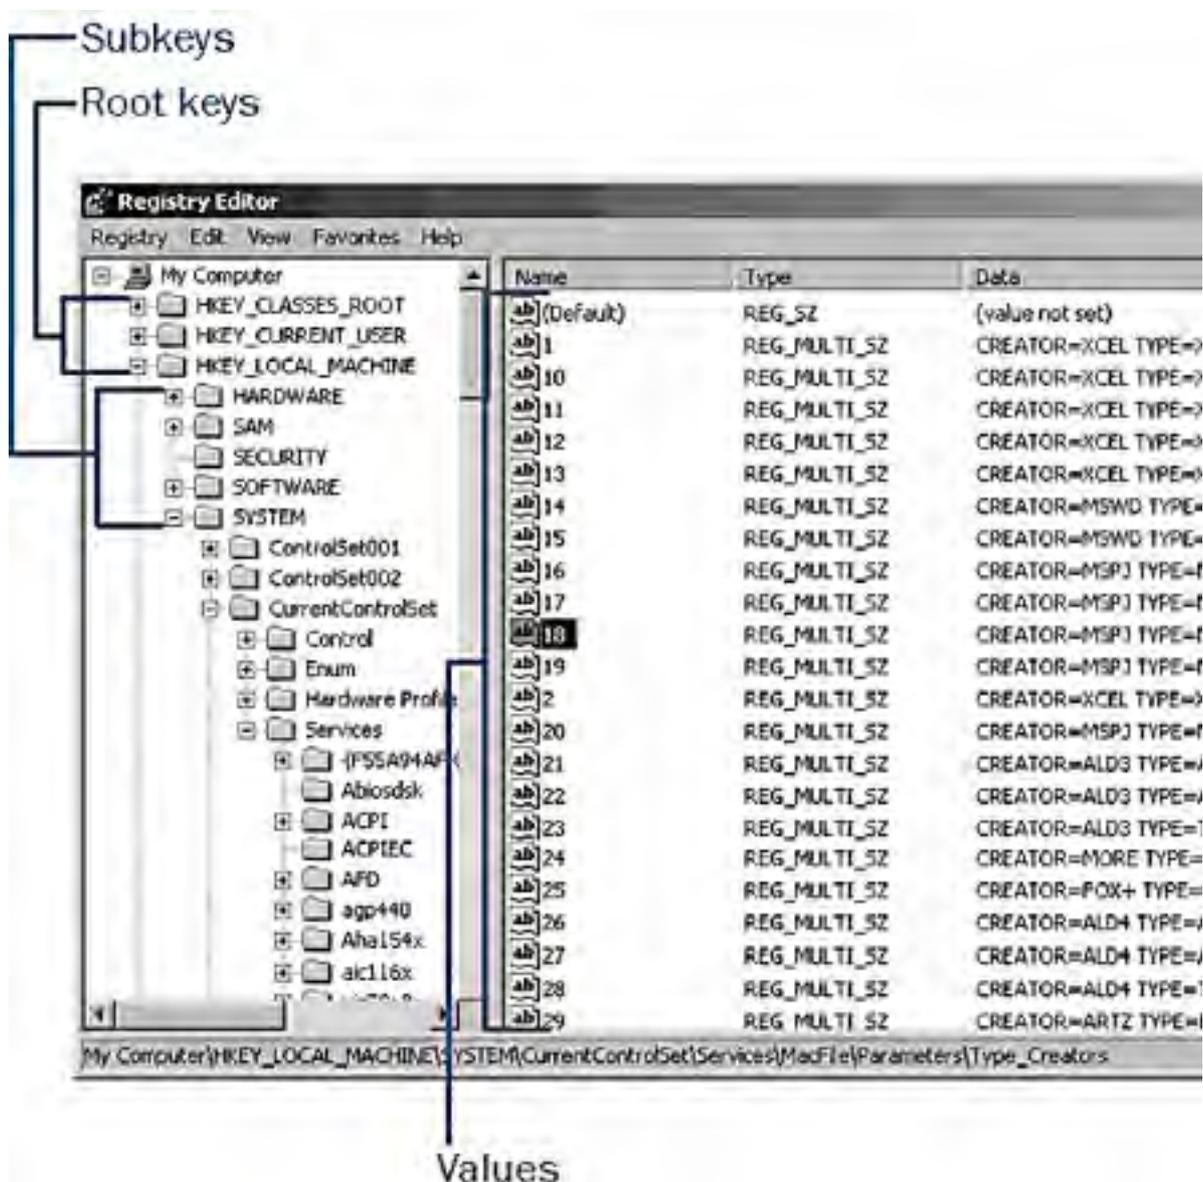

Figure 37-1. The three separate components of a registry value.

## The Root Keys

When you open the My Computer icon on your desktop, you always see certain items, such as icons that represent the logical disk volumes on your computer. The same is true of the registry. When you open it with a Registry Editor, you'll always see the same set of root keys. Each root key has a distinct purpose:

- HKEY\_LOCAL\_MACHINE (HKLM) stores all settings that pertain to the local machine. For example, the HARDWARE subkey of HKLM is where the system and its device drivers record and share information about the hardware devices that the system finds at boot time (as well as other Plug-and-Play devices that you can add after the system is booted). Applications are supposed to store data here only if it pertains to everyone who uses a machine; for example, a printer driver might store a set of default print settings here and copy them to each new user's profile when he or she logs on.
- HKEY\_USERS (HKU) contains one entry for each user who has previously logged on to your computer. Each user's entry is owned by that user's account, and it contains the profile settings that were in effect for that user. When you use group policies (see [Chapter 9](#)), the policy settings you specify are applied to an individual user's profile here.
- HKEY\_CURRENT\_CONFIG (HKCC) stores information about the system's current boot configuration. In particular, it contains information about the current set of system services and which devices were present at boot time. This root key is actually a pointer to sections inside HKLM.
- HKEY\_CURRENT\_USER (HKCU) points to the currently logged on user's profile inside HKU. Microsoft requires that Windows 2000 applications store any user-specific preferences in subkeys under HKCU; for example, HKCU\SOFTWARE\Binary Research\GhostSrv\Settings holds a user's personal preferences for Symantec's Ghost product. Another user's settings for the same product would be available in the same key only when that user is logged on.
- HKEY\_CLASSES\_ROOT (HKCR) ties file extensions and OLE class identifiers together; it actually points to HKLM\SOFTWARE\Classes. System components like Windows Explorer (and Microsoft Internet Explorer, for that matter) use these associations to determine which applications or components to use when opening or creating a particular type of file or data object. Because Windows 2000 relies heavily on the Component Object Model (COM), which in turn relies on the object identifiers stored in HKCR, this key and its subkeys are more important than you might think at first.

In the Windows 2000 documentation, Microsoft identifies only two registry root keys: HKLM and HKU. Because HKCU, HKCC, and HKCR are actually pointers to subkeys of HKLM and HKU, this is technically correct, but you might be confused if you're used to the idea of five separate root keys. To avoid that confusion, we'll use the old-style notation.

### Real World

#### HKCR in Windows 2000

One important registry change in Windows 2000 involves HKCR. In Windows NT 4 and earlier, the data in HKCR is the same for all users. In some ways, this was a reasonable design decision for Microsoft to make—all users on the machine have access to the same set of installed OLE components and file mappings.

However, one common complaint from administrators whose users have to share machines is that two users' preferred associations might differ. If one user chooses Netscape Navigator as the preferred Web browser, that modifies HKCR; if another user later sets Internet Explorer as the preferred browser at the same machine, that undermines the original choice. More importantly, the ability for users to change these values reduces system security in two ways: it allows users to change associations for other users (increasing the risk of introducing malicious code), and it forces administrators to remove permissions from HKLM \SOFTWARE\Classes, because all users need access to it.

In Windows 2000, Microsoft changed this behavior so that HKCR actually contains data from two sources: the user's profile (where user-specific customizations are stored) and HKLM\SOFTWARE\Classes, where systemwide settings live. Users can register and unregister COM components, change file associations, and so on without affecting other users. Administrators can adjust permissions on HKLM\SOFTWARE\Classes so users can't tamper with the systemwide settings you want them to have. Each user's unique settings are stored in the Usrclass.dat file, which is treated like its own registry hive. (See the section entitled [Where Data Goes on Disk](#) later in the chapter for more details on hive files.)

## Major Subkeys

Within these root keys, several subkeys are noteworthy. Because each root key has so much information under it, you'll usually hear these individual subkeys referred to—after all, HKLM\HARDWARE and HKLM\SOFTWARE don't have much in common except their root key.

### HKLM\HARDWARE

The HKLM\HARDWARE subkey stores information about the hardware found in the system. All of the values stored here are held only in RAM, not on disk, because of the device driver ordering problem mentioned earlier. When the hardware recognizer starts, it enumerates every device it can find, both by walking the system buses and by searching for specific classes of devices like parallel ports or keyboards. Three major subkeys live under HKLM\HARDWARE:

- The DESCRIPTION subkey contains descriptions of the CPUs, floating-point processors, and multifunction devices in the system. The information stored here is considerably expanded over what is available in Windows NT 4; for example, the CentralProcessor subkey now tracks a number of settings that aren't present in Windows NT 4. For computers that use multipurpose chipsets like Intel's BX series, one of the multifunction devices listed in this key reflects the chipset's integrated controllers, with separate entries for disk, keyboard, pointer, parallel, and serial controllers.
- The DEVICEMAP subkey links a specific device to a specific driver. For example, DEVICEMAP\Video has a value named \Device\Video1 that contains the string \REGISTRY\Machine\SYSTEM\ControlSet001\Services\mnmd\Device0, which is a pointer to the place where the driver for that video controller stores its parameters.
- The RESOURCEMAP subkey exists in Windows NT 4, but it is completely revamped in Windows 2000. It now contains three primary subkeys: one for the hardware abstraction layer (HAL) to use when keeping track of the devices it finds, one for the Plug-and-Play Manager to record devices it knows how to handle, and one that reflects the amount of system resources (Microsoft-speak for RAM) available on the machine.

Additional subkeys can exist, depending on the configuration of your machine. For example, systems that support the Advanced Configuration Power Interface (ACPI) have an ACPI subkey that contains information about the specific ACPI subfeatures that the computer supports.

### HKLM\SAM

Just because Windows 2000 includes the Active Directory service, don't assume that no vestiges of the Security Accounts Manager (SAM) have survived. When you create local accounts or groups on a Windows 2000 machine, they are stored in HKLM\SAM, just as they are in Windows NT. However, you can't normally view or change data in this subkey, and it is mostly useful for compatibility with earlier Windows NT code that expects SAM to exist. The programming routines that access SAM data have all been revamped to use Active Directory data when it exists, or SAM when no Active Directory server is present.

### HKLM\SECURITY

HKLM\SECURITY contains a lot of security information, as you might expect. Its format isn't documented, and you can't do anything in the subkey. However, the system caches logon credentials, policy settings, and shared server secrets in this subkey. The SECURITY\SAM subkey contains a copy of most of the data from HKLM\SAM.

### Look, But Don't Touch!

If you're feeling adventurous and want to see what's in HKLM\SAM and HKLM\SECURITY, you can open these keys by running Regedt32 in the LocalSystem security context. The easiest way to do this is to use the At command to schedule Regedt32 to run in an interactive session. Just schedule it to run a minute or so into the future, like this:

```
at 12:34 /interactive regedt32.exe
```

That command tells the system to schedule Regedt32 to run one minute from now (this being written at 12:33); when it runs, the system scheduler service launches the application, so it runs in the LocalSystem context instead of the context you're logged on as. Although this is an interesting way to see what's in these subkeys, be forewarned of two things. First, you won't be able to make much sense out of the values in these keys, because they're intentionally obfuscated. Second, and more importantly, remember that changing any of these values will provoke unintended and probably undesirable consequences. In other words, look, but don't touch.

## HKLM\SOFTWARE

The HKLM\SOFTWARE subkey serves as the root location for applications and system components to store their machine-wide settings. For example, HKLM\SOFTWARE\Microsoft\EnterpriseCertificates contains keys that hold the certificate trust lists (CTLs) and trusted CA certificates for this machine—individual users' CTLs and trusted CAs are stored elsewhere. Individual programs, control panels, and the like can create their own subkeys under HKLM\SOFTWARE; the de facto standard is for each vendor to create its own top-level key (for example, HKLM\SOFTWARE\Intel) and then create subentries beneath that key.

The most interesting parts of this subkey are HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion (which stores much of the GUI preference data; it's named the same as the corresponding key under Windows 95/98) and HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion. This latter subkey is significantly expanded in Windows 2000; for example, there are new keys for automatic server recovery handling, the Encrypting File System, the Security Configuration Editor, Terminal Services, and other new goodies.

## HKLM\SYSTEM\CurrentControlSet

When you boot Windows 2000, the last action in the boot phase is to update the registry to reflect which set of controls and services was last used for a successful boot. CurrentControlSet always points to the set of controls actually in use on the system. If you look under HKLM\SYSTEM, you'll see many ControlSetXXX keys. Each ControlSetXXX subkey represents a control set that existed at one time, whether or not it was successfully used to boot. CurrentControlSet is just a pointer to the most recent successful boot set, but because it isn't easy to determine *which* set that was, the OS and applications use CurrentControlSet instead.

Beneath this set are four keys whose names carry over from earlier versions of Windows NT, although their guts are somewhat different in Windows 2000:

- **Control** Contains control information for services and system tools. For example, Control\BackupRestore\KeysNotToRestore contains a list of keys that Windows 2000 Backup shouldn't restore (including the contents of the Plug-and-Play subkey) when it restores the registry.
- **Enum** Contains one entry for every physical device or pseudo-device that the system can find. For example, Enum\USB\Vid\_0461&Pid\_4d03\Inst\_0 contains information about the USB mouse plugged in to someone's laptop. Because it was present at boot time, it is included in the enumeration list.
- **Hardware Profiles** Contains one entry for each hardware profile defined on a machine. As with HKLM\SYSTEM itself, each profile has a serial number, starting with 0001. HKLM\SYSTEM\Hardware Profiles \Current always points to the profile that was selected at boot time.
- **Services** Contains one subkey for each installed service. These sub-keys, in turn, hold all the configuration information that the service needs. The exact set of subkeys on two machines are different if they have different services loaded on them.

## HKLM\SYSTEM\MountedDevices

Windows 2000 dynamic disk volumes (discussed in [Chapter 15](#)) are a neat technical achievement and a boon to administrators, but they depend on having information about the current configuration of the logical volumes on disk. Applications (and snap-ins, like the Disk Management snap-in) get this information from the Logical Volume Manager service; in turn, this service stores its list of mounted and available devices in the MountedDevices subkey.

## How Data Is Stored

Although programs and services that use the registry don't have to understand how registry data is stored, administrators do—that way you'll know where data is stored, how the registry handles different types of data, and which files need to be safeguarded as part of your backups. You don't need to understand the internal format that the registry tools use, but you should understand the basic data types and storage locations.

Each value in the registry (Microsoft calls them *value entries*) has three parts: a name, a data type, and an actual value. For example, if you see a Microsoft Knowledge Base article that talks about some key—REG\_SZ: HKLM\SYSTEM\CurrentControlSet\Services\Replicator\Parameters\GuardTime, for example—you're seeing a complete definition of a value entry (although it's always nice to see a full path for values, so you know where to add or remove them).

## Useful Data Types

Seven data types can be used to store data in the registry. Actually, only two of these types are used for most registry data: REG\_DWORD and REG\_SZ. The seven types are as follows:

- REG\_BINARY stores arbitrary binary data in raw form, without any reformatting or parsing. You can view binary data in binary or hex forms by using one of the Windows 2000 registry editors (described later in the chapter).
- REG\_DWORD stores an 8-byte long integer (or double word) value. This data type is usually used when a value indicates a count or interval, but it's also common to see REG\_DWORD flags—0 means the flag is off, and 1 means it's on.
- REG\_SZ is an ordinary Unicode string. These strings can be of any length; this data type is usually used to store paths, human-readable messages or device names, and so on.
- REG\_EXPAND\_SZ is a REG\_SZ with a twist—applications can embed a special token in the string and then expand the token when they read the value from the registry. For example, the value entry *Something* is a REG\_EXPAND\_SZ whose normal value is `%SystemRoot%\System32\Something`. When Windows 2000 reads the string, it expands `%System-Root%` to the full path where the operating system is installed.
- REG\_MULTI\_SZ is a collection of an arbitrary number of REG\_SZ values. For example, the list of DNS servers you specify in the TCP/IP Properties dialog box is stored in a REG\_MULTI\_SZ value. Applications must know how to pick apart a single REG\_MULTI\_SZ into its component parts.
- REG\_FULL\_RESOURCE\_DESCRIPTOR is a rare bird; it is used to encode information about the system resources required by a particular device. We've never seen it appear outside of subkeys of HKLM\HARDWARE.
- REG\_NONE is just a placeholder. It is used to indicate that a registry value exists but doesn't contain any actual data. Some components look for the presence or absence of a specified key or value to control their behavior at runtime; it's common for those components to look for an item of type REG\_NONE—because this type doesn't hold any data, users can't mess these values up.

In day-to-day administration, what you'll need to know about these data types is mostly restricted to understanding the difference between REG\_DWORD and REG\_SZ values. A REG\_DWORD value whose contents are 0 (the numeric value for zero) is different from a REG\_SZ whose contents are "0" (the character "0"). If you need to add a new registry value (perhaps because a Microsoft Knowledge Base article recommends doing so), you'll have to ensure that you get the type right, or you might have problems with the components that use the value.

## Volatile Keys

Some registry keys and values are *volatile*, in the original sense of the word—they aren't persistent and can evaporate at any moment. As an example, none of the data in HKLM\HARDWARE exists anywhere on disk; that entire subkey and all its contents reside entirely in memory. Every time you boot a Windows 2000 machine, that subkey is created anew, and when you shut it down, its contents disappear.

### Disk-Based Keys

Volatile keys are useful for data that doesn't need to stay around between reboots, but most of the data stored in the registry would be pretty useless if it weren't persistent. Imagine having to reconfigure all your preferences and settings after every reboot of your desktop machine—that would get old fast. The majority of registry keys are disk-based, meaning that their contents are held in structures on disk. When a key's contents are updated, the version on disk is updated too.

Even though disk-based keys are eventually stored on disk, Windows 2000 maps them into the paged memory pool (an area of memory whose contents can be written to the pagefile when not being used) to provide more efficient access. The registry size limit, discussed later in this chapter, regulates how much registry data can be stored in the paged pool.

### Where Data Goes on Disk

Microsoft uses the term *hive* to refer to a group of keys and values that belong together. A hive can be a root key, or it can be a subkey; for example, HKCC is a hive (even though it's just a pointer to part of HKLM), and so is HKLM\SAM. The important concept to remember about hives is that a hive is a self-contained unit that can be loaded and unloaded independently of other hives.

Windows 2000 uses six hives: DEFAULT (corresponding to HKU\DEFAULT), SAM (HKLM\SAM), SECURITY (HKLM\SECURITY), SOFTWARE (HKLM\SOFTWARE), and SYSTEM (HKLM\SYSTEM). The sixth hive, which corresponds to the contents of HKCU, is better known as a user profile—a *user profile* is really just a hive that is loaded into the registry when the user logs on and unloaded at logout.

Each hive exists in its own file on disk (the files have the same names as the hives), along with a separate log file that acts as a journal of all changes made to that hive. Hive files don't have extensions, and the system keeps them open all the time—that's why you have to use a special-purpose backup tool like Windows 2000 Backup or ARCServe to back them up.

So, where do these hive files live? As with so many other Windows 2000-related questions, the answer is a hearty "It depends." In this case, the answer depends on which hives you're talking about. The big five (DEFAULT, SAM, SECURITY, SOFTWARE, and SYSTEM), along with their .LOG files, are stored in the System32\Config subfolder of the Windows 2000 Install folder.

The location of the user profile files (Ntuser.dat and Ntuser.dat.log for the logged-on user, Default and Default.log for the default user) depends on which operating system, if any, was on the machine before Windows 2000. Machines that were upgraded from Windows NT 4, or those on which Windows 2000 was cleanly installed, keep these profiles in the Profiles\Username subfolder of the system root folder. (Each user has his or her own subfolder.) For machines that were upgraded from Windows 95 or Windows 98, profiles are stored in a folder named for the user in the system's Documents and Settings folder.

## Using the Registry Editors

On those occasions when you need to change values in the registry, you'll have to use some kind of registry editor. Many of the settings that you can change in control panels, Group Policy objects, or MMC snap-ins are actually stored in the registry, so you can think of these utilities as a kind of registry editor. Another kind is the custom-written script that you use to make a specific change, perhaps as part of a logon script or a file you distribute to your users. However, most of the time when you need to make a change directly to the registry, you'll use one of the two tools Microsoft includes with Windows 2000: Regedt32.exe or Regedit.exe.

### What You Get

Why are there two registry editors in Windows 2000? Blame it on Windows NT 4. When Windows NT 3.1, 3.5, and 3.51 shipped, they included a registry editor called Regedt32. This tool was written to manipulate Windows NT registry keys and values, and it reflects Microsoft's standards for user interface design at the time it was written—1992 or thereabouts.

When Windows 95 was being developed, Microsoft realized that Regedt32 wasn't a good match for the Windows 95 interface *or* the underlying structural differences between the two systems' registries. Because Windows 95 also needed a registry editor, Microsoft developed a companion tool, Regedit, and shipped it with Windows 95.

To complicate matters, Microsoft includes *both* Regedt32 and Regedit with Windows NT 4. Although this might seem unnecessarily redundant, it is actually an advantage, as the two programs have different and complementary abilities. Microsoft continued to ship both programs as part of Windows 2000; except for a few minor cosmetic tweaks and plumbing-related bug fixes, the Windows 2000 versions are identical to their predecessors.

Windows XP does away with Regedt32, integrating most of its functionality into Regedit (The Load Registry Hive feature is gone, but the need for it is lessened, as very few situations now require the editing of the registry from a parallel installation). Thus users get the best of both worlds: the interface and search capabilities of Regedit along with the Windows NT underpinnings of Regedt32.

### Regedit vs. Regedt32

With two editors to choose from, how do you know which one to use in a given circumstance? Both tools have the same fundamental capabilities. They allow you to do the following:

- Browse a graphical structure that represents the registry hierarchy
- See and modify keys, subkeys, values, and value contents, subject to the security privileges you have
- Connect to a remote computer for which you have privileges and inspect, or even change, the contents of its registry

However, some significant differences exist, most of which revolve around features that are in one editor but not the other. Let's start with Regedt32. Because it was engineered specifically for Windows NT, it has some useful features that carry over into Windows 2000:

- Allows you to see and change security ACLs on registry keys
- Allows you to enable auditing on keys so that you can see who has attempted—or who has succeeded—in removing, adding, or editing keys or their contents
- Supports all of the registry data types described earlier in the chapter; in addition, you can edit a value of one type using another type's editor (handy when editing REG\_BINARY values)
- Has a read-only mode that lets you inspect the registry without allowing changes
- Can save and load hive files or individual keys

- Uses the old-style multiple-document interface (MDI) paradigm, in which each root key has its own document window

In contrast, Regedit was designed to make full use of the Windows 95-style interface, so it looks quite a bit different from Regedt32. It also has the following different functionality:

- Searches keys, value names, and value contents for a specified string. This feature is invaluable and is the primary reason to use Regedit.
- Uses the familiar two-pane Windows Explorer interface, making it somewhat easier to compare the location of two keys or values. It also includes other Windows Explorer-like features, such as shortcut menus, in-place editing, and the familiar tree control.
- Imports and exports selected keys (and their subordinate items) in a human-readable text file, instead of importing and exporting registry keys in binary form.
- Includes a Favorites menu (in the Windows 2000 version), to which you can add whatever keys you feel the need to edit repeatedly.

How do you know which tool to use? Most of the time your personal preferences dictate which one you use. Some people like the way that Regedit works, whereas others prefer the old-school Regedt32 interface. If you're trying to find which key holds a particular value, you're better off using Regedit; on the other hand, if you need to set security permissions on a key, you'll have to use Regedt32.

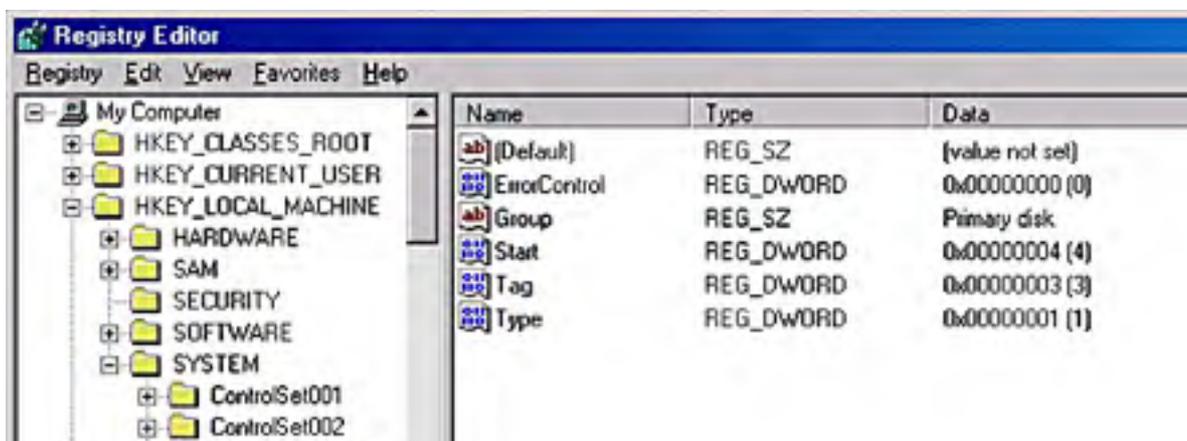

## A Whirlwind Tour of Regedit

As a user of Windows Explorer (or any version of Windows), you already know about 85 percent of what you need to use Regedit. This familiarity is entirely by design—Microsoft has tried to make it an easy-to-use tool by copying the user interface that you're already familiar with.

Regedit's main window is shown in Figure 37-2. The important parts of the interface are fairly simple to understand. Notice the following features:

- The tree in the left pane of the Registry Editor window shows all of the root keys and subkeys; what you see here depends on which keys and subkeys you've expanded.
- The right pane shows the values associated with the selected key in the left pane. Each value is shown with three items: the value name (the name (Default) is used for the unnamed default value that every key has), the value's type, and the value's contents or data.
- The status bar at the bottom of the window shows the full path to the currently selected key. (Regedit can also copy this key's path to the clipboard for you, thanks to the Copy Key Name command on the Edit menu; this is handy when you're writing a book or otherwise documenting your work.)

Because these interface features are written with the standard Windows controls, all the keyboard navigation and control shortcuts you're accustomed to using with Windows Explorer work here. For example, you can jump to a particular key by clicking anywhere in the left pane and typing the first few letters of the key's name. You can also use the arrow keys to move around in either half of the Regedit window.

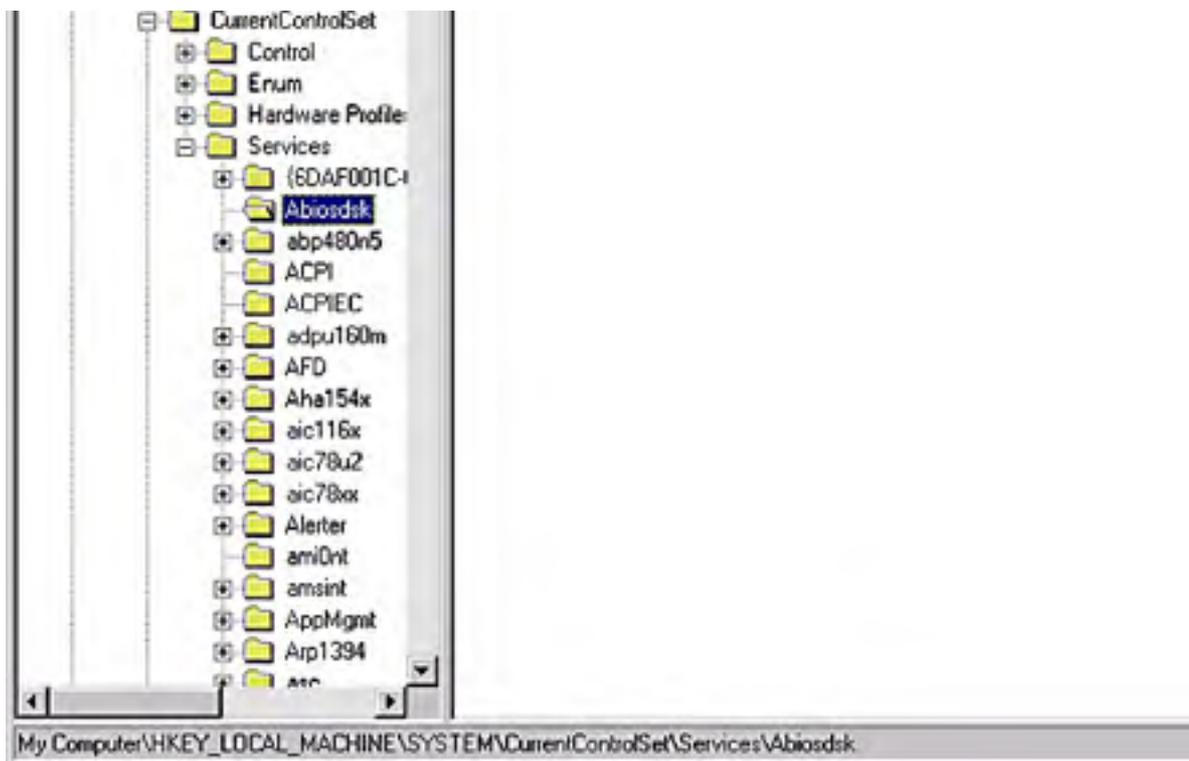

Figure 37-2. The Regedit user interface.

### Searching for Keys and Values

The Find command on the Edit menu in Regedit is worth its weight in gold when you need to find which key, or value, has a specific name or contents. The interface to this function is uncomplicated—as Figure 37-3 shows. Even with this simple interface, the tool is extremely valuable because it searches the entire registry for a specific value. Here's how to use the Find dialog box to get what you're looking for:

- Type the pattern you're looking for into the Find What box. You can search only for plain ASCII text—no wildcards are allowed. If you're searching for values, Regedit searches only string values (REG\_SZ, REG\_EXPAND\_SZ, and REG\_MULTI\_SZ) for the pattern you give.
- Use the options in the Look At box to control where Regedit looks for the specified value. By default, it searches for key names (the Keys check box), value names (the Values check box), and value contents (the Data check box), but you can fine-tune it.
- The Match Whole String Only check box tells Regedit to find the entire search string, not just a portion of it. For example, if you search for "Windows" with this check box selected, the search ignores HKLM \SOFTWARE\Microsoft\Windows NT.

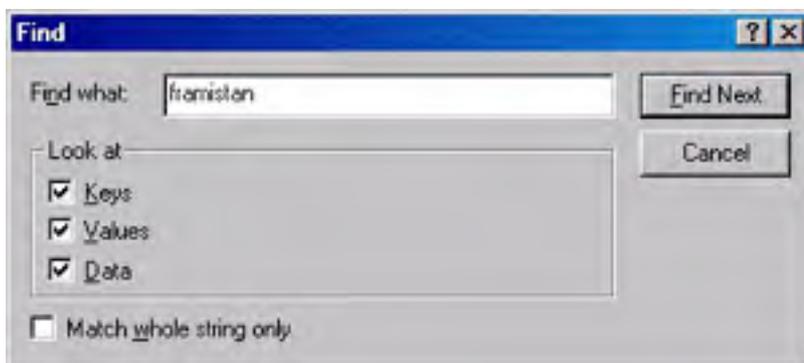

Figure 37-3. Regedit's Find dialog box.

When you have made your selections in the Find dialog box, click Find Next, and Regedit begins searching. Eventually, one of two things happens: either Regedit hits the end of the registry (in which case it tells you that it didn't find any matches), or it finds a match. In the latter case, the match is highlighted; if the match isn't really what you were looking for, choosing the Find Next command on the Edit menu (or F3, its accelerator) continues the search.

Every time you do a search, Regedit starts at the beginning of HKCR and works its way toward the end of HKCC. You can't change this search order, so you might as well get used to it.

## Editing Value Contents

The Modify command on the Edit menu lets you change the contents of the selected value entry. (You can also edit a value by selecting it and pressing Enter.) What you see next depends on the type of value you're editing; separate editor dialog boxes exist for string values, DWORD values, and binary values. Regedit lets you edit data types it doesn't support, such as REG\_FULL\_RESOURCE\_DESCRIPTOR or REG\_MULTI\_SZ; for those types, it opens the binary editor dialog box. The editor dialog boxes themselves are straightforward—each presents the current value and lets you edit it. The keyboard shortcuts for the Cut, Copy, and Paste commands work in the editor dialog boxes, too.

## Adding and Removing Keys and Values

Regedit also allows you to add and remove keys, subkeys, and individual values. Now is a good time to reiterate Microsoft's frequent warning: making unnecessary changes to the registry will likely damage your computer. Be careful when you add data, and be doubly careful when you remove it. (See the sidebar "Being on Your Best Behavior," earlier in this chapter, for more details on why this is a good idea.) To add a new key as a child of the selected key, open the Edit menu, point to New, and choose Key. Regedit creates a new key and selects its name so you can set it correctly. (It defaults to New Key #1.)

The new key automatically has an unnamed value attached to it. You can add more values using the three remaining commands on the New submenu: String Value, Binary Value, and DWORD Value. Note that Regedit can't create any other data types, and if you create a binary value, components interpret it as raw REG\_BINARY data. Creating a new value adds it as a child of the selected key and gives it a default name (New Value #1, New Value #2, and so on), which you can immediately change. Once you're done adding and naming the new values, you can use the standard editor dialog boxes to change their contents to the appropriate values.

Removing values and keys is simple. Select the item you want to remove and choose Delete from the Edit menu, or just press the Delete key. Regedit asks you to confirm your command; once you confirm it, the value or key is immediately removed.

## Importing and Exporting Registry Data

You can import and export registry data from Regedit. The resulting text files are easy to read, and you can safely move them from machine to machine. In fact, the default association for .REG files automatically launches Regedit and loads the contents of the file when you double-click it. The Export Registry File command on the Registry menu lets you save the selected key to a file, and the Import Registry File command does the reverse. Note that importing a registry file from within Regedit happens immediately—a confirmation dialog box appears that tells you whether the import succeeded or not, but you don't get a chance to stop it. (If you launch a .REG file by clicking it, however, you *do* get a confirmation dialog box.)

### Real World

#### Creating Your Own .REG Files

If you need to distribute registry changes to your users, one way to do it is with the policy mechanisms discussed in [Chapter 10](#). However, sometimes using a .REG file makes more sense. For example, sites that don't have direct access to Active Directory resources can't receive group policy updates. You can easily mail out .REG files and have your users double-click them. (Of course, that creates a potential security problem, because anyone can send your users the same kinds of files—make sure to educate them about proper e-mail etiquette.)

The first, and easiest, way to create your own .REG file for distribution is to use Regedit to export the keys and values you want to pass around. As an alternative, you can create your own files using NotePad or any other text editor. Here's an example:

```
Windows Registry Editor Version 5.00

[HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Font
"Auto"="1"
"Debugger"="drwtsn32 -p %ld -e %ld -g"
"UserDebuggerHotKey"=dword:00000000
```

The first line tells Regedit that it's looking at a .REG file. (The blank line that follows is required, too.) After that, the format is easy to understand: define a key by putting its full path in square brackets, and then follow it with each value you want to import, one per line. Enclose value names in double quotes, as well as string value contents. REG\_DWORD values are specified using the DWORD: prefix; they don't have to be enclosed in quotes. You can bundle multiple keys into the same file as long as you add a blank line before each key name; each key can contain any number of values.

One tip: while you're becoming proficient with .REG files, you should practice by using a harmless destination path. Create your own key (say, HKLM \SOFTWARE\Testing123) and import your .REG files under it until you're sure that they make only the changes you want made.

## Connecting to a Remote Machine's Registry

If you're logged on with the right permissions, you can use Regedit to connect to another computer's registry and inspect or edit it. To accomplish this voodoo, your account must have administrative privileges on both the machine on which you're running Regedit *and* the other machine whose registry you wish to inspect or edit. In addition, Group Policy settings might prevent you from gaining access.

Assuming that your credentials are in order, you actually connect to the remote machine by choosing Connect Network Registry from the Registry menu. This command lets you browse your network to find the machine you want to connect to; once you've successfully connected, the computer's name appears in the left pane on the same level as My Computer. You can expand its root keys, poke around in the subkeys, search, and modify data to your heart's content. When you're done, choose Disconnect Network Registry from the Registry menu and select the computer to disconnect.

By default, the Windows 2000 registry isn't adequately protected from anonymous network users. See the section entitled [Securing the Registry](#) later in this chapter for information about protecting the registry from anonymous access.

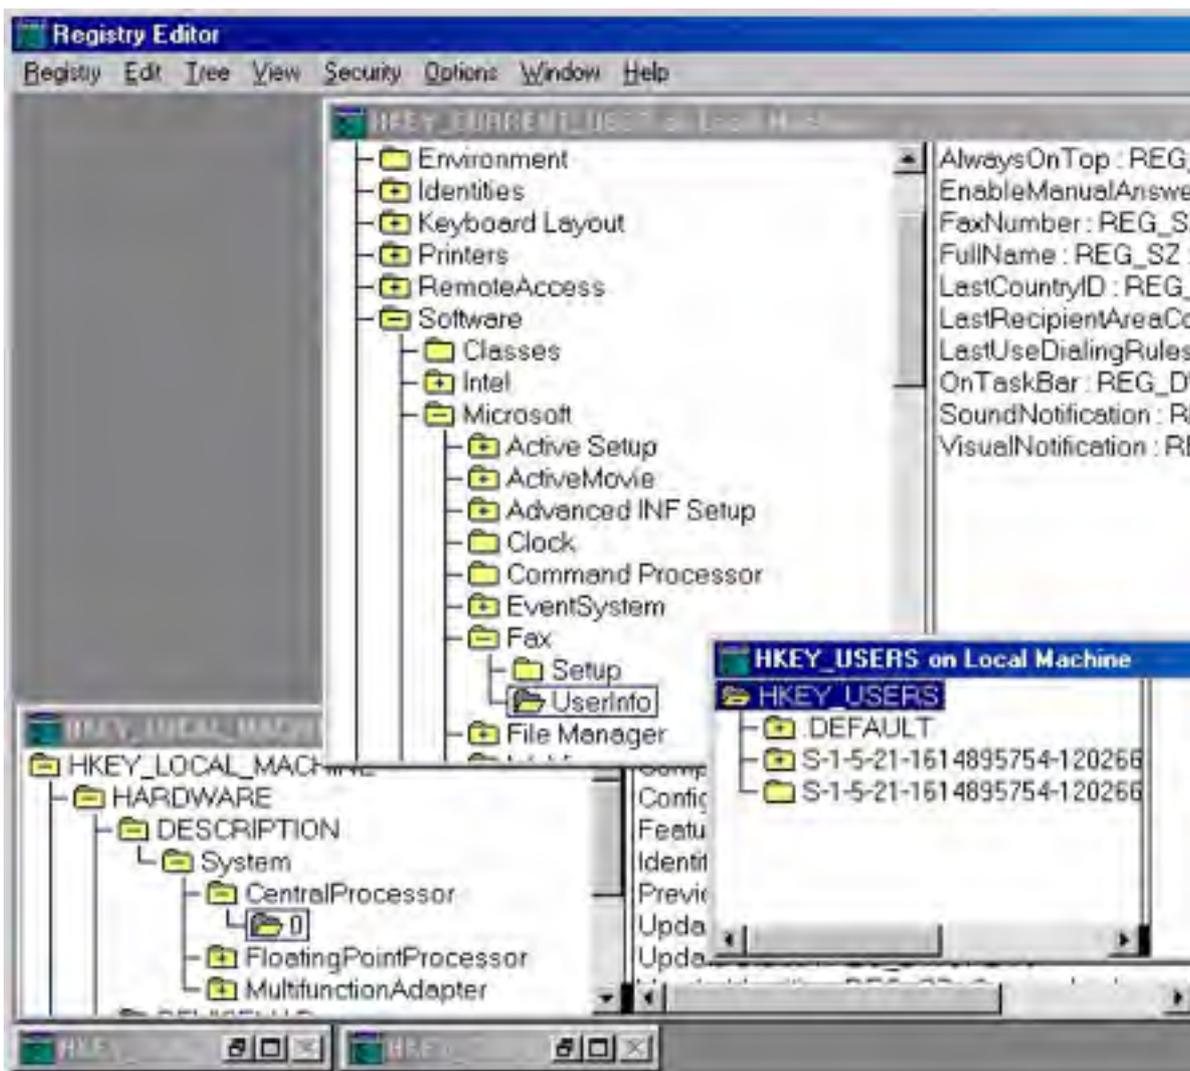

## Renaming Keys and Values

You can change the name of a key or a value by choosing Rename from the Edit menu. In most cases, you won't want or need to do this. Because software looks for specific named values in the registry, changing the name of one of them is a bad idea. However, when you add keys or values based on advice from Microsoft Knowledge Base articles, it's possible to misspell the name (or, worse yet, to type it correctly but find out that the name in the Knowledge Base article is wrong!), and the Rename command is your only alternative to deleting and re-creating the key.

## A Whirlwind Tour of Regedt32

Regedt32 is a more sophisticated and powerful tool than Regedit, but it's a little harder to use. Figure 37-4 shows a representative session. Notice that the user interface doesn't look like Windows Explorer. That's because Regedt32 uses the old-style MDI interface, in which each root key has its own child window. This arrangement actually works as an advantage, because it's easy to make icons of the windows you're not using (especially when you connect to a remote machine).

**Figure 37-4.** The old-style MDI interface and appearance of Regedt32.

## Editing Value Contents

To edit a value, just double-click it and the appropriate editor dialog box opens. This is easy enough, and the editors themselves are easy to understand—except the editor for REG\_FULL\_RESOURCE\_DESCRIPTOR. But that's OK because you shouldn't be editing items in HKLM\HARDWARE anyway, especially because changes won't be saved.

Regedt32 also allows you to edit an item as though it were of a different type. For example, you can edit a REG\_SZ as binary data, or a REG\_DWORD as a string. Most of the time this is fairly useless, but sometimes you'll need to take advantage of this facility to do something like editing a bit mask that's stored as a REG\_DWORD. Use the bottom four commands on the Edit menu—there's one for each supported data type (Binary, String, DWORD, and Multi String) that you can edit.

When using these data type editors, be aware of these quirks:

- In the Binary Editor, you can see items in either binary or hex. The editor marks offsets in the data by showing you a 32-byte offset count on the left and a 0-31 scale across the top. This makes it easy to locate bytes at specific offsets if you need them.
- The Multi-String Editor expects you to enter one string per line, using the Return or Enter keys to skip to the next line.
- The DWORD Editor lets you enter values in binary, hex, or decimal. The editor dialog box is smart enough to ignore any illegal keystrokes (like 2 when editing a binary value).

As with Regedit, Regedt32 doesn't do any sanity checking on the values you enter, so it's your responsibility to make sure that they're correct.

## Adding Keys and Values

To add a key, select the key under which you want the new key to appear. For example, to add a subkey to HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\ESSENT, you would select that key and then choose Add Key from the Edit menu, which opens a dialog box in which you name the new key. Once it's named, the new key immediately appears.

Unlike Regedit, Regedt32 doesn't automatically add an unnamed value to the new key, so if you need that default value for some reason, you'll have to add it manually. To add a value, you use the Add Value command on the Edit menu. Adding a value requires the following steps:

1. Select the key to which you want to add a value, and then use the Add Value command. The Add Value dialog box shown in Figure 37-5 appears.
2. Type the name of the new value into the Value Name field. (Leave it blank if you want to add the <No Name> default value.)
3. Use the Data Type list box to select the type for the new value. Click OK. A type-specific editor dialog box appears; which one you get depends on the type you specified in the Value Name field.

**Figure 37-5.** The Regedt32 Add Value dialog box.

4. Fill in the data you want stored in the value, and then click OK to save the new value or click Cancel to leave the registry untouched.

## Removing Keys and Values

Regedt32 allows you to remove a key (and all its subordinate items) or a single value—just select the target item and press the Delete key (or choose Delete from the Edit menu). By default, Regedt32 makes you confirm what you're doing; if you feel daring, you can save yourself an extra step by clearing the Confirm On Delete command on the Options menu (although we strongly recommend that you leave it selected).

## Loading, Unloading, and Importing Registry Data

Regedt32 offers you two different ways to move data between your registry and an external disk file. The first way involves loading and saving individual sets of keys with the Registry menu's Save Key and Restore commands, whereas the second involves loading and unloading entire hive files with the Load Hive and Unload Hive commands (from the Registry menu).

What's the difference? Recall that hive files are self-contained entities that contain a particular set of keys. When you save a key with the Save Key command, you're really creating a new hive that coexists equally with the predefined hives you read about earlier in the chapter. You can then reattach that hive in two ways: by creating a new key inside an existing hive (which is what the Load Hive command does) or by overwriting a key with the contents of the saved hive, as Restore does.

Creating a new hive with a set of saved keys in it is easy: Select the key you want to save, and then choose the Save Key command from the Registry menu. When prompted, give the new hive file a name, and Regedt32 saves it. Notice that you can't save a hive unless you have adequate permission to all subkeys of the selected key; for example, even when you are logged on as administrator, you can't save HKLM\HARDWARE to a hive.

Once you have saved the hive file, you can load it into a new key or load it over the top of an existing key. To load the hive file into a new key, select the HKLM or HKU root keys and then choose Load Hive from the Registry menu. (It will be disabled the rest of the time.) When prompted, choose the hive file you want to load, and then name the new key you want the hive to be loaded under.

To load a hive file over the top of an existing key, select the key you want to overwrite and then choose Load Key from the Registry menu; after you choose the file and confirm that you're ready to eliminate the selected key, Regedt32 loads the hive and replaces *all* of the key's existing contents with the hive contents (provided, of course, that you have permission to do so).

For example, let's say you save the contents of HKLM\SOFTWARE\AOL to a hive file. If you select HKLM and use the Load Hive command, you can create a new key (called, perhaps, AOL) and load the original contents into it. If you select the existing copy of HKLM\SOFTWARE\AOL and use the Restore command, then whatever is stored in the key before restoring the hive is lost.

## Connecting to a Remote Machine's Registry

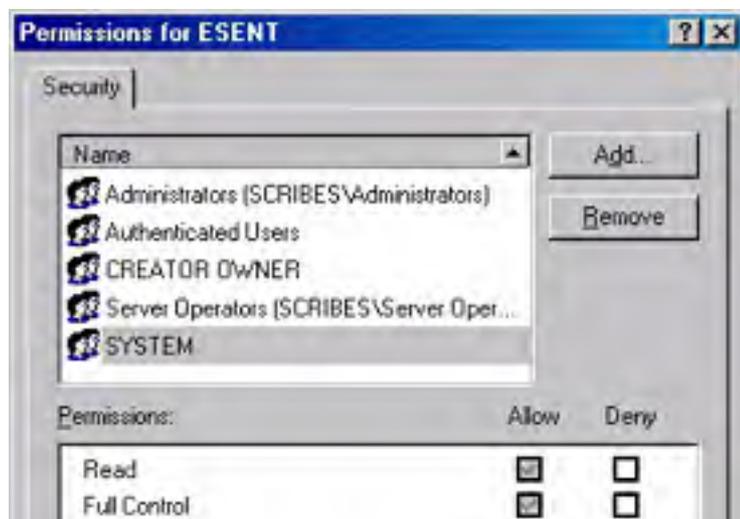

To connect to a remote machine using Regedt32, choose Select Computer from the Registry menu. The familiar Select Computer dialog box opens, in which you can browse your domain or workgroup and pick the machine whose registry you want to administer. You will be connected if you have administrative access to the remote machine; you might also see a dialog box alerting you that the registry keys from the remote machine won't be updated automatically. As soon as you dismiss that confirmation message, two more MDI windows open: one for HKLM and one for HKU. Each window's title includes the name of the remote machine (for example, HKEY\_LOCAL\_MACHINE on FALCON) so you can identify which windows contain what information.

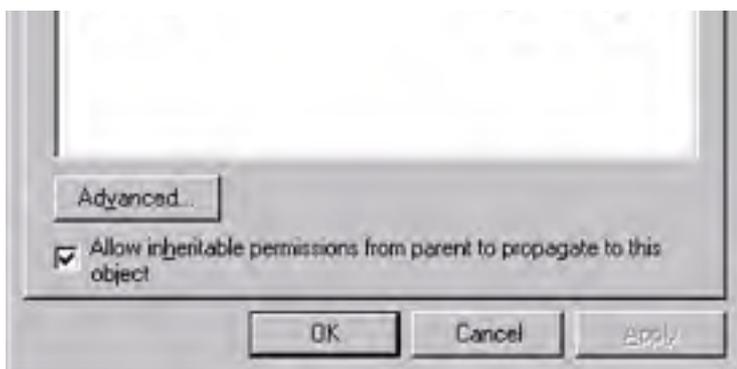

Once these windows are open, you can browse and edit just as you would on the local machine (subject, of course, to permissions on the keys you're editing). When you establish a connection to a remote machine, you're actually making a remote procedure call (RPC) connection, which remains open until you use the Close command to close the last window displaying data from that server.

By default, the Windows 2000 registry isn't adequately protected from anonymous network users. See the section entitled [Securing the Registry](#), later in this chapter for information about protecting the registry from anonymous access.

## Managing Security on Registry Keys

Regedt32 allows you to set security on registry keys by selecting a key and choosing the Permissions command from the Security menu. Everything you learned about setting permissions on files (see [Chapter 9](#)) is still true here, and the basic operations work exactly the same way: you select an object and then grant or deny specific privileges to specific users and groups. Figure 37-6 shows an example. Note that five security principles are shown in the Permissions dialog box: Administrators, Authenticated Users, CREATOR OWNER, Server Operators, and SYSTEM. The exact contents you see on your computer vary according to the security template you have applied; more restrictive templates might change these permissions significantly.

**Figure 37-6.** The standard Permissions dialog box for a registry key.

In the Permissions dialog box, you can grant and deny the Read and Full Control permissions on keys. However, in general, you shouldn't do so on keys owned by the system; that's why Microsoft includes the security templates. You can easily set permissions accidentally that are so restrictive that software that needs registry access can't get it, or you can easily err in the opposite direction and set permissions that are unnecessarily loose.

When you set permissions using the Permissions dialog box, be sure to note whether you select the Allow Inheritable Permissions From Parent To Propagate To This Object check box. By default, this check box is selected, so when you apply new permissions, they are automatically propagated to all subkeys of the selected key. Depending on the level at which you apply these permissions, inheritance might have unintended consequences—if you loosen permissions on a key, you might accidentally loosen permissions on a subkey that should remain secure. Before you change permissions on any keys, be sure to make a good backup of your registry *and* make a note of the changes you've made so you can reverse them later.

Settings that belong to applications, of course, are another matter altogether. In Windows NT 4, the only way to determine appropriate permissions for most applications' keys is to tighten them down as much as possible, then gradually relax controls until the application starts working properly. Unfortunately, this approach is still required in Windows 2000.

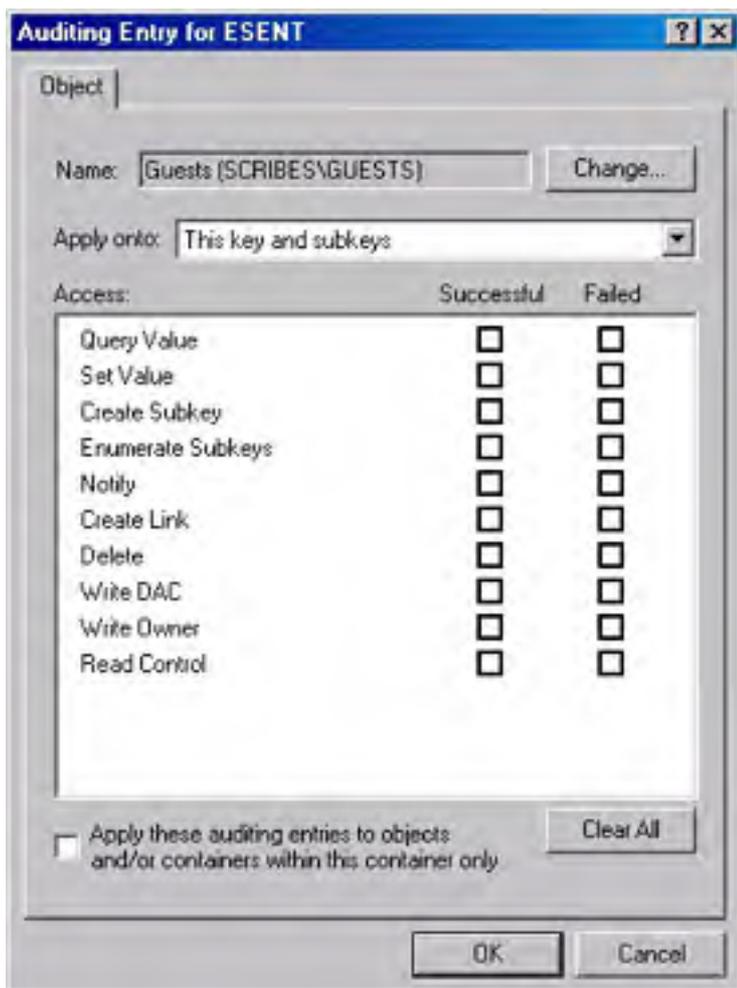

When you click Advanced in the Permissions dialog box, you open the three-tabbed Access Control Settings dialog box. Each tab has a special meaning for registry keys:

- The Permissions tab's View/Edit button allows you to assign more granular permissions to individual users. For example, you can fine-tune who can create new values in a key by adjusting the setting for the Set Value permission. Table 37-1 shows the permissions you can grant or deny. Because most registry keys gain their permissions from inheritance, be aware that you might not be able to make changes here without turning inheritance off.
- The Auditing tab lets you set auditing permissions for the selected key. First, you specify the users or groups whose actions you want to audit; next, you specify which particular actions you want recorded (Figure 377). Note that the actions you can audit are the same as the permissions shown in Table 37-1. You can audit successful or failed attempts to exercise these permissions.
- The Owner tab lets you reassign ownership of the selected key, either with or without propagating that change to all subitems beneath it. Note that depending on your security settings, a change in ownership might result in an audit trail being generated.

**Table 37-1.** What the registry permissions mean

Permission	What Happens When Granted
Query Value	Allows user to query the registry for a specific value by providing the full path to that value
Set Value	Allows user to create new values beneath a key or to overwrite an existing value
Create Subkey	Allows user to create a new subkey beneath the specified key
Enumerate Subkeys	Allows user to get a list of all subkeys of a particular key; similar to directory traversal of an NTFS volume
Notify	Allows user to register a callback function that is triggered when the selected

	value changes
Create Link	Allows user to create a link to a specified key (just as HKCR links to HKLM\Classes)
Delete	Allows user to delete an individual value or key
Write DAC	Allows user to rewrite access controls on the specified key
Write Owner	Allows user to take ownership of the selected key
Read Control	Allows user to read the discretionary access control list (DACL) for the specified key

**Figure 37-7.** Assigning auditing permissions.

### Miscellaneous Useful Tricks

Four useful Regedt32 commands don't really fit elsewhere in this exposition:

- Regedt32 can't search values, but it can look for a key with a specified name. The Find Key command on the View menu lets you search the registry (beginning with the selected key and proceeding either up or down) for a particular key name. Searches can be case sensitive or not, and you can choose to search for the supplied text on its own or when it appears as part of another name.
- You've already briefly worked with the Confirm On Delete command on the Options menu. When selected (as it is by default), Regedt32 asks you to confirm your intentions when you attempt to remove a key.

- The Read Only Mode command on the Options menu toggles Regedt32 between read-only and normal modes. Read-only mode is a great boon because you can't mess anything up when it's on. It's a great way to learn by exploring with no risk of accidental damage.
- The Auto Refresh command on the Options menu controls whether Regedt32 automatically updates your root key windows periodically. By default, it is enabled, so Regedt32 updates local windows by itself. On machines where lots of registry changes exist, you might want to disable automatic updates and use the View menu's Refresh All and Refresh Active commands to trigger updates only when you need them.

## Securing the Registry

For the most part, the Windows 2000 registry is secure because only locally logged on users with sufficient permissions can access it, and only Administrators and Backup Operators can access the registry from across the network. At least that's the theory, but without Service Pack 3 you might still be vulnerable.

To be sure that the registry is adequately protected against anonymous network access, and the Local Security Authority (LSA) component of the registry is closed to anonymous users, follow these steps:

1. Open Regedt32.
2. Go to the HKEY\_LOCAL\_MACHINE\SYSTEM hive.
3. Open the \CurrentControlSet\Control\SecurePipeServers key.
4. Select the \Winreg value.
5. Choose Permissions from the Security menu and verify that Administrators have Full Control and that Backup Operators have Read access (if you want to enable Backup Operators to back up the registry from across the network).

If the key and values mentioned here don't exist, see Microsoft Knowledge Base Article Q153183 for information about creating them.

Windows 2000 systems that were upgraded from Windows NT might not have the appropriate registry ACLs, because existing ACLs aren't changed during the upgrade process. If this is the case, you should refer to the "Default Access Control Settings in Windows 2000" white paper for the appropriate ACLs. This document is available at <http://www.microsoft.com/technet/prodtechnol/windows2000serv/maintain/security/secdefs.asp>.

Anonymous access to the Local Security Authority (LSA) should be restricted, making it difficult for anonymous users to obtain security information from a computer. Windows 2000 systems running Service Pack 3 or newer should have anonymous access restricted, but to verify the restriction, use the following steps:

1. Open Regedt32.
2. Go to the HKEY\_LOCAL\_MACHINE\SYSTEM hive.
3. Open the \CurrentControlSet\Control\LSA key.
4. Double-click the \RestrictAnonymous value and verify that the data reads 1. If the value doesn't exist, create a new key with the following attributes:
  - **Key Name** restrictanonymous
  - **Class** REG\_DWORD
  - **Data** 1

## Backing Up and Restoring the Registry

In [Chapter 35](#) you learned how to use the Windows 2000 Backup application to back up and restore the overall state of your system. This is somewhat different from Windows NT, where you can easily back up the registry by making an emergency repair disk (ERD) or running Ntbackup and selecting the Include Local Registry check box.

The reason for these differences revolves around Active Directory. In Windows NT, a registry backup contains a copy of the SAM database for the local machine (as well as the domain SAM, when you back up a domain controller). In a network using Active Directory, the directory contains most of the information that was formerly in the SAM, which is why you have to perform a two-step recovery process for domain controllers. (See the section entitled [Restoring the System State](#) in [Chapter 35](#) for more details on how the process works.) First you restore the local machine's SAM registry hive so you can log on, and then you restore the Active Directory store.

As a side effect of the way these changes are implemented, the emergency repair disk no longer contains registry information—the only backup copy on the computer itself is in the `%SystemRoot%\Repair` folder. With no ERD to fall back on, it's especially important to make regular and usable backups.

## Choosing a Backup Method

Because the registry is more than an ordinary file, it makes sense that you have to give your backup and restore procedures more than the ordinary amount of thought. You can back up and restore your registry in other ways besides making a complete backup of the entire system state. Of course, you should still perform regular backups of your data *and* the system state for each computer you administer. It is still useful to back up the registry by itself, because the registry is where most applications and system components store their preferences and settings.

### Windows 2000 Backup

When you use the Windows 2000 Backup utility to back up the system state, it includes a complete copy of that machine's registry. It also includes copies of the system volume (on domain controllers), certificate data, COM+ class registration information, and other information that is unrelated to what is in the registry. On the other hand, Windows 2000 Backup automates the process of backing up the registry, so it's easy to use and understand. In addition, keeping your registry data with the rest of your server data ensures that you'll be able to recover everything without having to hunt for third-party CDs, drivers, and the like.

### The Emergency Repair Disk

You can use Windows 2000 Backup's Emergency Repair Disk feature to back up the registry, too; most Windows NT administrators use this as their first line of defense against a failure, because the repair tools included on the Windows NT 4 CD can restore registry data from an ERD. Windows 2000 uses ERDs too, but they don't include registry information. When you use Windows 2000 Backup to create an ERD, you must manually specify that you want registry information backed up, and it doesn't get stored on the ERD floppy disk itself—you have to manually save a copy and then replace registry files during recovery by copying them using the recovery console.

### Third-Party Products

Many Windows NT and Windows 2000 sites use third-party backup tools like Computer Associates' ARCserve or St. Bernard Software's OpenFile Manager. In general, these tools provide more sophisticated backup capabilities than the tools that Microsoft ships; for example, ARCserve can use tape autoloaders and optical media, and it can back up machines running several operating systems. If you're using a third-party backup product, you might want it to back up your registry, too. Be sure that you have everything on hand that you would need to restore data backed up with a third-party tool, and double-check to make sure that your vendor's software is fully compatible with the version of Windows 2000 that you're running.

### Do-It-Yourself Backups

Because Regedt32 allows you to load and unload hive files and keys, you might think that you can approximate what Windows 2000 Backup does by manually saving to a hive file the keys you're most interested in, copying the resulting files someplace safe, and reloading them if you need them. This approach works fine, but it's labor-intensive, because there's no way to automate the process of telling Regedt32 which keys to save. (At that point, you might as well use the Win32 registry programming interfaces to write your own backup program!)

## Backing Up the Registry

When you're ready to make a backup, you'll be happy to see how simple the process is—it's a great improvement over Windows NT 4.

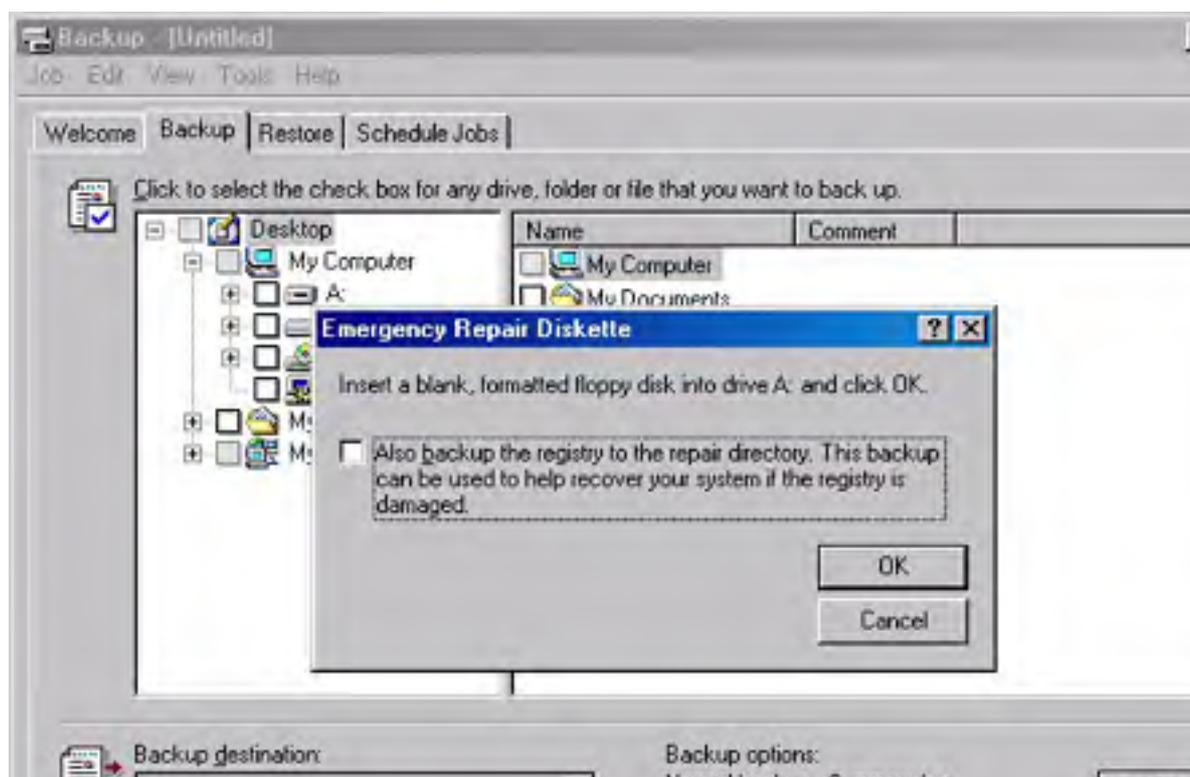

## Using Windows 2000 Backup

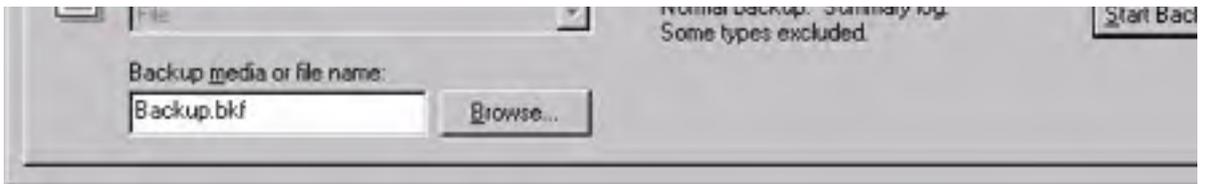

[Chapter 35](#) covered the mechanics of backing up and restoring your system state, of which the registry is a small but critical part. If you're comfortable with the process of making and restoring a system state backup with Windows 2000 Backup, you're in good shape. However, a quick review might be in order:

1. Launch the Windows 2000 Backup application; when it appears, click the Backup tab.
2. Specify the backup device or location you want to use with the Backup Destination and Backup Media Or File Name options.
3. If necessary, expand the My Computer icon.
4. Select the System State check box. (Remember, the system state items are interrelated and can't be backed up individually.)
5. Click Start Backup. When the system backs up the system state information, the registry files are included, so you can restore them later.

## Saving a Copy of the Registry

When you create an ERD, Windows 2000 Backup offers to save a copy of the registry for you (Figure 37-8). When you select the check box, an extra copy of your registry hive files is stored in the `%SystemRoot%\Repair\REGBACK` folder. Besides the standard hive files (SECURITY, SAM, SYSTEM, SOFTWARE, DEFAULT, Ntuser.dat, and Usrclass.dat), you'll also see files representing any hives you have manually loaded into your registry.

**Figure 37-8.** Saving a copy of the registry.

Once Windows 2000 Backup has finished copying these files, they're all yours—you can move them, copy them, back them up, or do whatever you want to. In particular, you can compress them and store them on a floppy, or you can move them to any kind of removable media that you have on hand.

If you store your backup files in compressed format or on any medium that requires a special device, make sure you will be able to access the files when you're restoring the machine.

## Restoring the Registry

The process of restoring the registry from a system state backup is discussed at length in [Chapter 35](#), so we won't go into it here. However, just be aware that if you have a backup of the `%SystemRoot%\Repair\REGBACK` folder, you can use the system's Recovery Console to restore the backup of the registry. Once you start the Recovery Console, you can copy the registry files you need to restore back to their normal locations on disk, and then restart the machine. Remember that by doing so, you'll wipe out any changes you've made since the time the files were backed up.

## **Summary**

Windows 2000 depends on the registry for storing and retrieving vital configuration data. Knowing what's in it, how and when to edit the registry, and how to back it up and restore it is vital for system administrators. In particular, knowing how Regedit and Regedt32 work and what they can do is a key skill you'll need to keep your Windows 2000 machines healthy. The next chapter addresses troubleshooting relative to isolating and recovering from network troubles of all kinds.

# Chapter 38

## Troubleshooting and Recovery

Disasters occur no matter how good an operating system is. Furthermore, it is the nature of disasters to occur unexpectedly and at the most inconvenient time. This chapter focuses mainly on disaster scenarios involving a nonbooting system. Other scenarios are covered elsewhere in this book (for example, for problems with devices, refer to [Chapter 6](#); for printing problems, refer to [Chapter 8](#)). Additional help is available at Microsoft's Help and Support center (<http://support.microsoft.com/default.aspx>). Be sure to read [Chapter 34](#)—before running into trouble—for details on disaster preparation.

## Troubleshooting Startup Problems

A server that won't boot defines "emergency" for most system administrators. Therefore, you'll want to haul out your disaster recovery plan (as described in [Chapter 34](#)) and follow the procedures step by step. If you're reading this section for the first time because you're in the middle of a disaster and you don't have a disaster recovery plan, don't panic. You can still survive.

The recovery steps outlined in this section proceed from least drastic to most drastic. In any recovery procedure, always adopt a minimalist approach. Start with the least invasive steps. If they succeed, you'll have minimized both the loss of information and the impact on the network and your users.

Recovering a domain controller is no different from recovering a normal server, except if you want to restore the Active Directory and SYSVOL volume from a backup. To do this, you need to boot the server using the directory services restore mode, as described in [Chapter 34](#).

### Figure Out What Happened

Computers rarely "just fail." Usually something happens to cause a system to fail. Therefore, the first thing to do is ask yourself what changed between the last time the system started and now. If you performed any of the following tasks since the last reboot, an imaginary red flag should be waving in front of your eyes:

- Added or removed a device
- Updated a device driver
- Installed a hot fix, patch, or service pack
- Installed or uninstalled a program, especially a utility program
- Used a configuration tool, MMC snap-in, or utility program to alter system or disk settings
- Edited the registry

If you recently installed a new device driver, it's a good bet that the new driver is to blame. Try booting into safe mode (discussed later) and switching back to an older driver, or use the Last Known Good startup option.

If you installed a program, hot fix, patch, or service pack, you can try booting into safe mode and uninstalling the suspect program or you can use the Last Known Good startup option. You can also use this approach to recover from a registry-related difficulty.

If your system started making bad mechanical sounds or producing smoke, you might have hardware trouble. After putting out any flames, check to see if all the fans in the system are functioning properly and listen to determine whether the hard drives are still working. If you can't get the system to boot to its initial startup screen (displayed by the BIOS before Windows has a chance to load), you definitely have hardware trouble, most likely with the CPU, power supply, or RAM.

Display malfunctions can often be fixed simply by booting using the Enable VGA Mode option, available from the Windows Advanced Options menu (discussed in the next section). Once you have booted into Windows, select a more conservative display setting (lower the resolution, refresh rate, or both) or choose a different display driver.

### Using the Last Known Good Configuration

It's what every system administrator dreads: you reboot the system, and it hangs or crashes. Although this is indeed a dire situation, fear not (yet), for Windows comes with an arsenal of tools that you can use to get the system running again. The first tool to try is the Last Known Good Configuration (if your system boots but produces an error message, skip to the section of this chapter entitled [Fixing the Underlying Problem](#)).

The Last Known Good boot option can help start a Windows system that won't boot because of changes made to the registry (usually by a new device driver). As such, when you start a computer using the last known good configuration, Windows restores the HKEY\_LOCAL\_MACHINE\System\CurrentControlSet registry key to the state it was in immediately after the last successful boot (other registry keys are unaffected).

The Last Known Good Configuration option is probably the quickest way to get a system back up and running, if it works. To use this approach, follow these steps:

1. Restart or turn on the computer.
2. If the computer displays a choice of operating systems select the Windows installation into which you want to boot and then press F8. Otherwise press F8 when the computer displays the Starting Windows text (but before any color images are displayed).
3. Choose Last Known Good Configuration and then press Enter. Windows attempts to start using the registry settings from the last successful boot. If this fails, move on to starting using Safe Mode. If it succeeds, evaluate what caused the trouble in the first place (probably a new device driver) and then plan future maintenance of the system accordingly (that is, don't use the same driver again).

## Using Safe Mode

Windows safe mode, introduced with Windows 95, and brought to the Windows NT codebase by Windows 2000, is a special diagnostic mode that disables all unnecessary services and drivers, maximizing the chances of booting successfully. As such, it's one of the most important troubleshooting tools for dealing with a Windows machine that won't boot.

Once the computer boots into safe mode, you have full access to the system, making it much easier to fix the underlying condition. To boot using the Safe Mode option, use the following procedure:

1. Restart or turn on the computer.
2. If the computer displays a choice of operating systems, select the Windows installation into which you want to boot and then press F8. Otherwise press F8 when the computer displays the Starting Windows text (but before any color images are displayed).
3. Choose Safe Mode and then press Enter. Windows attempts to boot into safe mode.

You can also choose Safe Mode With Networking if you require network access (and the fault doesn't lie in the networking subsystem) or Safe Mode With Command Prompt to bypass the Explorer shell and instead use simply a command prompt interface (further increasing the chances of a successful boot).

4. If Windows successfully boots into safe mode, you now have the full power of Windows at your troubleshooting disposal. See the section entitled [Fixing the Underlying Problem](#) later in this chapter for information about what to do at this point.
5. If Windows doesn't boot successfully, you need to move on to a more drastic approach, such as attempting to repair your current installation using the Recovery Console (as discussed in the sections that follow). You should also test your system for viruses, because some can prevent Windows from booting.

## Using the Emergency Repair Process

If you can't boot using one of the boot options mentioned earlier in this chapter, try the emergency repair process. This method involves booting from either the Windows 2000 CD-ROM or the four setup disks, and then using the Windows 2000 repair process. To do so, follow these steps:

1. Boot from the Windows 2000 setup disks or the Windows 2000 CDROM.
2. Type *R* to choose to repair an existing Windows 2000 installation.
3. Type *R* again to use the emergency repair process to fix an existing installation of Windows 2000.

4. Type *F* to use the Fast Repair option to automatically repair registry faults, system files, the boot sector of the boot volume, and problems with the startup environment if you have a dual-boot system.

Fast Repair repairs registry errors by using a backup copy of the system registry that was created when Windows 2000 was installed. Using this option might result in the loss of settings and preferences created since that installation. If you want to keep these settings, restore from a recent backup after you get the system booting properly.

Type *M* to use the Manual Repair option to manually specify what you want to repair, although the registry cannot be repaired in this way. (You can use the Recovery Console to manually repair individual registry files or to replace the entire registry if you like.)

5. If you chose Manual Repair, select the repair options you want by using the arrow keys and pressing Enter to select or clear each check box. Table 38-1 provides a list of the repair options. When you're done, select the Continue option and press Enter.
6. After you've selected the repair options, insert the emergency repair disk (ERD) and press Enter. (Creating an ERD is discussed in [Chapter 34](#).) If you don't have an ERD, type *L*. Windows 2000 searches for the installation and displays any that it finds. To repair the found installation, press Enter; otherwise press Esc.

**Table 38-1.** Manual Repair options

Option	Purpose
Inspect Startup Environment	Examines the files used to boot the computer (Boot.ini, Ntldr, and so on) and fixes any faults it finds.
Verify Windows 2000 System Files	Scans the Windows 2000 system files for changes or corruption and restores changed files from the Windows 2000 CD-ROM.
Inspect Boot Sector	Checks the master boot record (MBR) and fixes any problems that were preventing the Windows 2000 system from booting. Note that this doesn't eradicate MBR viruses.

## Using a Boot Disk to Recover the System

You don't need us to tell you how to use a boot disk (insert disk, boot computer). However, it's useful to know a little more about what a boot disk does and doesn't do. (For information about creating a Windows 2000 boot disk, see [Chapter 34](#).)

Because Windows 2000 Server is installed on an NTFS partition (avoid FAT and FAT32 partitions on servers for security reasons), you can't just pop in any old Windows 98 boot disk and access the computer's hard drive. Instead, either use a specially made Windows 2000 Server boot disk, or boot using the Recovery Console (covered later).

When you boot the system from a Windows 2000 Server boot disk, you are bypassing the hard disk's master boot record, boot sector, and startup environment, but do not end up at a command prompt. Instead, the system boots straight from the floppy drive into the operating system you choose from the floppy's Boot menu (Windows 2000 Server).

This provides access to Windows on a system with a corrupted MBR, boot sector, or startup environment. After the system boots properly, you've narrowed down the difficulty to the Boot.ini file, MBR, boot sector, or Windows startup environment. You can edit the Boot.ini file and replace missing or corrupted Windows files such as Ntldr or Ntdetect.com while in Windows (as discussed later in this chapter), but to fix the MBR or boot sector you'll have to reboot using the Recovery Console, which is discussed next.

## Using the Recovery Console

The Recovery Console is an incredibly powerful tool that was introduced with Windows 2000. It quite definitively eliminates the need for FAT system partitions or parallel recovery installations of Windows.

The Recovery Console allows secure access to the root directory and system folder of a nonbooting Windows computer using a special command prompt. At the command prompt, you can perform numerous recovery tasks, such as the following:

- Fixing disk errors
- Fixing the MBR and boot sector
- Starting and stopping services
- Extracting and copying files

Before you use the Recovery Console, it's important to understand its limitations. Although you can use the Recovery Console to securely log on to a Windows 2000 Server installation and access any NTFS, FAT, or FAT32 drives, by default you can use only the root folder of each drive, the *%SystemRoot%* folder and subfolders, the *Cmdcons* folder (if present), and any removable media drives attached to the system. By default you cannot copy files from the hard disk to a floppy disk, although you can copy files from a floppy to the hard disk or from one hard disk to another.

You can enable full access to your hard drives from the Recovery Console by changing the Recovery Console setting in the relevant Group Policy object. Just keep in mind that this exposes potentially sensitive data to anyone who can boot the system using the Recovery Console (in other words, anyone who gains access to the local system administrator password and physical access to the server).

To use the Recovery Console, follow these steps:

1. Boot from the Windows CDRom or setup disks (you might have to change the boot order in your BIOS to boot from the CD-ROM first). You can also boot directly into the Recovery Console, if you've installed it (see [Chapter 34](#)).
2. After Windows Setup loads, type *R* to choose to repair an existing Windows 2000 installation. Then type *C* to access the Recovery Console.
3. Enter the number corresponding to the Windows 2000 installation to which you want to log on and press Enter.
4. Enter the local system administrator password. (This is the password you originally assigned when installing Windows 2000.)
5. Type *help* at the command prompt for a list of available commands, or enter the commands you want to execute. See [Appendix D](#) for a list of the commands available and a description of what they do.
6. Some commands you might want to use include the following:
  - *chkdsk /r* to locate bad sectors and fix them
  - *disable* to disable a service or driver you suspect might be causing trouble
  - *diskpart* to view and modify disk partitions
  - *expand* to extract compressed files
  - *fixboot* to write a new boot sector onto the specified partition
  - *fixmbr* to write a new master boot record (MBR) on the specified disk drive
  - *format* to format a disk
  - *listsvc* to list the services and drivers installed on the system

The password used to log on to a domain controller is the directory services restore mode password you set when you promoted the computer to a domain controller. To change the password, restart the domain controller in directory service restore mode and type *net user administrator new\_password* at a

command prompt, replacing *new\_password* with the desired password (or use the Local User and Groups snap-in). See Microsoft Knowledge Base article Q239803 for more information.

## Booting from Mirrored Boot Partitions

If the primary boot drive fails on a system with mirrored boot partitions, the system continues to operate normally until the next reboot, at which point the system fails unless the drives and controllers involved in the mirror set are *exactly* the same (down to the firmware revisions and partitioning schemes).

If you can't boot a system with a failed mirror set, you'll need to create a boot floppy disk using the procedure outlined in [Chapter 34](#), with one additional step. Edit the Boot.ini file on the floppy to change the ARC name of the boot partition to point to the secondary mirror drive, rather than the primary one. So, for example, if you have a pair of Adaptec 38SCSI adapters and you have duplexed your boot drives using the SCSI BIOS to boot from the primary partition on the first hard disk, you might have a line like this in your Boot.ini file:

```
multi(0)disk(0)rdisk(0)partition(1)\WINNT="Microsoft Windows 2000  
Advanced Server" /fastdetect
```

However, if you need to boot from the secondary mirror pair, you would need to change that line to

```
multi(1)disk(0)rdisk(0)partition(1)\WINNT="Microsoft Windows 2000  
Advanced Server" /fastdetect
```

Once you've booted your system and replaced the failed drive, re-create the mirror (as described in [Chapter 15](#)).

### More Info

See Microsoft Knowledge Base article Q167045 or the *Microsoft Windows 2000 Server Resource Kit* for more information about how Windows 2000 Server and Windows 2000 deal with failed mirror sets.

## Restoring a Completely Failed Server

So the worst has happened. You've had a server totally crash. You've replaced the failed hard disk, and you've got a backup tape to restore with, but you have to be able to boot before you can restore the tape.

The first step is to reinstall Windows 2000 Server on the new disk. Use a temporary directory name so it doesn't interfere with the original installation. Once you have the minimal system installed, you can restore the registry and partition information using your emergency repair disk and the backup tape. Run the Windows 2000 Backup program and restore the operating system and System State. The tape drive should be locally attached, and you'll want to make sure you select the Restore Local Registry option to recover the rest of your registry information. Restart the server and you're ready to go.

This process can take a significant amount of time. In an environment such as manufacturing or another production operation, where the server *must* be available, you might find that you can't afford the time this process takes. The most efficient solution to this dilemma is to mirror or, better yet, duplex the system disk, preferably with a hardware RAID controller. However, even using Windows 2000 Disk Management to mirror the system disk will save you significant amounts of downtime.

## Fixing the Underlying Problem

Once you have the system booting again, you might need to perform some further troubleshooting. Booting the computer successfully in safe mode is a relief, but it is of little consolation if you still can't boot normally. Unfortunately, solving the underlying trouble can be very complex and, as a result, the recommendations here are only a starting point. If these recommendations don't fix the trouble, consult the *Microsoft Windows 2000 Server Resource Kit* and the Microsoft Knowledge Base for further information. With that stipulation, the advice dispensed in the next several sections can help you fix the majority of the difficulties you are likely to encounter.

When troubleshooting, act like a scientist running an experiment. Change only one thing at a time to minimize the likelihood of confounding variables. Also, do some deep thinking about the results you get. If you see that the system is hanging on a certain service that is failing, check to make sure that the failing service isn't dependent on some other services that aren't starting. For your own sanity, start with the least painful steps first. Save formatting your hard disk and reinstalling Windows for last.

## Maybe It'll Go Away

The first thing to try after successfully booting a system in safe mode is to attempt rebooting normally. Oddly enough, this actually works sometimes and is worth a try if the system just mysteriously refuses to boot one day.

## Check the Microsoft Knowledge Base

If Windows displays any specific error messages, go to Microsoft's online Help and Support center (<http://support.microsoft.com/default.aspx>) and search under the Windows 2000 Server category for a few keywords from the error message. Often this speeds the troubleshooting process by letting you quickly home in on the cause. Otherwise, use the rest of this chapter to troubleshoot it yourself (but refer back to the Knowledge Base if you manage to generate any notable error messages during your troubleshooting process).

## Undo Anything You've Changed

As mentioned earlier in the chapter, malfunctions are usually the result of some action: installing a new driver or program, changing a registry setting, formatting the system drive, and so on. Therefore, the first thing to do once you get the system booting again is to undo anything that you've done recently (if possible).

Start by booting using the Last Known Good Configuration (if you haven't already). Also trying uninstalling any recently added drivers, or programs (especially utilities), and removing or disabling any recently added devices (see the section entitled [Check Device Manager](#) later in this chapter for more information about checking for hardware problems).

## Check Event Viewer

One of your first moves when trying to track down the source of system problems should be to check Event Viewer, which is available either as a part of the Computer Management console or by itself from the Administrative Tools folder. Event Viewer (Figure 38-1) often gives you a string of clues as to the cause of the trouble and sometimes even tells you what to do to fix it. For more information about using Event Viewer, see [Chapter 10](#). Carefully examine errors or warnings in the system log and other relevant logs. Don't forget the Information events, sometimes a source of valuable clues.

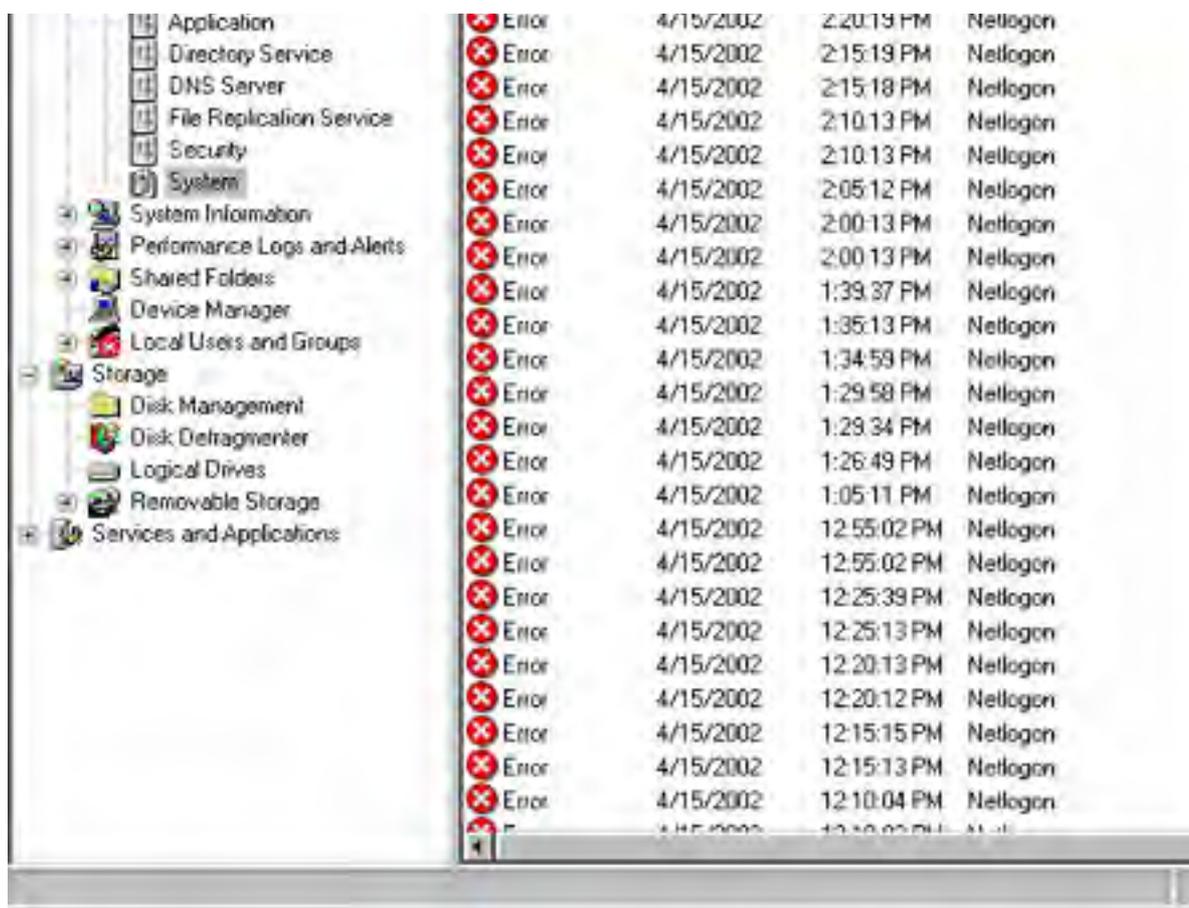

Figure 38-1. The Event Viewer window.

## Check Device Manager

If a device in the system is causing a resource conflict or some other impasse, check Device Manager, located in the Computer Management snap-in. Examine the system for devices with conflicts or errors, and consider disabling these devices or removing them from the system. (Note that removing them from Device Manager usually just causes the devices to be redetected the next time the system boots, potentially causing the same problem.) It is standard practice when troubleshooting resource conflicts to disable or remove every device in the system that you can boot without (such as sound cards, network cards, and modems). Once the system works normally, add the devices back one by one until the problem reappears. Then you can troubleshoot the device in question. [Chapter 6](#) includes more information about troubleshooting hardware.

Advanced Configuration Power Interface (ACPI) systems automatically configure all PCI devices, preventing you from changing a device's resource settings to resolve a conflict. To deal with resource conflicts, remove the devices in question from Device Manager and allow it to rescan them, or change which PCI slots the cards are plugged into.

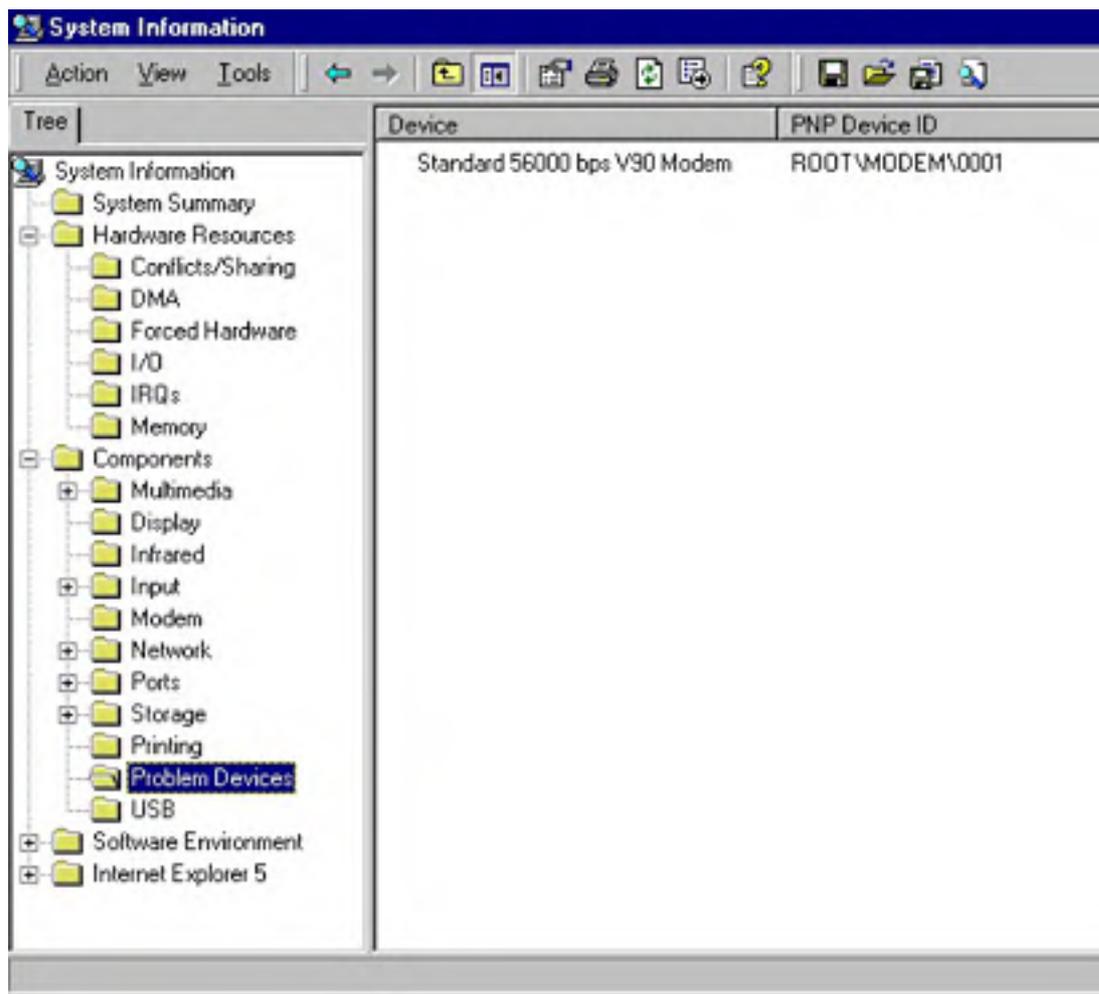

## Use System Information to Check the Configuration

Besides checking Event Viewer and Device Manager, use the Windows 2000 Server system information tools to gather further information about the system and any possibly problematic hardware or software (although most of the time you can find and fix trouble more quickly using Event Viewer and Device Manager alone).

To view system information, use the following procedure:

1. Click Start, choose Programs, Accessories, System Tools, and finally System Information (or type `msinfo32` in the Run dialog box or at a command prompt).

2. Select Components and then Problem Devices, as shown in Figure 38-2. Make a note of any devices listed here and then use Device Manager to troubleshoot them.

**Figure 38-2.** The System Information console in the Computer Management window.

3. In System Information, select Hardware Resources and then Conflicts/Sharing to view a list of hardware conflicts and shared resources. Note that most shared resources don't cause any difficulties on a modern system, but some devices don't like to share, so this is a place to check if a device is causing trouble.
4. If you suspect an ill-behaved startup program might be the source of your difficulty, select Software Environment, and then Startup Programs to see a list of programs that start with Windows.

## Check the Services

As with Microsoft Windows NT, checking the services in Windows 2000 can be invaluable in solving a dilemma. If a key service isn't starting, you're going to have trouble. Make sure that key services are set to start automatically, and consider disabling services that could potentially cause trouble, or at least set them to start manually (although an automatically starting service starts any services it needs—even services set to start manually—unless the services are disabled).

You might also want to specify what actions to take if the service fails. To perform some of these actions with the Services snap-in, follow these steps:

1. Launch the Services snap-in from the Administrative Tools folder on the Programs menu.

2. Use the window shown in Figure 38-3 to view the status of the services.

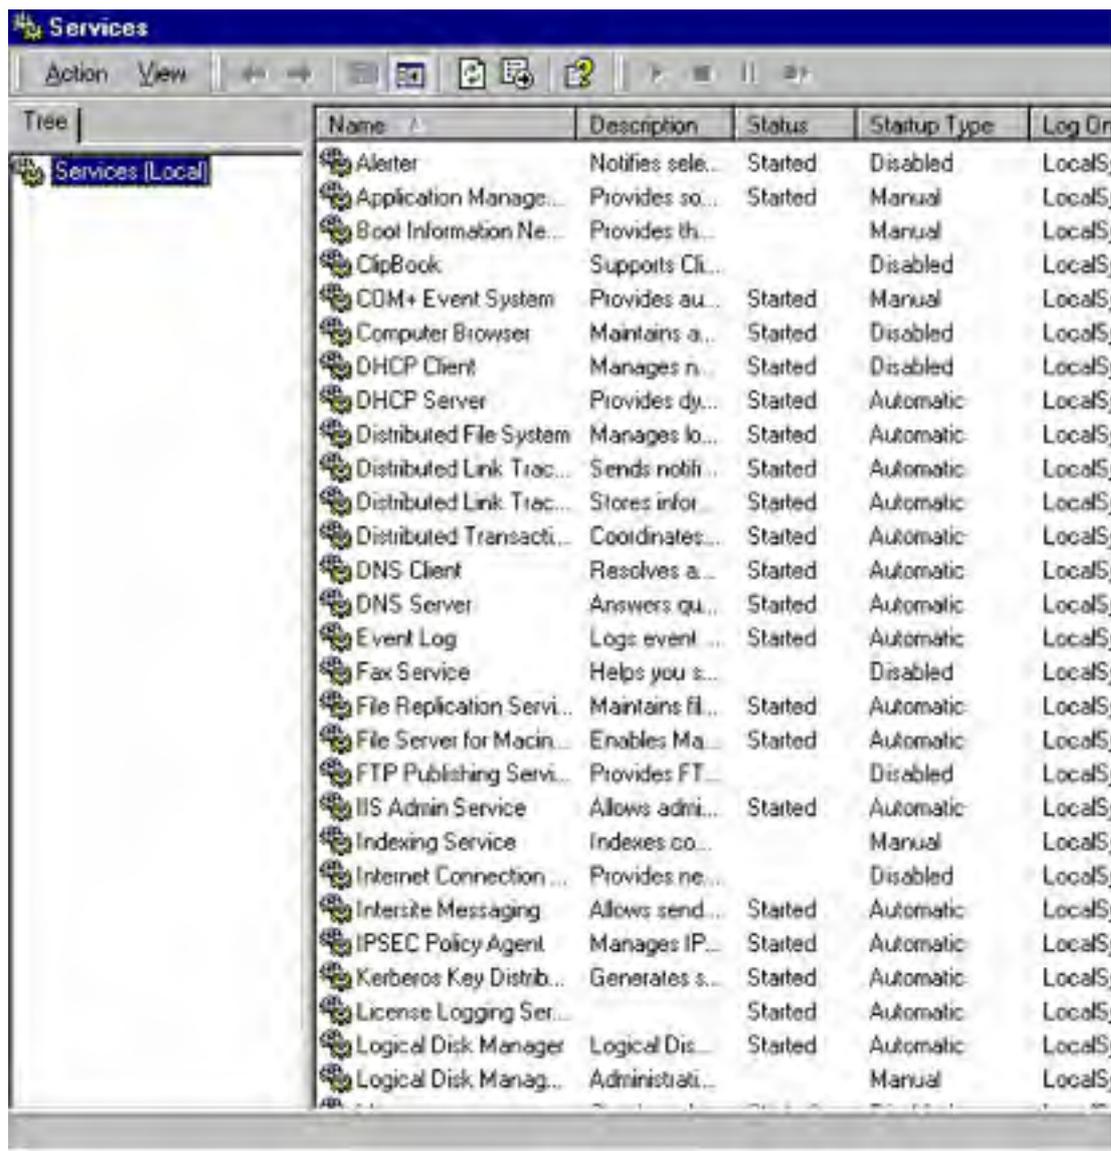

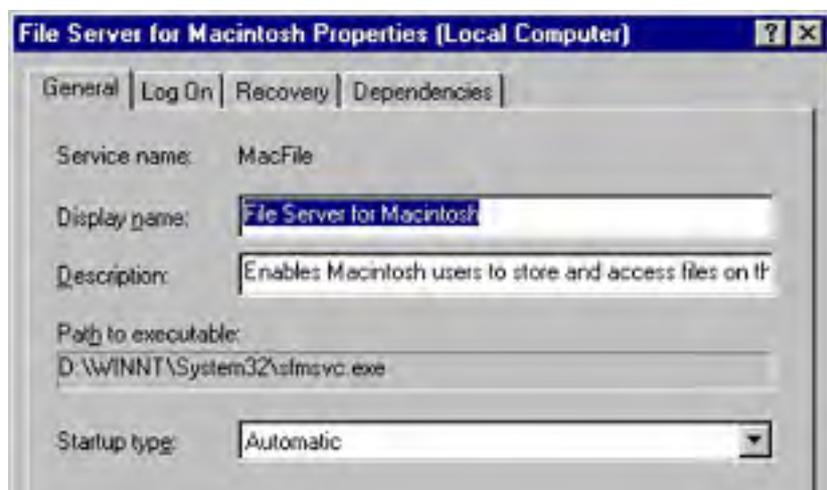

Figure 38-3. The Services window.

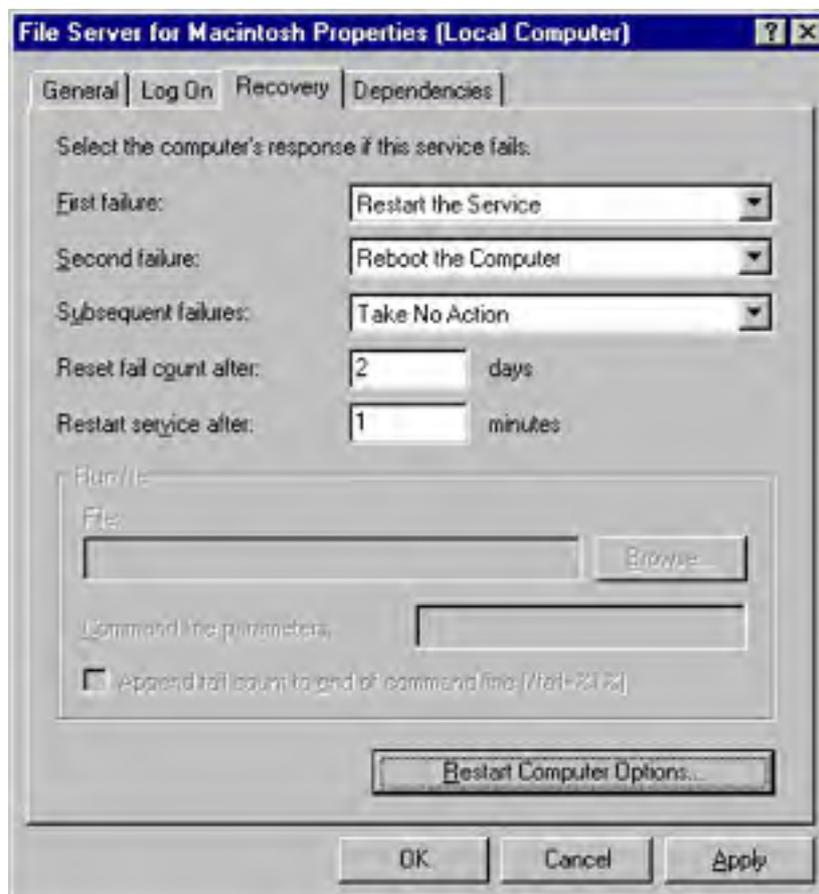

3. Use the Start Service, Stop Service, Pause Service, and the especially useful Restart Service toolbar buttons to make changes to the state of the services.
4. To change advanced settings for a service, double-click the service to open its Properties dialog box, shown in Figure 38-4.

**Figure 38-4.** A service's Properties dialog box.

5. Use the Startup Type list box in the General tab to change how you want the service started.
6. Use the Log On tab to choose which account you want the service to log on. The default is the LocalSystem account, but you can change this to a user account as needed.
7. Click the Recovery tab, and then choose what actions you want to take on the first, second, and subsequent failures of the service, as shown in Figure 38-5.

**Figure 38-5.** The Recovery tab of a service's Properties dialog box.

8. In the Reset Fail Count After box, enter the number of days after which you want to start over counting service failures.
9. Click the Dependencies tab to view the services that the specified service is dependent on.

## Examine the Boot Log

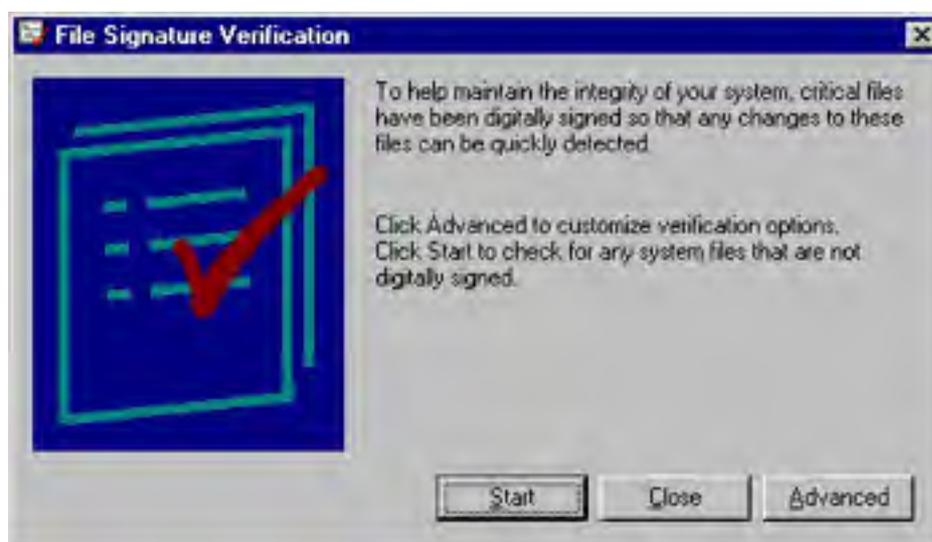

Sometimes it's useful to create a log file of the Windows startup process, documenting which devices, drivers, and services start up properly and which don't. To create a boot log, start the computer in any safe mode by pressing F8 during the boot process and then choosing the desired safe mode or choosing the Enable Boot Logging option from the Windows Advanced Options menu.

This creates a log file with all of the drivers and services loaded or failed during the boot process. The file is called Ntbtlog.txt and is stored in the %Windir% folder.

## Use the File Signature Verification Utility

A system that uses only Microsoft certified and signed device drivers and system files exhibits better stability than a system that doesn't, all else being equal. Although Windows 2000 Server blocks the installation of unsigned device drivers, this can be overridden with the appropriate permissions. If you suspect that an unsigned system file or device driver could be the cause of your difficulties, use the File Signature Verification utility to locate any unsigned files. To do so, use the following procedure:

1. Choose the Run command from the Start menu, type *sigverif* in the Open box, and then click OK. Alternatively, open the System Information tool (Msinfo32.exe) and choose the Windows command from the Tools menu, and then choose File Signature Verification Utility from the submenu.
2. Click Start to scan for unsigned system files (Figure 38-6), or click Advanced to specify other file types and folders to scan for unsigned files (instead of the Windows system files). To scan for unsigned device drivers, search the \Windows\Wystem32\Drivers folder and subfolders.

**Figure 38-6.** The File Signature Verification utility.

3. Make a note of any unsigned drivers (or refer to the Sigverif.txt log file saved in the Windows folder), and disable them by disabling the associated device (or updating the driver) in Device Manager, uninstalling the driver using Add/Remove Programs, or renaming the driver in the \Windows\System32\Drivers folder.

## Use the System File Checker

The System File Checker is a command-line tool that allows you to verify that all of the protected system files are intact. This tool can be handy if you suspect that the system files might be corrupt. If the System File Checker finds that a protected system file has been overwritten, it retrieves the correct version from the %SystemRoot%\System32\Dllcache folder and uses it to replace the incorrect version.

To use the System File Checker, log on locally as an administrator, go to a command prompt, and type *sfc* followed by the appropriate parameter. See Table 38-2 for a list of parameters and what they do.

If the %SystemRoot%\System32\Dllcache folder becomes corrupted or is deleted, use one

of the following commands to repair the folder: `sfc /scannow`, `sfc /scanonce`, or `sfc /scanboot`.

**Table 38-2.** *System File Checker options*

Parameter	Action
<code>/scannow</code>	Immediately scans all protected system files.
<code>/scanonce</code>	Scans all protected files a single time.
<code>/scanboot</code>	Scans all protected files every time the computer is booted.
<code>/cancel</code>	Cancels all scheduled scans.
<code>/quiet</code>	Scans and replaces incorrect files without prompting the user for action.
<code>/enable</code>	Resets Windows File Protection to its default status. Users are prompted to restore any files that are overwritten.
<code>/purgecache</code>	Deletes all files in the <code>%SystemRoot%\System32\Dllcache</code> folder (the Windows File Protection cache) and immediately scans the protected system files.
<code>/cachesize=x</code>	Specifies how large (in megabytes) the <code>%SystemRoot%\System32\Dllcache</code> folder (the Windows File Protection file cache) should be.

## Editing the Boot.ini File

The `Boot.ini` file controls with what options Windows boots (such as Safe Mode or VGA display), or which operating system boots if there are multiple operating systems installed.

It's occasionally necessary to edit the `Boot.ini` file, sometimes simply to reduce the boot time delay or change the default startup options, but sometimes it's to get a system booting again (such as when a system with mirrored system disks fails).

To edit the `Boot.ini` file, open it using any text editor (you'll have to temporarily remove the hidden, read-only and system attributes by typing `attrib c:\boot.ini -h -r -s` at a command prompt). Table 38-3 lists some `Boot.ini` switches that you can use to make troubleshooting easier in the future (although these switches by themselves don't repair anything).

**Table 38-3.** *Boot.ini switches for the various Windows 2000 boot options*

Boot Option	Switch to Use in Boot.ini
Safe Mode	<code>/safeboot:minimal /sos /bootlog /noguiboot</code>
Safe Mode With Networking	<code>/safeboot:network /sos /bootlog /noguiboot</code>
Safe Mode With Command Prompt	<code>/safeboot:minimal(alternateshell) /sos /bootlog /noguiboot</code>
Enable Boot Logging	<code>/bootlog</code>
Enable VGA Mode	<code>/basevideo</code>
Directory Service Restore Mode (domain controllers only)	<code>/safeboot:dsrepair /sos</code>
Debugging Mode	<code>/debug</code>

## Restore from a Backup

If you can start Windows 2000 and you're confident that the system was in a good state at the last backup, consider restoring from the backup rather than wasting time trying to track down a corrupt file. Remember, however, that any changes you've made since the last backup will most likely be lost, so use this option as one of your last choices.

## Reinstall Windows

Reinstalling Windows is your last resort. It provides a way to thoroughly clean the system, possibly without reinstalling programs. If you run Setup from within Windows you can perform an upgrade install right over the old installation and preserve the settings.

Your problems, however, might be so deeply rooted that even this type of reinstall can't fix them. In such cases, the source might be the settings, which are largely preserved during a reinstall. It then becomes necessary to perform a clean install, either by uninstalling Windows using the method described in the section entitled [Uninstalling Windows](#), later in this chapter (or by just formatting the disk) or by performing a parallel installation (after which you probably will want to delete the damaged installation). See [Chapter 5](#) for information about performing a clean installation of Windows.

## Miscellaneous Challenges

This section covers some tasks (we like to call them "challenges") that you might need to perform. If you don't find the solution here, don't panic; check the Microsoft Knowledge Base—the definitive source for information about problems with Windows.

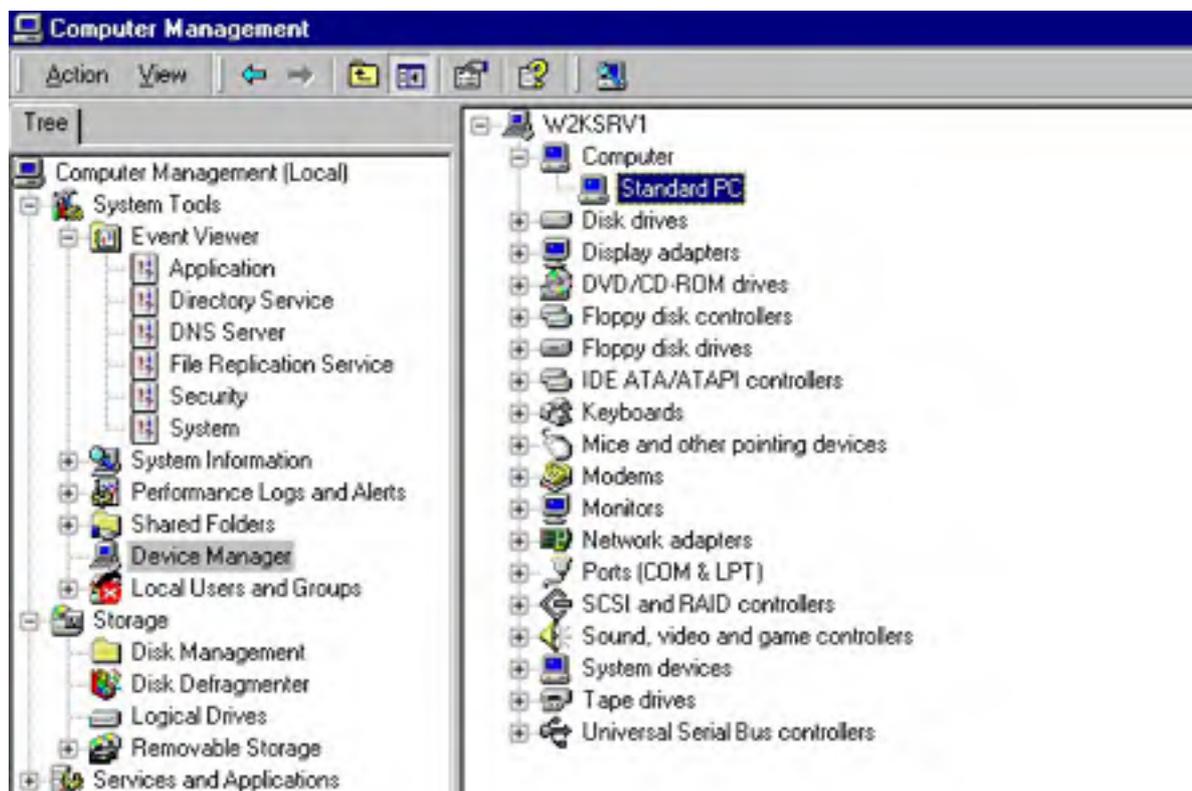

### Adding a Processor to the System

Occasionally you might find yourself adding a second processor to a dualprocessor-capable system. The procedure for doing this is a little different in Windows 2000 than it was in Windows NT 4.

Upgrading from a single-processor Windows 2000 system to a multiprocessor system is actually a major change, causing Windows to alter its entire hardware abstraction layer (HAL). Thus, it is very important that you don't mess around when choosing a HAL. Stick with the one Windows picks, because if you choose an incompatible HAL, the only way to recover is to perform a clean install of Windows 2000.

After installing your additional processor, use the following procedure to switch HALs from uniprocessor to multiprocessor:

1. Launch the Computer Management snap-in from the Administrative Tools folder on the Programs menu.
2. Click Device Manager in the console tree.
3. In the details pane, expand the Computer branch of the Device Manager tree, as shown in Figure 38-7.
4. Right-click the computer item (most likely ACPI Uniprocessor PC) and choose Properties from the shortcut menu.
5. Click the Driver tab and then click Update Driver.
6. Use the Upgrade Device Driver Wizard to locate a more suitable HAL for the multiprocessor system. If Windows doesn't automatically find a different HAL, contact the system manufacturer for an updated HAL or system BIOS. Do not manually choose a HAL, as it might render the system inoperable.

**Figure 38-7.** *The Computer Management console.*

## Windows Hangs When Shutting Down

Although the Windows 2000 Server family usually shuts down reliably, it can occasionally hang up during shutdown. Here are some suggestions for solving the problem (for more in-depth information, use the Help system's Startup and Shutdown Troubleshooter or search the Microsoft Knowledge Base):

- Disable antivirus programs that might be scanning floppy drives. Try uninstalling the program and restarting.
- Go back to an older video driver or to a standard VGA driver.
- Disable sound cards.
- Disable network cards and modems.
- Check to see if the Exit Windows sound file is damaged. If it is, change the Exit Windows sound to none, extract a new copy of the file from the Windows CD, or copy it from another computer.

## Uninstalling Windows

Yes, there are times when you want to uninstall Windows. Perhaps you need to perform a clean installation without reformatting the hard drive. Or maybe you've decided that you'd rather have the raw power of MS-DOS 4 again. To remove Windows 2000 follow these steps:

1. Verify the location of Windows 2000 and the partitioning of the hard drive. (The Disk Management snap-in located in the Computer Management console shows the partition information.)
2. Make sure that no valuable files are located in the `%SystemRoot%` or Program Files folders.
3. Determine what you want to do with the partitions. If you will be using an operating system other than Windows XP, Windows 2000, or Windows NT 4 with Service Pack 4 or later, you'll need to repartition and reformat any NTFS partitions that you want to be able to access from that operating system.
4. To completely remove Windows 2000 from the system, replace the Windows 2000 boot sector with that of the operating system you want to use. (See the operating system's manual. For MS-DOS or Windows 95/98, boot from a floppy and type `sys c:` at the command prompt. Windows NT users can use the emergency recovery process.)

Alternately, you can leave the Windows 2000 boot sector intact and simply edit the `Boot.ini` file to remove the Windows 2000 installation you're uninstalling, set the default to the desired operating system, and optionally set the timeout to 0 to boot the default operating system without displaying the Boot menu.

5. Delete the `%SystemRoot%` folder in which the Windows 2000 installation was located, as well as the Program Files, Documents and Settings (be careful with the data though!), Recycler, and System Volume Information folders, as desired, to free up disk space.
6. Delete the following files in the root directory of the boot partition:
  - `Pagefile.sys`

- Ntdetect.com
- Ntbootdd.sys (if you're using a SCSI system)
- Cmlldr
- Cdldr
- Arclldr.exe
- Arcsetup.exe
- Boot.ini (do not delete if you want to keep using the Windows Boot menu)
- Ntldr (do not delete if you want to keep using the Windows Boot menu)

Uninstalling Windows 2000 isn't a consumer-level process like that offered by some Microsoft operating systems in the past. If you've upgraded to Windows 2000, you're out of luck if you want to switch back to the old operating system. Fortunately, few of us will ever feel the need to uninstall Windows 2000, making the inconvenience manageable.

## Summary

Windows 2000 provides a great set of tools that you can use to recover from the disasters that inevitably occur, even in relatively stable operating systems like Windows 2000. The most frequently used are the boot options, such as safe mode (à la Windows 95/98) and the Last Known Good Configuration option, which is useful for recovery from registry errors. If you still can't boot the system, you can use Windows 2000's emergency repair process to get the system running again. Windows 2000 also features the new Recovery Console, which allows you to access the drives (including secure access to limited areas of NTFS drives) using a command prompt when all else fails.

### [Appendix E](#)

Windows 2000 Support Tools 1494

# Appendix A

## A Quick Guide to Interface Changes

Initially, both the Microsoft Windows 2000 Professional and Server interfaces look much like the Microsoft Windows NT 4 interface, but enough differences exist that you might find yourself periodically stymied by a "missing" function. This appendix lists some of the components that have been renamed, moved, or introduced since the first release of Windows NT 4. These components are listed by their Windows NT name if they have a new name in Windows 2000.

### Clipboard Viewer

Clipboard Viewer has been renamed ClipBook Viewer. ClipBook Viewer shows any information you've copied to the clipboard. This information can be stored permanently in your Local ClipBook and shared with other users. The Local ClipBook opens when you start ClipBook Viewer. To open ClipBook Viewer, select Run from the Start menu, type *clipbrd*, and then press Enter.

### Compression Agent

Windows 2000 doesn't include Compression Agent. You can compress NTFS drives by following these steps:

1. Open My Computer.
2. Right-click the drive you want to compress and choose Properties from the shortcut menu.
3. In the General tab, select Compress Drive To Save Disk Space. Click OK.

To compress a single file or folder, follow these steps:

1. Open Microsoft Windows Explorer. Right-click the file or folder to be compressed and choose Properties from the shortcut menu.
2. Click Advanced. Select the Compress Contents To Save Disk Space check box. Click OK twice.
3. If you're compressing a folder, you'll be asked whether you want changes to apply to only the folder or to subfolders and files as well. Select the option you want. Click OK again.

The compression option is available only on disks formatted with NTFS. When you add or copy a file into a compressed folder, it is compressed automatically. If you move a file from a *different* NTFS drive into a compressed folder, it is also compressed. However, if you move a file from the *same* NTFS drive into a compressed folder, the file retains its original state, whether it is compressed or uncompressed. Compressed files can't be encrypted, and encrypted files can't be compressed unless you first decompress or decrypt the files.

### Computers Near Me

If your Windows 2000 Professional is a member of a workgroup, Computers Near Me appears inside My Network Places. Computers Near Me shows the computers and other resources that are accessible by members of the workgroup. Computers Near Me won't be created when Windows 2000 is installed on a machine that is a member of a domain.

### Devices

Devices has been renamed Device Manager and is located in Computer Management. On a machine running Windows 2000 Server or Windows 2000 Professional, right-click My Computer and choose Properties from the shortcut menu. Click the Hardware tab. Click Device Manager. From a machine running Windows 2000 Server, an administrator can view Device Manager on a remote computer by following these steps:

1. Launch Active Directory Users and Computers.

2. In the console pane under the appropriate domain, click Computers.
3. In the details pane, right-click the computer name and select Manage.
4. In the new Computer Management window, click System Tools and then Device Manager.

## Dial-Up Networking

You can find Dial-Up Networking in Network and Dial-Up Connections in Control Panel. You can also right-click My Network Places and choose Properties from the shortcut menu. Unless you're logged on as an administrator or a member of the Administrators group, some features of Network and Dial-Up Connections won't be available.

## Disk Administrator

Disk Administrator has been renamed Disk Management. Disk Management is a graphical tool for managing disks and volumes. It supports partitions, logical drives, new dynamic volumes, and remote disk management. To open Disk Management, right-click My Computer and choose Manage from the shortcut menu. In the console pane, click Storage and then click Disk Management.

## Find

In Windows 2000, Find has been renamed Search and it is located on the Start menu.

## MS-DOS Prompt

The MS-DOS prompt has been renamed the Command Prompt and is now located on the Accessories menu (actually Windows NT 4 calls it a command prompt as well, but Windows 9.x does not). The Command Prompt now comes with a number of functions, including file and folder autocompletion. See [Chapter 10](#) for more information.

You set Command Prompt options such as color and font by right-clicking the Command Prompt title bar and selecting Properties; in the Apply Properties To Shortcut dialog box, select the Modify Shortcut That Modified This Window option. To set these options for a single session, right-click the Command Prompt title bar and choose Properties; in the Apply Properties To Shortcut dialog box, select the Apply Properties To Current Window Only option.

## My Briefcase

You can now access My Briefcase, a default presence on the Windows NT 4 desktop, by right-clicking the desktop and selecting New and then Briefcase. A briefcase is created and placed on the desktop.

## My Documents

My Documents is a new folder on every Windows 2000 desktop that serves as the default location for saved files. Inside My Documents is the subfolder My Pictures, the default location for graphics files. My Documents is one of the special folders that can be redirected to a location on the network. See [Chapter 9](#) for information on using Group Policy for folder redirection.

## Network Neighborhood

Network Neighborhood has been replaced by My Network Places. My Network Places shows the shared computers, files and folders, printers, and other resources on the network to which your computer is connected. Right-click My Network Places and choose Properties to view Network and Dial-Up Connections and Computers Near Me.

## Personalized Menus

By default, Windows 2000 uses personalized menus for the Start menu and its offshoots. This means that Windows 2000 keeps track of how often you access items on each menu and places the most frequently used items at the top. Figure A1 shows a personalized Programs menu. Click the double arrowheads at the bottom of the menu—or just rest the mouse pointer on the double arrowheads for a few seconds—to see the rest of the menu items.

**Figure A-1.** A personalized Programs menu.

To return to menus where all items are shown, right-click the taskbar and choose Properties. Clear the Use Personalized Menus check box, and click OK.

## Quick Launch Bar

The Quick Launch bar is a Microsoft Windows 98 feature that has been incorporated into the taskbar in Windows 2000. By default, shortcuts for Microsoft Internet Explorer, Microsoft Outlook Express, and the Desktop are on the Quick Launch bar. You can drag other shortcuts to the Quick Launch bar and drag off any of the default ones. The Desktop icon is particularly handy because it allows you to minimize all open windows with a single click. Click the Desktop icon a second time and the windows you just minimized all reopen.

## Start Menu

The Start menu isn't new, but it has changed somewhat from Windows NT 4. For example, the Logoff command is no longer on the Start menu by default, and the Control Panel can now be expanded in its own menu. To add these, use the following steps:

1. Click Start, point to Settings, and then click Taskbar & Start Menu.
2. Click the Advanced tab.
3. In Start Menu Settings, select Display Logoff and Expand Control Panel (you might want to poke around with the other settings here as well).

In the Advanced tab, note the other additions you can make to the Start menu. You can still drag and drop shortcuts on the Start button to add items to the menu. Now you can also click and drag those items on the menu to change their order and right-click any of the added items to rename them.

## System Information

System Information displays your system configuration data. To see System Information, right-click My Computer and choose Manage from the shortcut menu. In the console pane, click System Tools and then System Information. From a machine running Windows 2000 Server, you can view System Information on a remote computer by following these steps:

1. Launch Active Directory Users and Computers.
2. In the console pane under the appropriate domain, click Computers.

3. In the details pane, right-click the computer name and select Manage.
4. In the new Computer Management window, click System Tools and then System Information.

## **TCP/IP**

To install, remove, or configure TCP/IP in Windows 2000, open Network and Dial-Up Connections. Right-click the connection and choose Properties.

## **User Manager**

In Windows 2000, User Manager has been renamed Local Users and Groups and is located in Computer Management. Right-click My Computer and choose Manage from the shortcut menu.

## **User Manager for Domains**

Most of the functions of User Manager for Domains have been replaced by Active Directory Users and Computers. On Windows 2000 Server, Active Directory Users and Computers is on the Administrative Tools menu. Active Directory Domains and Trusts is used for creating and managing trust relationships.

## **View Options**

In Windows 2000, View Options has been renamed Folder Options and is on the Tools menu in many places, including My Computer, My Documents, My Network Places, and Control Panel. Use Folder Options to change the appearance of your desktop and folder content and to specify how folders open. You can also specify whether folders open with a single click or a double click, and you can set how folders display.

## **Windows NT Explorer**

Windows NT Explorer has been renamed Windows Explorer and is located on the Accessories menu.

# Appendix B

## Optional Components

The Microsoft Windows 2000 Server platforms have a number of optional components that you can install or remove to configure your system the way you want it. Some of these components are available only as part of Windows 2000 Advanced Server and are so indicated.

## Adding and Removing Windows Components

To add or remove one of these optional components, click the Add/Remove Windows Components button on the left side of the Add/Remove Programs Control Panel dialog box. The various components are grouped by type, with the currently installed components checked.

To remove a component, clear its check box; to add a component, select its check box. After you've made your selections, click Next. If you've selected Terminal Services, you'll be prompted for the mode to use: remote administration mode or application server mode. For more on what these modes mean, see [Chapter 26](#). Click Next again, and your Windows components are updated. You might be prompted to insert your Windows 2000 CD-ROM. Once the update completes, click Finish. In some cases, you might be prompted to reboot the server, depending on the changes you're making, so it's best to add or remove components when you can afford to have the server offline for long enough to reboot.

## Accessories and Utilities

Within the Accessories and Utilities grouping, there are additional component groups. To see the specifics of any component grouping, select the grouping and click Details. If the Details button is unavailable, that means you are selecting an individual component and not a group of components.

## Accessibility Wizard

The Accessibility Wizard allows you to configure your system to make it more accessible to those with special vision, hearing, and mobility needs. Installed with the wizard are additional accessibility tools, including narrator, magnifier, and on-screen keyboard, as well as the Utility Manager to manage the configuration of these utilities.

## Accessories

Accessories is a grouping of applications and features each designed for a single use or purpose. These include the following:

- **Calculator** A simple on-screen graphical calculator
- **Character Map** Displays all the characters in any installed font and allows you to insert special characters and symbols into your current document
- **Clipboard Viewer** Enables you to view and save the contents of the clipboard
- **Desktop Wallpaper** Provides additional background images and pictures for enhancing your Windows desktop
- **Document Templates** Allows opening of new documents using your right mouse button
- **Mouse Pointers** Provides additional mouse pointers, including larger pointers and animated pointers
- **Object Packager** Allows documents to include embedded or linked objects from another source
- **Paint** A basic bitmap painting program
- **WordPad** A simple word processor that can read Microsoft Word documents and handle ASCII text documents

## Communications

Communications is a grouping of three simple programs that enhance the Windows 2000 communications abilities. The three programs are as follows:

- **Chat** Installs a useful chat application but doesn't create an icon for it on your Start menu. To use Chat, open the Start menu, choose Run, and type *Winchat.exe*.
- **HyperTerminal** Uses a modem (or null modem cable) to connect to other computers or online services that still require terminal emulation.
- **Phone Dialer** Allows you to dial a phone through your attached modem.

## Games

Games is a grouping of four games that are normally installed in Windows 2000 Professional but are optional in Windows 2000 Server and Advanced Server. The four games are as follows:

- **FreeCell** A difficult solitaire card game
- **Minesweeper** The familiar strategy game
- **Pinball** A 3-D computer version of an arcade pinball machine
- **Solitaire** The classic card game

## Multimedia

Multimedia is a collection of utilities and sounds to take advantage of your server's multimedia capabilities. The group includes these features:

- **CD Player** Plays music CDs in your computer's CD-ROM drive
- **Media Player** Plays a variety of audio and video formats
- **Sample Sounds** Provides a collection of sound clips
- **Sound Recorder** Records sounds using your sound card
- **Utopia Sound Scheme** Provides a collection of sounds that can be attached to various actions on your computer
- **Volume Control** Lets you adjust the output volume from your sound card

## Certificate Services

Microsoft Certificate Services includes a certification authority server that can issue public-key security certificates. It also includes support for adding Web pages to your Web server that allow you to submit and issue certificates.

## Cluster Service (Advanced Server Only)

The Windows 2000 Cluster service allows multiple servers to act together to provide highly available and scalable applications. See [Chapter 16](#) for more on clusters.

## Indexing Service

The Windows 2000 Indexing Service speeds up full-text searching of files. See [Chapter 27](#) for more on the Indexing Service.

## Internet Information Services

Internet Information Services (IIS) includes several components you can add to any Windows 2000 server:

- **Common Files** Required IIS program files used by many of the components
- **Documentation** Documentation for the various IIS components, including samples

- **File Transfer Protocol (FTP) Server** Support for uploading and downloading files using the FTP protocol
- **FrontPage 2000 Server Extensions** Support for additional functionality when running Microsoft FrontPage 2000-created Web pages
- **Internet Information Services Snap-In** MMC snap-in for managing IIS and its services
- **Internet Services Manager (HTML)** HTML-based management interface for IIS services
- **NNTP Service** Support for running a News server
- **SMTP Service** Support for forwarding and receiving Internet Mail using SMTP
- **Visual InterDev RAD Remote Deployment Support** Allows you to remotely deploy applications on your Web server
- **World Wide Web Server** The IIS Web server

## Management and Monitoring Tools

Management and Monitoring Tools is a group of three management and monitoring applications or protocols, including the following:

- **Connection Manager Components** Adds the Phone Book Services and the Connection Manager Administration Kit
- **Network Monitor Tools** Allows you to capture and analyze network traffic at the packet level
- **Simple Network Management Protocol** Provides SNMP support, allowing monitoring and reporting of the activity of a variety of network devices

## Message Queuing Services

Install the Microsoft Message Queuing service to improve network communications from supported applications. See [Chapter 27](#) for more on Message Queuing.

## Networking Services

Networking services is a group of optional networking components that you can add. The components in the Networking services group include the following:

- **COM Internet Services Proxy** Provides support for DCOM objects to use HTTP and IIS
- **Domain Name System (DNS)** Adds the Microsoft dynamic DNS server
- **Dynamic Host Configuration Protocol (DHCP)** Adds a DHCP server to automatically assign IP addresses and configuration information to network client computers
- **Internet Authentication Service** Adds support for the RADIUS protocol for dial-up and VPN users
- **QoS Admission Control Service** Provides support for specifying network connection quality by individual subnets
- **Simple TCP/IP Services** Provides support for a variety of minor TCP/IP services including Echo and Quote of the Day
- **Site Server ILS Services** Updates directory information by scanning TCP/IP stacks
- **Windows Internet Name Service (WINS)** Adds a WINS server for supporting NetBIOS names in mixed-mode networks

## Other Network File and Print Services

This is a group of three file and print services that provide support for clients on other operating systems, as follows:

- **File Services for Macintosh** Support for Macintosh computers to both store files and access files on Windows 2000 servers

- **Print Services for Macintosh** Supports Macintosh computers printing to Windows 2000 printers
- **Print Services for UNIX** Supports UNIX and Linux users printing to Windows 2000 printers using line printer remote (LPR)

## Remote Installation Services

Remote Installation Services adds support for remote installation of Windows 2000 Professional onto client computers with appropriate remote boot-enabled network cards.

## Remote Storage

Remote Storage provides services and tools to allow you to store less frequently accessed files and data on tape, freeing up hard disk space.

## Script Debugger

Script Debugger enables you to more easily debug Web pages, Active Server Pages, and other script files.

## Terminal Services

You can use Windows 2000 Terminal Services to switch between remote management mode and application server mode. See [Chapter 26](#) for more on Windows 2000 Terminal Services. Terminal Services also installs the necessary files to create Terminal Services Client setup disks.

## Terminal Services Licensing

Terminal Services Licensing provides client access licenses on the network. The Terminal Services license server must run on a domain controller.

## Windows Media Services

Windows Media Services provides support for using Windows 2000 Server as a streaming media server. Media Services includes both the actual media server and the administrator program used to manage the service.

# Appendix C

## The OSI Reference Model

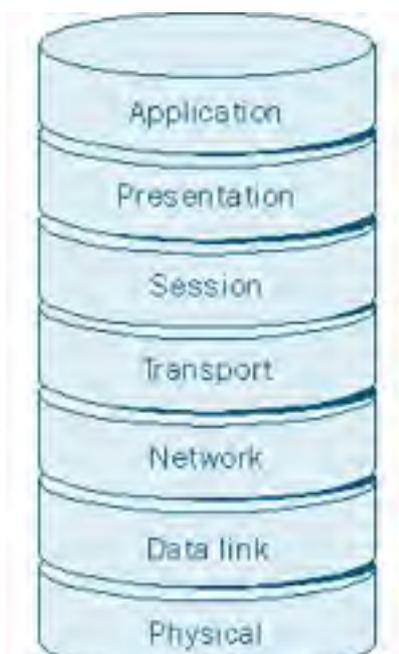

As with any emerging technology, the early days of networking were characterized by strictly proprietary hardware and software. No one agreed on any particular method of building and implementing networks. That meant choices for suppliers were limited.

You could choose to buy your network from IBM, DEC, Burroughs, or a few others. This decision was momentous because after purchasing components from one manufacturer, you were locked in. No one else's equipment or software would work with yours. You had to buy everything from the original vendor, and if they didn't happen to make a product that you really, truly needed, you were just out of luck.

To cut across this entirely proprietary universe, the International Organization for Standardization developed a standard to make possible open systems that could communicate with one another no matter who manufactured them. Today, many proprietary systems still exist, and they don't always communicate with one another as well as we might hope, but they do have the Open Systems Interconnection (OSI) reference model in common. This model provides a framework for depicting the organization of network components and can give you a clearer picture of how these components relate to one another.

The OSI reference model is made up of seven layers. Each layer has its job to do and has to relate only to the layers directly on either side of it. The layers are shown in Figure C-1. From the bottom up, they are as follows:

- Physical
- Data link
- Network
- Transport
- Session
- Presentation
- Application

**Figure C-1.** *Layers of the OSI reference model.*

Each layer in a network communication model assumes that it's speaking to the same layer on another machine and uses a common protocol. The collection of protocols is called a *protocol stack*.

## Physical Layer

The physical layer deals with how the data signals are transmitted on the network cable or other transmission medium. The physical layer handles the mechanical and electrical procedures and is oblivious to whether the signal is made up of digital bits or is in analog form. Parts of the physical layer include the type of cabling and the network interface card (NIC).

## Data Link Layer

The data link layer is the first layer that handles the packet as such. It groups bits that have been organized into low-level logical units called *frames*. It then waits for acknowledgment that the frames were received and retransmits any frames that are lost, performing a cyclical redundancy check (CRC) on each frame. The data link layer connects the physical aspects of a network with the abstractions of software.

All network adapters have a Media Access Control (MAC) address, which functions at the data link layer. Bridges operate at the data link layer, using MAC addresses to segment a network into two sections.

## Network Layer

The network layer builds on the connection made by the data link layer. It adds the unit of information called *packets*. The network layer handles routing (the process of delivering packets through an internetwork) and congestion control. It also handles logical addressing, of which IP addresses are the most famous example.

Routers operate at the network layer, routing packets according to logical IP addresses.

Examples of network layer protocols are IPX, IP, and AppleTalk's Datagram Delivery Protocol (DDP).

## Transport Layer

The transport layer builds on the error-control mechanisms of the lower layers. This is the last stop for ensuring that corrections are made in the sending and receiving of packets. The transport layer breaks up large pieces of data into smaller pieces and assigns sequence numbers. Examples of transport layer protocols are TCP, SPX, User Datagram Protocol (UDP), and the AppleTalk Transaction Protocol (ATP).

## Session Layer

The session layer deals with two-way communications between nodes. When a dialog between nodes begins, a session is initiated. A good example of this is when a workstation connects to a Windows 2000 server. Rules are established about how the two will communicate and the protocols to be used. If a system is running multiple network applications, the system layer organizes communications so that incoming data is directed to the correct application. Remote procedure calls (RPCs) and NetBIOS are examples of session layer functionality.

## Presentation Layer

The presentation layer handles how data is represented. It handles how data is formatted, how lines of characters are to be shown, whether data is encoded, and so forth. For example, if you're sending encrypted communications over the Internet, it is the function of the presentation layer to encrypt and decrypt the data. SNMP and Unicode are examples of presentation layer protocols supported in Microsoft Windows 2000.

## Application Layer

The application layer handles the information transfer between two network applications, including remote file services, message handling for e-mail, and remote database access. Many of the services under this layer are called application programming interfaces (APIs). APIs are programming libraries used to write applications.

The OSI model layers are usually numbered in the order listed in Figure C1. If you see a reference to Layer 3 of the OSI model, you'll know it's the network layer being described.

The OSI reference model is useful because every networking protocol stack is based in some way on the OSI structure. None of the protocol stacks you encounter will fit the model exactly, but there's always enough correspondence to help you understand the relationship among the parts—and certainly enough to get you started if you want to delve deeper into the technical core of networking.

## The Microsoft TCP/IP Stack

Microsoft's TCP/IP protocols use a four-layer conceptual model, also called the PC model, that combines some of the OSI model layers. Table C-1 compares the two models. The layers are simplified, but the same elements are present in the Microsoft TCP/IP stack as in the traditional OSI model.

**Table C-1.** Comparing conceptual models

Microsoft Model	OSI Model
Network interface layer	Physical and data link layers
Internet layer	Network layer
Transport layer	Transport layer
Application layer	Session, presentation, and application layers

## The OSI Model in Action

Let's say you want to retrieve a spreadsheet file called Budget.xls from a network file server. Here's how the layers would work to accomplish the retrieval.

First the application layer on your computer detects that you're asking for information from a remote server and formulates a request that Budget.xls should be read from the file server's hard disk. The presentation layer then encrypts the request, if necessary, and passes the packet to the session layer. The session layer adds information about which application is requesting the information and which service is being requested from the file server. The packet is then handed off to the transport layer.

The transport layer verifies that a reliable connection exists to the file server and then breaks down the accumulated information into blocks. If more than one frame is necessary, sequence numbers are added. Next, the blocks are passed to the network layer.

The network layer adds the network address, usually an IP address, for both the system that is the source of the request and the file server. This is added to each chunk of information before it is passed to the data link layer.

The data link layer packages the blocks into frames and adds a frame header and the source and destination MAC addresses. The MAC addresses plus the content of the frame are used to create a CRC trailer. The frames are then handed off to the physical layer. The physical layer knows no more about frames than a highway knows about cars. It is just the road by which the data is moved.

At the file server, the data link layer reads the transmitted frame and identifies the MAC address for the destination system as its own MAC address. The data link layer performs a CRC and if all is well, strips off the header and trailer and passes the frame to the network layer. (If the CRC isn't valid, the data link layer discards the frame and requests a replacement from the source computer.)

The network layer on the file server analyzes the information that was added by the network layer on the source computer, notes the network address of the source computer, and records it in a table. The frames are then passed up to the transport layer.

The transport layer reviews the information in the frame that was supplied by the transport layer on the source system. If sequencing was used, it queues the frames until all are received. The sequencing is used to identify any missing frames, and a request for any missing data is sent to the source computer. If all the data is present, the transport layer passes the request to the session layer.

The session layer verifies that the data is from a valid connection and that all security criteria have been met. The data is then passed to the presentation layer. The presentation layer performs any necessary decryption and passes the data on to the application layer. The application layer passes the request to the process responsible for access to the file system.

Then, incredibly enough, the process reads the requested file and passes the information back to the application layer, and the whole process begins again. That a file request can be processed in less than a day is remarkable—that in reality it takes only a few seconds is quite astounding.

Although when this model is broken down into steps, it appears to be complex (and it is), it's also a good way to ensure flexibility and reliability. Because Ethernet confines its functionality to the data link layer, it can work with any number of protocols such as IP and IPX, which operate in the network layer. You should also bear in mind that the OSI model is a *model* and isn't exactly adhered to anywhere.

# Appendix D

## Using the Windows 2000 Recovery Console

The Windows 2000 Recovery Console is a special command-line environment that you can use to boot a nonfunctioning system. The Recovery Console is discussed in [Chapter 38](#); this appendix covers some aspects of the console and provides a command reference.

### Starting the Recovery Console

To start the Recovery Console, use the following steps:

1. Boot from the Windows CD-ROM or setup disks (you might have to change the boot order in your BIOS to boot from the CD-ROM first).
2. After Windows Setup loads, type **R** to choose to repair an existing Windows 2000 installation. Then type **C** to access the Recovery Console.
3. Enter the number corresponding to the Windows 2000 installation to which you want to log on and press Enter.
4. Enter the local system administrator password. (This is the password you originally assigned when installing Windows 2000.)

You can also install the Recovery Console on your hard drive so that it's available as a boot option by using Winnt32.exe with the /cmdcons switch. Another option is to install the Recovery Console on a Remote Installation Service (RIS) server so that systems can perform a network boot into the Recovery Console. For information on this, see Microsoft Knowledge Base Article Q222478.

### Using the Command Console

After you start the Recovery Console, you receive the following message:

```
Windows 2000(TM) Recovery Console Command Interpreter.  
WARNING:  
The Recovery Console provides system repair and recovery functionality.  
Type `exit' to quit the recovery console and restart the computer.  
1: C:\WINNT  
Which Windows 2000 installation would you like to log on to? (To cancel
```

After you enter the number for the appropriate Windows 2000 installation, enter the Administrator account password. Note that if you use an incorrect password three times, the Recovery Console quits. Also, if the SAM database is missing or damaged, you will not be able to use the Recovery Console because you cannot be properly authenticated. After you enter your password and the Recovery Console starts, typing *exit* restarts your computer.

### Restrictions and Limitations of the Recovery Console

From the Recovery Console you can access only the following folders:

- The root folder.
- The %SystemRoot% folder and the subfolders of the Windows 2000 installation you are currently logged on to.
- The Cmdcons folder.
- Removable media drives such as CD-ROM drives.

If you try to obtain access to other folders, you receive an "Access Denied" error message. Also, while in the Recovery Console you cannot copy a file from the local hard disk to a floppy disk. You can copy a file from a floppy disk or CD-ROM to a hard disk, and from one hard disk to another hard disk.

You can enable full access to your hard drives from the Recovery Console by changing the Recovery Console setting in the relevant Group Policy object. Just keep in mind that this exposes potentially sensitive data to anyone who can boot the system using the Recovery Console (that is, anyone who gains access to the local system administrator password and can gain physical access to the server).

## Available Commands

### HELP

HELP lists all of the following supported commands:

```
ATTRIB DEL EXPAND MAP RMDIR
BATCH DELETE FIXBOOT MD SET
CD DIR FIXMBR MKDIR SYSTEMROOT
CHDIR DISABLE FORMAT MORE TYPE
CHKDSK DISKPART HELP RD
CLS ENABLE LISTSVCS REN
COPY EXIT LOGON RENAME
```

### ATTRIB

The ATTRIB command with any of the following parameters can change attributes of a file or folder:

-R	Removes read-only attribute
+R	Makes file read-only
-S	Removes system file attribute
+S	Marks the file as a system file
-H	Removes hidden attribute
+H	Hides the file
-C	Uncompresses the file
+C	Compresses the file

At least one attribute must be set or cleared. To view attributes use the DIR command.

### BATCH

BATCH *inputfile* [*outputfile*]

Executes commands specified in a text file.

*inputfile* Specifies the text file that contains the list of commands to be executed.

*outputfile* If specified, contains the output of the specified commands. If not specified, the output is displayed on the screen.

### CD and CHDIR

CD and CHDIR [*drive:*] [...] [*path*]

The CD and CHDIR commands change the folder. *CD ..* specifies that you want to change to the parent folder. Type *CD drive:* to display the current folder in the specified drive. Type *CD* without parameters to display the current drive and folder. The CD and CHDIR commands treat spaces as delimiters (unlike their behavior under a normal Windows 2000 command prompt). Because of this, you must enclose a subfolder name that contains a space with quotation marks. For example: *CD "driver cache"*

The CHDIR command operates only within the system folders of the current installation of Windows 2000, removable media, the root folder of any hard disk partition, or the local installation sources.

## CHKDSK

CHKDSK [*drive:*] [/P] [/R]

Checks, and if needed, repairs or recovers a drive. Also marks bad sectors and recovers readable information.

*drive:* Specifies the drive to check. The /P switch instructs CHKDSK to do an exhaustive check of the drive even if the drive is not marked with problems, and it corrects any errors found. The /R switch locates bad sectors and recovers readable information. Note that specifying the /R switch implies the /P switch. CHKDSK can be specified without arguments, in which case the current drive is implied with no switches. Optionally, the listed switches are accepted. The CHKDSK command requires the Autochk.exe file. CHKDSK automatically locates this file in the bootup folder. This would typically be the Cmdcons folder if the Recovery Console was preinstalled. If it cannot be found in the bootup folder, CHKDSK tries to locate the Windows 2000 CD-ROM installation media. If the installation media cannot be found, CHKDSK prompts you to provide the location of the Autochk.exe file.

## CLS

Clears the screen.

## COPY

COPY [*source*] [*destination*]

Copies a file.

*source* Specifies the file to be copied. Wildcards or folder copies are not permitted. A compressed file from the Windows 2000 CD-ROM is automatically decompressed as it is copied.

*destination* Specifies the folder or filename for the new file. If this is not specified, it defaults to the current folder. If the file already exists, you are prompted to overwrite it.

## DEL and DELETE

DEL [*drive:*] [*path*] [*filename*]

DELETE [*drive:*] [*path*] [*filename*]

Deletes a file.

*drive: path filename* specifies the file to delete.

The DELETE command operates only within the system folders of the current Windows 2000 installation, removable media, the root folder of any hard disk partition, or the local installation sources. The DELETE command does not accept wildcard (\*) characters.

## DIR

DIR [*drive:*] [*path*] [*filename*]

Displays a list of files and subfolders in a folder.

*drive: path filename* Specifies drive, folder, and/or files to list. The DIR command lists all files including hidden and system files. Files can have the following attributes:

```
D - Directory R - Read-only file
H - Hidden file A - Files ready for archiving
S - System file C - Compressed
```

## E - Encrypted P - Reparse Point

The DIR command operates only within the system folders of the current Windows 2000 installation, removable media, the root folder of any hard disk partition, or the local installation sources.

### **DISABLE**

DISABLE *servicename*

The DISABLE command disables a Windows 2000 system service or driver.

*servicename* The name of the service or device driver to be disabled. Use the LISTSVCS command to display all eligible services or drivers to disable. DISABLE prints the old start\_type of the service before resetting it to SERVICE\_DISABLED. Because of this, you should record the old start\_type, in case it is necessary to re-enable the service.

The start\_type values that the DISABLE command displays are as follows:

SERVICE\_DISABLED

SERVICE\_BOOT\_START

SERVICE\_SYSTEM\_START

SERVICE\_AUTO\_START

SERVICE\_DEMAND\_START

### **DISKPART**

DISKPART [/add] | /delete] [*device name* | *drive name* | *partition name*] [*size*]

Use the DISKPART command to manage the partitions on your hard disk volumes.

*/add* Create a new partition.

*/delete* Delete an existing partition.

*device name* Device name for creating a new partition. The name can be obtained from the output of the MAP command (for example, \Device\HardDisk0)

*drive name* This is a drive-letter-based name for deleting an existing partition (for example, D).

*partition name* This is a partition-based name for deleting an existing partition and can be used in place of the drive name argument (for example, \Device\HardDisk0\Partition1).

*size* Size of the new partition in megabytes.

If no arguments are used, a user interface for managing your partitions appears.
--

### **ENABLE**

ENABLE *servicename* [*start\_type*]

You can use the ENABLE command to enable a Windows 2000 system service or driver.

*servicename* The name of the service or device driver to be enabled. Use the LISTSVCS command to display all eligible services or drivers to enable. The ENABLE command prints the old start\_type of the service before resetting it to the new value. You should note the old value, in case it is necessary to restore the start\_type of the service.

*start\_type* Valid start\_type values are as follows:

SERVICE\_BOOT\_START

SERVICE\_SYSTEM\_START

SERVICE\_AUTO\_START

SERVICE\_DEMAND\_START

If you do not specify a new start\_type, ENABLE prints the old start\_type for you.

## EXIT

You can use the EXIT command to quit the Recovery Console and restart your computer.

## EXPAND

EXPAND *source* [/F:*filespec*] [*destination*] [Y]

EXPAND *source* [/F:*filespec*] /D

Expands a compressed file.

*source* Specifies the file to be expanded; cannot include wildcards.

*destination* Specifies the folder for the new file. The default is the current folder.

/F:*filespec* If the source contains more than one file, this parameter is required to identify the specific file(s) to be expanded; can include wildcards.

/Y Do not prompt before overwriting an existing file.

/D Do not expand; only display a folder of the files that are contained in the source.

The destination can be any folder within the system folders of the current Windows 2000 installation, the root of any drive, the local installation sources, or the Cmdcons folder, but not removable media. The destination file cannot be read-only.

## FIXBOOT

FIXBOOT *drive*

Writes new Windows 2000 boot sector code on the boot partition. This fixes problems where the Windows 2000 boot sector is corrupted. The emergency repair process also fixes the boot sector.

*drive* Drive letter where the boot sector will be written. This overrides the default of writing to the system boot partition.

## FIXMBR

FIXMBR *device name*

Repairs the master boot record (MBR) of the boot partition. This is used in scenarios where a virus has damaged the MBR and Windows 2000 cannot start.

This command has the potential to damage your partition tables if a virus is present or a hardware problem exists. This command might lead to inaccessible partitions. Microsoft suggests running antivirus software before using this command.

*device name* Optional device name that specifies the device that needs a new MBR. The name can be obtained from the output of the MAP command. If this is left blank, the boot device's MBR is fixed. For example:

FIXMBR \device\harddisk2

If FIXMBR detects an invalid or nonstandard partition table signature, it prompts you for permission before rewriting the MBR.

## FORMAT

FORMAT [*drive:*] [IQ] [/FS:*file-system*]

Formats the specified drive to the specified file system.

*drive:* Drive letter of the partition to format.

/Q Performs a quick format of the drive.

*/FS:file-system* Specifies the type of file system to use: FAT, FAT32, or NTFS. If none is specified, then the existing file system format is used, when available.

## LISTSVC

The LISTSVC command lists all available services, drivers, and their start types for the current Windows 2000 installation. This might be useful when using the DISABLE and ENABLE commands.

These are extracted from the %SystemRoot%\System32\Config\SYSTEM hive. Should the SYSTEM hive become damaged or missing, unpredictable results might occur.

## LOGON

LOGON

The LOGON command lists all detected installations of Windows 2000 and Windows NT, and then requests the local administrator password for the copy of Windows you chose to log on to. If more than three attempts to log on do not succeed, the console quits and your computer restarts.

## MAP

MAP [*arc*]

The MAP command lists drive letters, file system types, partition sizes, and mappings to physical devices.

*arc* The *arc* parameter tells MAP to use ARC paths instead of Windows 2000 Device paths.

## MD and MKDIR

The MD and MKDIR commands make folders. Wildcard characters are not supported. The MKDIR command operates only within the system folders of the current installation of Windows 2000, removable media, the root folder of any hard disk partition, or the local installation sources.

## MORE

MORE *filename*

The MORE command displays a text file to the screen.

## RD and RMDIR

The RD and RMDIR commands delete a folder. They operate only within the system folders of the current Windows 2000 installation, removable media, the root folder of any hard disk partition, or the local installation sources. The folder must be empty for the command to work properly.

## REN and RENAME

The REN and RENAME commands can rename a file. Note that you cannot specify a new drive or path for your destination file. The REN and RENAME commands operate only within the system folders of the current Windows 2000 installation, removable media, the root folder of any hard disk partition, or the local installation sources.

## SET

The SET command allows you to display or modify four environment options:

```
AllowWildCards = FALSE
AllowAllPaths = FALSE
AllowRemovableMedia = FALSE
NoCopyPrompt = FALSE
```

The SET command is disabled by default. To enable it, use the Enables The Set Command For The Recovery Console attribute of a security template, located under the Local Computer Policy/Computer Configuration/Windows Settings/Security Settings/Local Policies/Security Options container.

## **SYSTEMROOT**

The SYSTEMROOT command sets the current working folder to the *%SystemRoot%* folder of the Windows 2000 installation you are currently logged on to.

## **TYPE**

TYPE *filename*

The TYPE command displays a text file.

# Appendix E

## Windows 2000 Support Tools

This appendix contains a list of the Windows 2000 Support Tools available on the Windows 2000 CD-ROM in the Support.cab file located in the \Support\Tools folder. Updated tools are available with Service Pack 2 and Service Pack 3 but aren't installed by default. (You must install them from the Support.cab file located in the \Support\Tools folder of the Service Pack CD or download them from Microsoft's Web site at <http://www.microsoft.com/windows2000/downloads/servicepacks>. A patch is also available there to update previously installed support tools.)

Support tools that have been updated are listed with the Service Pack revision in which they were updated.

Tool	Filename	Format	Description
ACL Diagnostics	Acldiag.exe	Cmd	Diagnoses and troubleshoots permissions problems
Active Directory Administration Tool	Ldp.exe	GUI	Performs Lightweight Directory Access Protocol (LDAP) operations
Active Directory Diagnostic Tool	Dsastat.exe	Cmd	Compares two directory trees within a domain or across different domains
Active Directory Object Manager	Movetree.exe	Cmd	Moves objects (such as users) between domains, leaving all linked group policies intact
Active Directory Replication Monitor	Replmon.exe	GUI	Displays Active Directory replication information
Active Directory Search Tool	Search.vbs	Cmd	Script tool used to search an LDAP directory
ADSI Edit	Adsiedit.msc	GUI	Low-level editor for Active Directory; enables adding, moving, and deleting objects within Active Directory
Advanced Power Management Status	Apmstat.exe	Cmd	Provides information on Advanced Power Management features in older laptop computers
Application Compatibility Program (Service Pack 3)	Apcompat.exe	Cmd, GUI	Runs incompatible programs in special compatibility modes
Browser Status	Browstat.exe	Cmd	Determines whether a browser is running in a domain
Clone Principal	Clonepr.dll	Cmd	Creates clones of Windows NT 4 users and groups so they can be migrated to Windows 2000
Dependency	Depends.exe	GUI	Scans any Win32 module and reports all

Walker			dependent modules; used to find the minimum set of files needed to load an application and to find what functions a module uses or exports
Distributed file system Utility (Service Pack 2)	Dfsutil.exe	Cmd	Queries and troubleshoots Dfs
DNS Troubleshooting Tool (Service Pack 2)	Dnscmd.exe	Cmd	Allows administrators to view and modify DNS servers, zones, and resources
Domain Controller Diagnostic Tool (Service Pack 2)	Dcdiag.exe	Cmd	Analyzes and reports on the state of domain controllers in an enterprise
DsAcls	Dsacls.exe	Cmd	Manages access control lists
Dump Check	Dumpchk.exe	Cmd	Reports and analyzes dump files
File and Directory Comparison	Windiff.exe	Cmd, GUI	Compares ASCII text files or folders
FileVer	Filever.exe	Cmd	Reports version information for a file or folder
Global Flags Editor	Gflags.exe	GUI	Edits global registry settings or flags in use by the kernel
Kerberos Keytab Setup	Ktpass.exe	Cmd	Configures a non-Windows 2000 Kerberos service to be a security principle in Windows 2000
Kerberos Setup	Ksetup.exe	Cmd	Configures Windows 2000 clients to use an MIT Kerberos server
Memory Profiling Tool	Memsnap.exe	Cmd	Takes a snapshot of the memory resources being used by all processes and reports the information to a log file
Migration Planning Document	Dommig.doc	GUI	Considers plans for migrating Windows NT domains to Windows 2000
Network Connectivity Tester (Service Pack 2)	Netdiag.exe	Cmd	Troubleshoots network connectivity
Nltest (Service Pack 2)	Nltest.exe	Cmd	Queries the status of trusts; lists primary domain controllers; forces a shutdown; forces a user database into sync on a Windows NT domain; usable on both Windows NT and Windows 2000
Point-to-Point Tunneling Protocol Ping (PPTP Ping)	PptpInt.exe, Pptpsrv.exe	Cmd	Tests functionality of PPTP clients and servers
Poolmon	Poolmon.exe	Cmd	Detects memory leaks
Process Resource Monitor	Pmon.exe	Cmd	Tracks CPU and memory usage to measure process resource usage
Process Viewer	Pviewer.exe	GUI	Changes process priority; allows the killing of processes

Registry Console Tool	Reg.exe	Cmd	Modifies the registry database from the command line; used to query, add, delete, copy, save, and restore entries
Remote Command Line	Remote.exe	Cmd	Runs command-line programs on remote computers using named pipes only
Remote Storage Diagnostic Utility	Rsddiag.exe	Cmd	Queries and reports on remote storage databases
Remote Storage File Information Utility	Rmdir.exe	Cmd	Displays information for files in remote storage
Replication Diagnostics Tool	Repadmin.exe	Cmd	Diagnoses replication problems between controllers in Windows 2000
Security Administration Tools	Sidwalk.exe, Showaccs.exe, Sidwalk.msc	Cmd, Cmd, GUI	Manage access control lists
Security Descriptor Check Utility	Sdcheck.exe	Cmd	Displays the effective access controls on an object
SNMP Query Tool	Snmputilg.exe	GUI	Graphical version of Snmputil.exe used to troubleshoot Simple Network Management Protocol
System Information	Msiinfo32.exe	Cmd	Reports system configuration information
Task Killing Utility	Kill.exe	Cmd	Ends one or more processes
Task List Viewer	Tlist.exe	Cmd	Displays list of currently running processes
Windows 2000 Domain Manager (Service Pack 2)	Netdom.exe	Cmd	Provides command-line administration of domains and trust relationships
Windows 2000 Error and Event Messages Help	W2000msgs.chm	GUI	Lists error and system-information messages in an HTML document
Windows Installer Cleanup Utility	Msicuu.exe, Msizap.exe	GUI, Cmd	Removes registry entries from a faulty installation
Windows Report Tool	Winrep.exe	GUI	Gathers information about a Windows problem for uploading to a support center or help desk
Winsock Remote Console	Wsremote.exe	Cmd	Allows a connection to a server running a console operation using sockets or named pipes
Winsock Direct Ping	Wsdping.exe	Cmd	Ping utility for System Area Network (SAN) servers, using Winsock Direct

## Glossary

### A

**Access control entry (ACE)** An entry in an access control list (ACL) that defines the level of access for a user or group.

**Access control list (ACL)** A set of data associated with a file, directory, or other resource that defines the permissions users or groups have for accessing it. In Active Directory, the ACL is a list of access control entries (ACEs) stored with the object it protects. In Microsoft Windows NT, an ACL is stored as a binary value called a security descriptor.

**Account lockout** A security feature that disables a user account if failed logons exceed a specified number in a specified period of time. Locked accounts can't log on and must be unlocked by an administrator.

**Active Directory** In Microsoft Windows 2000 Server, Active Directory replaces the Windows NT collection of directory functions with an integrated implementation that includes DNS, DHCP, LDAP, and Kerberos.

**Active Server Pages (ASP)** A specification for dynamically created Web pages that contain either Microsoft Visual Basic or Microsoft JScript code. When a user requests such a page, the script is executed on a server and the page is transmitted to the user as an HTML document.

**ActiveX** A loosely defined set of technologies that allows software components to interact with each other in a networked environment.

**ActiveX control** A software component that adheres to the ActiveX specification and can operate in an ActiveX-compliant environment.

**Address** A precise location where a piece of information is stored in memory or on disk. Also, the unique identifier for a node on a network. On the Internet, the code by which an individual user is identified. The format is *username@hostname*, where *username* is your user name, logon name, or account number, and *hostname* is the name of the computer or Internet provider you use. The host name might be a few words strung together with periods.

**Address Resolution Protocol (ARP)** A TCP/IP and AppleTalk protocol that provides IP-address-to-MAC (media access control) address resolution for IP packets.

**Advanced Configuration Power Interface (ACPI)** An industry specification defining power management on a range of computer devices. ACPI compliance is necessary for devices to use the power management capabilities in Windows 2000.

**Allocation unit** The smallest unit of managed space on a hard disk or logical volume. Also called a cluster.

**Anonymous FTP** A way to use the FTP program to log on to another computer to copy files when you don't have an account on that computer. When you log on, enter *anonymous* as the user name and your address as the password. This gives you access to publicly available files. See *File Transfer Protocol (FTP)*.

**AppleTalk** Local area network architecture built into Macintosh computers to connect them with printers. A network with a Windows 2000 server and Macintosh clients can function as an AppleTalk network with the use of AppleTalk network integration (formerly Services for Macintosh).

**Associate** To connect files having a particular extension to a specific program. When you double-click a file with the extension, the associated program is launched and the file you clicked is opened. In Windows, associated file extensions are usually called registered file types.

**Asynchronous Transfer Mode (ATM)** A network technology based on sending data in cells or packets of a fixed size. It is asynchronous in that the transmission of cells containing information from a particular user isn't necessarily periodic.

**Attribute** A characteristic. In Windows 2000 file management, it is information that shows whether a file is read-only, hidden, compressed, encrypted, ready to be backed up (archived), or should be indexed.

**Audit policy** Defines the type of security events to be logged. It can be defined on a server or an individual computer.

**Authentication** Verification of the identity of a user or computer process. In Windows 2000 and Windows NT, authentication involves comparing the user's security identifier (SID) and password to a list of authorized users on a domain controller.

## B

**Backup domain controller (BDC)** In a Windows NT domain, a computer that stores a backup of the database that contains all the security and account information from the primary domain controller (PDC). The database is regularly and automatically synchronized with the copy on the PDC. A BDC also authenticates logons and can be promoted to a PDC when necessary. In a Windows 2000 domain, backup domain controllers aren't required; all domain controllers are peers, and all can perform maintenance on the directory. Windows NT 3.51 and 4 BDCs can participate in a Windows 2000 domain when it is running in mixed mode.

**Backup media pool** A logical set of backup storage media used by Windows 2000 Backup.

**Bandwidth** On a network, the transmission capacity of a communications channel stated in megabits per second (Mbps). For example, Ethernet has a bandwidth of 10 Mbps. Fast Ethernet has a bandwidth of 100 Mbps.

**Binding** A software connection between a network card and a network transport protocol (such as TCP/IP).

**BOOTP** Boot Protocol. Used on TCP/IP networks to enable a diskless workstation to learn its own IP address, the location of a BOOTP server on the network, and the location of a file to be loaded into memory to boot the machine. This allows a computer to boot without a hard disk or a floppy disk.

**Broadcasting** To simultaneously send a message to everyone on a network. See *multicasting*.

**Browser service** The service that maintains a current list of computers and provides the list to applications when needed. When a user attempts to connect to a resource in the domain, the Browser service is contacted to provide a list of available resources. The lists displayed in My Network Places and Active Directory Users and Computers (among others) are provided by the Browser service. Also called the Computer Browser service.

## C

**Certificate** A credential used to prove the origin, authenticity, and purpose of a public key to the entity that holds the corresponding private key.

**Certificate authority (CA)** The service that accepts and fulfills certificate requests and revocation requests and that can also manage the policy-directed registration process a user completes to get a certificate.

**Certificate revocation list (CRL)** A digitally signed list (published by a certificate authority) of certificates that are no longer valid.

**Child domain** Domains located directly beneath another domain name (parent domain). For example, Engineering.scribes.com is a child domain of scribes.com, the parent domain. Also called a subdomain.

**Child object** An object inside another object. For example, a file is a child object inside a folder, which is the parent object.

**Cluster** A set of computers joined together in such a way that they behave as a single system. Clustering is used for load balancing as well as fault tolerance. Members of a cluster are referred to as *nodes*.

**Cluster service** The collection of software on each node that manages all cluster-specific activity.

**Console tree** The default left pane in Microsoft Management Console (MMC) that shows the items contained in a console.

**Container** An Active Directory object that has attributes and is part of the Active Directory namespace. Unlike other objects, it doesn't usually represent something concrete. It is a package for a group of objects and other containers.

**Cross-link trust** A transitive trust relationship between two Windows 2000 domains in different domain trees but within the same forest. Cross-link trusts must be explicitly created.

## D

**Daemon** A background program that runs unattended, gathering information or performing other tasks.

**Delegation** Assigning administrative rights over a portion of the name-space to another user or group.

**Directory service** Provides the means for storing directory data and making this data available to network users and administrators. For example, Active Directory stores information about user accounts, such as names, passwords, phone numbers, and so on, and enables other authorized users on the same network to access this information.

**Disk quota** A limitation set by an administrator on the amount of disk space available to a user.

**Distinguished name (DN)** In the context of Active Directory, "distinguished" means the qualities that make the name distinct. The distinguished name identifies the domain that holds the object as well as the complete path through the container hierarchy used to reach the object.

**Distributed file system (Dfs)** A file management system in which files can be located on separate computers but are presented to users as a single directory tree.

**DNS name servers** Servers that contain information about part of the Domain Name System (DNS) database. These servers make computer names available to queries for name resolution across the Internet. Also called domain name servers.

**Domain** In Windows 2000, a group of computers that share a security policy and a user account database. A Windows 2000 domain is not the same as an Internet domain. See *domain name*.

**Domain controller** A server in a domain that accepts account logons and initiates their authentication.

**Domain local group** A local group used on ACLs only in its own domain. A domain local group can contain users and global groups from any domain in the forest, universal groups, and other domain local groups in its own domain.

**Domain name** In Active Directory, the name given to a collection of networked computers that share a common directory. On the Internet, the unique text name that identifies a specific host. A machine can have more than one domain name, but a given domain name points to only one machine. Domain names are resolved to IP addresses by DNS name servers.

**Domain Name System (DNS)** A service on TCP/IP networks (the Internet included) that translates domain names into IP addresses. This allows users to employ friendly names like FinanceServer or Ourbusiness.com when querying a remote system, instead of using an IP address such as 198.45.233.59.

**Domain naming master** The one domain controller assigned to handle the addition or removal of domains in a forest. See *Operations Master*.

**Downlevel** Term used to describe Microsoft services for clients, servers, and networks prior to Windows 2000, when viewed from Windows 2000.

**Dynamic Data Exchange (DDE)** Communication between processes implemented in the Windows family of operating systems. When programs that support DDE are running at the same time, they can exchange data by means of conversations. Conversations are two-way connections between two applications that transmit data alternately.

**Dynamic Host Configuration Protocol (DHCP)** A TCP/IP protocol used to automatically assign IP addresses and configure TCP/IP for network clients.

**Dynamic-link library (DLL)** A program module that contains executable code and data that can be used by various programs. A program uses the DLL only when the program is active, and the DLL is unloaded when the program closes.

## E

**Enterprise** Term used to encompass all of a business's operation, including all remote offices and branches.

**Environment variable** A string of environment information such as a drive, path, or filename

associated with a symbolic name. The System option in Control Panel or the Set command from the command prompt can be used to define environment variables.

**Ethernet** A local area network protocol developed by Xerox Corporation in 1976. Ethernet supports data transfer rates of 10 Mbps and uses a bus topology and thick or thin coaxial, fiber-optic, or twisted-pair cabling. A newer version of Ethernet called Fast Ethernet supports data transfer rates of 100 Mbps, and an even newer version, Gigabit Ethernet, supports data transfer rates of 1000 Mbps.

**Extended partition** A nonbootable portion of a hard disk that can be subdivided into logical drives. There can be only a single extended partition per hard disk.

## F

**File allocation table (FAT)** A file system consisting of a table that keeps track of the size and location of files on a hard disk.

**File Transfer Protocol (FTP)** A method of transferring one or more files from one computer to another over a network or telephone line. Because FTP has been implemented on a variety of systems, it's a simple way to transfer information between usually incongruent systems such as a PC and a minicomputer.

**Firewall** A protective filter for messages and logons. An organization connected directly to the Internet uses a firewall to prevent unauthorized access to its network. See *proxy server*.

**Folder redirection** An option in Group Policy to place users' special folders such as My Documents on a network server.

**Forest** A group of one or more Active Directory trees that trust each other through two-way transitive trusts. All trees in a forest share a common schema, configuration, and Global Catalog (GC). When a forest contains multiple trees, the trees don't form a contiguous namespace. Unlike trees, a forest doesn't need a distinct name.

**Fully qualified domain name (FQDN)** A domain name that includes the names of all network domains leading back to the root to clearly indicate a location in the domain namespace tree. An example of an FQDN is Accts.finance.datafointl.com or Sales.europe.microsoft.com.

## G

**Gateway** A device used to connect networks using dissimilar protocols so that information can be passed from one to another.

**Global Catalog (GC)** Contains a full replica of all directory objects in its host domain plus a partial replica of all directory objects in every domain in the forest. A GC contains information about all objects in all domains in the forest, so finding information in the directory doesn't require unnecessary queries across domains. A single query to the GC produces the information about where the object can be found.

**Global group** A group that can be used in its own domain and in trusting domains. However, it can contain user accounts and other global groups only from its own domain.

**Globally unique identifier (GUID)** Part of the identifying mechanism generated by Active Directory for each object in the directory. If a user or computer object is renamed or moved to a different name, the security identifier (SID), relative distinguished name (RDN), and distinguished name (DN) will change, but the GUID will remain the same.

**Group Policy** Setting of rules for computers and users in Windows 2000. Group Policy includes the registry-based policy found in Windows NT Server 4 but is also able to store policies for file deployment, application deployment, logon/logoff scripts, startup/shutdown scripts, domain security, Internet Protocol security (IPSec), and so on.

**Group Policy object (GPO)** A collection of policies stored in two locations: a Group Policy container (GPC) and a Group Policy template (GPT). The GPC is an Active Directory object that stores version information, status information, and other policy information (for example, application objects). The GPT is used for file-based data and stores software policy, script, and deployment information. The GPT is located in the system volume folder of the domain controller.

## H

**Hive** One of five sections of the registry on a hard disk. Each hive is a discrete body of keys,

subkeys, and values that record configuration information for the computer. Each hive is a file that can be moved from one system to another but can be edited only by using the Registry Editor.

**Host** Any device on the network that uses TCP/IP. A host is also a computer on the Internet you might be able to log on to. You can use FTP to get files from a host computer and use other protocols (such as Telnet) to make use of the host computer.

**Hosts file** A local ASCII text file that maps host names to IP addresses. Each line represents one host, starting with the IP address, one or more spaces, and then the host's name.

**Hypermedia** A system that can link text, pictures, sound, video, or all four.

**Hypertext** A system of writing and displaying text that enables the text to be linked in multiple ways, available at several levels of detail. Hyper-text documents can also contain links to related documents, such as those referred to in footnotes.

**Hypertext Markup Language (HTML)** A system used for writing pages for the World Wide Web. HTML allows text to include codes that define fonts, layout, embedded graphics, and hypertext links.

**Hypertext Transfer Protocol (HTTP)** The method by which Web pages are transferred over the network.

## I

**IntelliMirror** A suite of technologies that allows a complete operating environment to follow the user to other computers, as well as offline. Components include the user's profiles, data, and applications.

**Internet** The vast collection of interconnected networks that all use TCP/IP and that evolved from ARPANET of the late 1960s and early 1970s. The Internet connects roughly 70,000 independent networks into a global network.

**Internet Control Message Protocol (ICMP)** A protocol used to report problems encountered with the delivery of data, such as unreachable hosts or unavailable ports. ICMP is also used to send a request packet to determine whether a host is available. The receiving host sends back a packet if it is available and functioning. See *ping*.

**Internet Explorer** Microsoft's Windows-based, Winsock-compliant program for browsing the World Wide Web.

**Internet Protocol (IP)** The inter-network layer protocol used as a basis of the Internet. IP enables information to be routed from one network to another in packets and then reassembled when they reach their destination.

**Internet Protocol next generation (IPng) or IP version 6 (IPv6)** A new version of Internet Protocol. The official name of IPng is IPv6, where "v6" stands for version 6. The current version of IP is version 4, also known as IPv4. IPng is an evolutionary upgrade and will coexist with version 4 for some time.

**Internet Relay Chat (IRC)** A system that enables Internet users to talk with each other in real time over the Internet.

**Internetwork Packet Exchange/ Sequenced Packet Exchange (IPX/SPX)** Transport protocols used in Novell NetWare networks.

**IP number or IP address** A four-part number separated by periods (for example, 165.113.245.2) that uniquely identifies a machine on the Internet. Every machine on the Internet has a unique IP number; if a machine doesn't have an IP number, it isn't really on the Internet. Most machines also have one or more domain names that are easier for people to remember.

**IPSec** Internet Protocol security. An Internet Engineering Task Force (IETF) standard for creating virtual private networks (VPNs).

## J

**Java** An advanced programming language similar to C and C++ used in Web pages to provide animation and other advanced features that make Web pages unique.

## K

**Kerberos** An identity-based security system that authenticates users at logon. It works by assigning a unique key, called a *ticket*, to each user who logs on to the network. The ticket is then embedded in messages to identify the sender of the message. The Kerberos security protocol is the primary authentication mechanism in the Windows 2000 operating system.

**Kernel** The part of the executive (or operating system) that manages the processor. The kernel performs thread scheduling and dispatching, interrupt and exception handling, and multiprocessor synchronization.

## L

**Lightweight Directory Access Protocol (LDAP)** A protocol used to access a directory service. LDAP is a simplified version of the Directory Access Protocol (DAP), which is used to gain access to X.500 directories. LDAP is the primary access protocol for Active Directory.

**LISTSERV** A family of programs that manage Internet mailing lists by distributing messages posted to the list, adding and deleting members automatically.

**Lmhosts file** An ASCII text file like Hosts but used to associate IP addresses to host names inside a network. To remember which is which, remember Lmhosts as LAN Manager Hosts.

**Local area network (LAN)** A group of connected computers, usually located close to one another (such as in the same building or the same floor of the building) so that data can be passed among them.

**Log on** The act of entering into a computer system; for example, "Log on to the network and read your e-mail."

**Logon** The account name used to gain access to a computer system. Unlike a password, the logon name isn't a secret.

**Logon script or logoff script** Typically a batch file set to run when a user logs on or logs off a system. A logon script is used to configure a user's initial environment. A logoff script is used to return a system to some predetermined condition. Either script can be assigned to multiple users individually or through Group Policy.

## M

**Media access control (MAC) address** A unique 48-bit number assigned to network interface cards by the manufacturer. MAC addresses are used for mapping in TCP/IP network communication.

**Member server** A computer running Windows 2000 Server or Windows NT Server that is *not* a domain controller. Member servers can be dedicated to managing files or printer services or other functions. A member server doesn't verify logons or maintain a security database.

**Mirror** 1. Two partitions on two hard disks configured so that each will contain identical data to the other. If one disk fails, the other contains the data and processing can continue. 2. An FTP server that provides copies of the same files as another server. Some FTP servers are so popular that other servers have been set up to mirror them and spread the FTP load to more than one site.

**Mixed mode** A domain in which domain controllers running both Windows 2000 and earlier versions of Windows NT coexist. In mixed mode, the domain features from previous versions of Windows NT Server are still enabled, while some Windows 2000 features are disabled. Windows 2000 Server domains are installed in mixed mode by default. In mixed mode, the domain might have Windows NT 4 backup domain controllers present. Nested groups aren't supported in mixed mode.

**Modem (modulator/demodulator)** A device that connects a computer and a telephone line to allow the computer to talk to other computers through the system. Modems convert the computer's digital signals into analog waves that can be transmitted over standard voice telephone lines. Modem speeds are measured in bits per second (bps)—also sometimes expressed as kilobits (thousands of bits) per second (Kbps). For example, 28.8 Kbps and 28,800 bps are the same measurement—28,800 bits per second.

**Multicasting** Simultaneously sending a message to more than one destination on a network. Multicasting is distinguished from broadcasting in that multicasting sends to only selected recipients.

**Multimaster replication** A feature of Active Directory, multimaster replication automatically

propagates every object (such as users, groups, computers, domains, organization units, security policies, and so on) created on any domain controller to each of the other participating domain controllers. All domain controllers contain the same directory data, so the domain doesn't depend on a single source for directory information.

**Multitasking** Computer legerdemain by which tasks are switched in and out of the processor so quickly that it appears they are all happening at once. The success of a multitasking system depends on how well the various tasks are isolated from one another.

**Multithreading** The simultaneous processing of several threads inside the same program. Because several threads can be processed in parallel, one thread doesn't have to finish before another one can start. See *thread*.

## N

**Name resolution** The process of mapping a name to its corresponding address.

**Namespace** A name or group of names defined according to a naming convention; any bounded area in which a given name can be resolved. Active Directory is primarily a name-space, as is any directory service. The Internet uses a hierarchical name-space that partitions names into categories known as top-level domains, such as .com, .edu, and .gov.

**Native mode** The condition of a domain when all domain controllers have been upgraded to Windows 2000 and the administrator has enabled native mode operation. See *mixed mode*.

**Net Logon service** Accepts logon requests from any client and provides authentication from the Security Accounts Manager (SAM) database of accounts.

**NetBIOS Enhanced User Interface (NetBEUI)** A small and fast protocol that requires little memory but can't be routed. Remote locations linked by routers can't use NetBEUI to communicate.

**Network** Two or more computers connected for the purpose of sharing resources.

**Network News Transfer Protocol (NNTP)** A protocol defined for distribution, inquiry, retrieval, and posting of news articles on the Internet.

**Newsgroup** On the Internet, a distributed bulletin board system about a particular topic. USEnet News (also known as Netnews) is a system that distributes thousands of news-groups to all parts of the Internet.

**Node** A location on a tree structure with links to one or more items below it. On a LAN, a device that can communicate with other devices on the network. In clustering, a computer running Windows 2000 Advanced Server that is a member of a cluster.

**NTFS file system** The native file system for Windows 2000 and Windows NT. Supports long filenames, a variety of permissions for sharing files, and a transaction log that allows the completion of any incomplete file-related tasks if the operating system is interrupted.

## O

**Object** An object is a particular set of attributes that represents something concrete, such as a user, a printer, or an application. The attributes hold data describing the thing that is identified by the object. Attributes of a user might include the user's given name, surname, and e-mail address. The classification of the object defines which types of attributes are used. For example, the objects classified as users might allow the use of attribute types like common name, telephone number, and e-mail address, whereas the object class of organization allows for attribute types like organization name and business category. An attribute can take one or more values, depending on its type.

**Object identity** Every object in Active Directory has a unique identity. Objects can be moved or renamed, but their identities never change. Objects are known internally by their identity, not their current name. An object's identity is a globally unique identifier (GUID), which is assigned by the Directory System Agent (DSA) when the object is created. The GUID is stored in an attribute, the object GUID, which is part of every object. The object GUID attribute can't be modified or deleted. When storing a reference to an Active Directory object in an external store (for example, a database), you should use the object GUID because, unlike a name, it won't change.

**Operations Master** Active Directory operations that are single master—that is, operations that are

not permitted to occur at different places in the network at the same time. Examples of these operations include the primary domain controller (PDC) emulator, schema modification, domain naming, and the relative identifier (RID) allocator.

**Organizational unit (OU)** A container object in Active Directory used to separate computers, users, and other resources into logical units. An organizational unit is the smallest entity to which Group Policy can be applied.

## P

**Packet** The basic unit of information sent over a network. Each packet contains the destination address, the sender's address, error-control information, and data. The size and format of a packet depends on the protocol being used.

**Page** A document, or collection of information, available over the World Wide Web. A page can contain text, graphics, video, and sound files. Also, a portion of memory that the virtual memory manager can swap to and from a hard disk.

**Paging** A virtual memory operation in which pages are transferred from memory to disk when memory becomes full. When a thread accesses a page that's not in memory, a page fault occurs and the memory manager uses page tables to find the page on disk and then loads the page into memory.

**Peer-to-peer** A network in which two or more machines can communicate with each other without the need for any intermediary device. On a peer-to-peer network, a computer can be both a client and a server.

**Ping** A network management tool that checks to see whether another computer is available and functioning. It sends a short message to which the other computer automatically responds. If the other computer doesn't respond to the ping, you usually can't establish communications.

**Point of presence (POP)** A physical site in a geographic area where a network access provider, such as a telecommunications company, has equipment to which users connect. The local telephone company's central office in a particular area is also sometimes referred to as their POP for that area.

**Point-to-Point Tunneling Protocol (PPTP)** A protocol that provides router-to-router and host-to-network connections over a telephone line (or a network link that acts like a telephone line). See *Serial Line Internet Protocol (SLIP)*.

**Post Office Protocol (POP)** A protocol by which a mail server on the Internet lets you access your mail and download it to a PC or Macintosh. Most people refer to this protocol with its version number (POP2, POP3, and so on) to avoid confusing it with points of presence (POPs).

**Primary domain controller (PDC)** In a Windows NT domain, the server that authenticates domain logons and maintains the security policy and master database for a domain. In Windows 2000, running in mixed mode, one of the domain controllers in each domain is identified as the PDC for compatibility with down-level clients and servers.

**Primary partition** A portion of the hard disk that's been marked as a potentially bootable logical drive by an operating system. MS-DOS can support only a single primary partition, but Windows NT and Windows 2000 can support multiple partitions. Only four primary partitions can live on any hard disk.

**Profile** Loaded by the system when a user logs on, the profile defines a user's environment, including network settings, printer connections, desktop settings, and program items.

**Proxy server** A server that receives Web requests from clients, retrieves Web pages, and forwards them to clients. Proxy servers can dramatically improve performance for groups of users by caching retrieved pages. Proxy servers also provide security by shielding the IP addresses of internal clients.

**Public-key cryptography** A method of secure transmission in which two different keys are used—a public key for encrypting data and a private key for decrypting data.

## Q

**Quality of Service (QoS)** A set of standards for assuring the quality of data transmission on a network.

## R

**Redundant array of independent disks (RAID)** A range of disk management and striping techniques to implement fault tolerance.

**Relative distinguished name (RDN)** Active Directory uses the concept of a relative distinguished name (RDN), which is the part of the distinguished name that is an attribute of the object itself.

**Relative identifier (RID)** The part of the security identifier (SID) that is unique to each object.

**Remote Access Service (RAS)** Allows users to connect from remote locations and access their networks for file and printer sharing and e-mail. The computer initiating the connection is the RAS client; the answering computer is the RAS host.

**Remote Authentication Dial-In User Service (RADIUS)** A security authentication system used by many Internet service providers (ISPs). A user connects to the ISP and enters a user name and password. This information is verified by a RADIUS server, which then authorizes access to the ISP system.

**Remote Installation Services (RIS)** Allows clients to boot from a network server and use special preboot diagnostic tools installed on the server or to automatically install Windows 2000 Professional on the client system.

**Replication** On network computers, enables the contents of a directory, designated as an export directory, to be copied to other directories, called import directories.

**Requests for comments (RFCs)** An evolving collection of material that details the functions within the TCP/IP family of protocols. Some RFCs are official documents of the Internet Engineering Task Force (IETF), defining the standards of TCP/IP and the Internet, whereas others are simply proposals trying to become standards, and others fall somewhere in between. Some are tutorial in nature, whereas others are quite technical.

**Router** A special-purpose computer (or software package) that handles the connection between two or more networks. Routers look at the destination addresses of the packets passing through them and decide which route to use to send them.

## S

**Schema** A definition of the object classes and attributes that can be stored in Active Directory. Like other objects in Active Directory, schema objects have an access control list (ACL) to limit alterations to only authorized users.

**Schema master** The single domain controller assigned to track all updates to a schema within a forest.

**Scope** In DHCP, the range of IP addresses available to be leased to DHCP clients by the DHCP service. In groups, scope describes where in the network permissions can be assigned to the group.

**Security Accounts Manager (SAM)** Manager of user account information including group membership. A logon service of both Windows 2000 and Windows NT.

**Security Identifier (SID)** A unique number assigned to every computer, group, and user account on a Windows 2000 or Windows NT network. Internal processes in the operating system refer to an account's SID rather than a name. A deleted SID is never reused.

**Serial Line Internet Protocol (SLIP)** A protocol used to run IP over serial lines or telephone lines using modems. Rapidly being replaced by Point-to-Point Tunneling Protocol (PPTP).

**Server** A computer that provides a service to other computers on a network. A file server, for example, provides files to client machines.

**Site** In Active Directory, an area of one or more well-connected subnets. When users log on to a site, clients use Active Directory servers in the same site. See *well connected*.

**Smart card** A credit card-sized device that securely stores user credentials such as passwords, certificates, public and private keys, and other types of personal information.

**Snap-in** A tool that can be added to a console supported by the Microsoft Management Console (MMC). You can add a snap-in extension to extend the function of a snap-in.

**Socket** An endpoint to a connection. Two sockets form a complete path for a bidirectional pipe for

incoming and outgoing data between networked computers. The Windows Sockets API is a networking API for programmers writing for the Windows family of products.

**Subdomain** A domain in the DNS namespace that is located directly under another domain. See *child domain*.

**Subnet** The portion of a TCP/IP network in which all devices share a common prefix. For example, all devices with an IP address that starts with 198 are on the same subnet. IP networks are divided using a subnet mask.

**Superscope** A collection of scopes grouped into a single administrative whole. Grouping scopes together into a superscope makes it possible to have more than one logical subnet on a physical subnet.

**SystemRoot** The path and folder where the Windows 2000 system files are located. The value %SystemRoot% can be used in paths to replace the actual location. To identify the SystemRoot folder on a computer, type %SystemRoot% at a command prompt.

## T

**Telnet** The protocol and program used to log on from one Internet site to another. The Telnet protocol/program gets you to the logon prompt of another host.

**Terminal** A device that allows you to send commands to another computer. At a minimum, this usually means a keyboard, a display screen, and some simple circuitry. You will usually use terminal software in a personal computer—the software pretends to be, or emulates, a physical terminal and allows you to type commands to another computer.

**Thread** An executable entity that belongs to one (and only one) process. In a multitasking environment, a single program can contain several threads, all running at the same time.

**Transitive trust** The standard trust between Windows 2000 domains in a domain tree or forest. Transitive trusts are always two-way trusts. When a domain joins a domain tree or forest, a transitive trust relationship is established automatically.

**Transmission Control Protocol/Internet Protocol (TCP/IP)** The protocol that networks use to communicate with each other on the Internet.

**Tree** A tree in Active Directory is just an extension of the idea of a directory tree. It's a hierarchy of objects and containers that demonstrates how objects are connected, or the path from one object to another. Endpoints on the tree are usually objects.

**Trojan horse** A destructive program designed to disguise itself as a benign application. Unlike viruses, Trojan horses don't replicate themselves, but they can be just as dangerous.

**Trust relationship** A security term meaning that one workstation or server trusts a domain controller to authenticate a user logon on its behalf. It also means a domain controller trusts a domain controller in another domain to authenticate a logon.

## U

**Uniform Resource Locator (URL)** The standard way to give the address of any resource on the Internet that is part of the World Wide Web. For example, <http://www.capecod.net/~fcollege/index.htm>. The most common way to use a URL is to enter it into a Web browser program, such as Microsoft Internet Explorer or Netscape Navigator.

**Universal group** A group that can be used anywhere in a domain tree or forest. Members can come from any domain, and rights and permissions can be assigned at any domain. Universal groups are available only when the domain is in native mode.

**Universal Naming Convention (UNC)** A PC format for indicating the location of resources on a network. UNC uses the following format: \\Server\Shared\_resource\_path. To identify the Example.txt file in the Sample folder on the server named Ample, the UNC would be \\Ample\Sample\Example.txt.

**UNIX** A computer operating system designed to be used by many computer users at the same time (multiuser) with TCP/IP built in. The most common operating system for servers on the Internet.

**User account** A user's access to a network. Each user account has a unique user name and security ID (SID).

**User profiles** Information about user accounts. See *profile*.

## V

**Viewer** A program used by Gopher, Wide Area Information Server (WAIS), or Web client programs to show files with contents other than text. You use a viewer to display graphics or video files or to play sound files.

**Virtual Reality Modeling Language (VRML)** A file format for 3-D models and scenes that is used primarily on the World Wide Web. VRML objects and scenes can be viewed and inter-actively navigated with a VRML browser, and VRML scenes can have embedded hyperlinks, allowing for a type of three-dimensional Web site.

## W

**Well connected** Sufficiently fast and reliable for the needs of Active Directory clients and servers. The definition of "sufficiently fast and reliable" for a particular network depends on the work being done on the specific network.

**Wide area network (WAN)** Any Internet or network that covers an area larger than a single building or campus.

**Windows Internet Name Service (WINS)** A name resolution service that converts computer names to IP addresses in a routed environment.

**Windows Sockets (Winsock)** Winsock is a standard way for Windows-based programs to work with TCP/IP. You can use Winsock if you use SLIP to connect to the Internet.

**Workstation** In Windows NT, a computer running the Windows NT Workstation operating system. In a wider context, used to describe any powerful computer optimized for graphics or computer-aided design (CAD) or any of a number of other functions requiring high performance.

**World Wide Web (WWW) or Web** A hypermedia-based system for accessing information on the Internet.

## X

**X.500** A standard for a directory service established by the International Telecommunications Union (ITU). The same standard is also published by the International Standards Organization/International Electro-technical Commission (ISO/IEC). The X.500 standard defines the information model used in the directory service. All information in the directory is stored in entries, each of which belongs to at least one object class. The actual information in an entry is determined by attributes that are contained in that entry.

## Z

**Zone** A part of the DNS namespace that consists of a single domain or a domain and subdomains managed as a single, separate entity.

## About the Authors

**Charlie Russel** and **Sharon Crawford** are co-authors of numerous books on operating systems. Their titles include *Running Microsoft Windows NT Server 4*, *UNIX and Linux Answers*, *NT and UNIX Intranet Secrets*, and *Upgrading to Windows 98*.

Charlie Russel is currently an information technology consultant, specializing in combined Windows and UNIX networks. He's also the co-author (with Linda Gaus) of *SCO OpenServer: The Windows Network Solution*. He regularly writes about Windows XP Professional for the Microsoft Windows XP Expert Zone (<http://www.microsoft.com/windowsxp/expertzone>) and is the author of many case studies and white papers on Microsoft Services for UNIX.

Sharon Crawford is a veteran, even grizzled, writer of computer books. In addition to the books with Charlie, she has written a dozen or so more, the most recent being *Windows 2000: The Missing Manual* and *Windows 2000 Professional for Dummies* (with Andy Rathbone). Sharon writes a regular column on using Windows XP at home for the Microsoft Windows XP Expert Zone at <http://www.microsoft.com/windowsxp/expertzone>.

**Jason Gerend** has co-authored several books, including *The Effective Executive's Guide to Outlook 2002*, *The New Webmaster's Guide to Dreamweaver 4*, and the *New Webmaster's Guide to FrontPage 2002*. He also helped Sharon and Charlie write the first edition of the *Microsoft Windows 2000 Server Administrator's Companion*, and *Windows 2000 Pro: The Missing Manual*. A Microsoft Certified Systems Engineer (MCSE), Jason enjoys hiking and installing operating systems for fun. He's been fooling around with computers since the days of MS-DOS 2, was a big fan of OS/2 2.1, and has been a freelance Webmaster and computer consultant since 1995.

## Microsoft Press Support Information

Every effort has been made to ensure the accuracy of this book. Microsoft Press provides corrections for books through the Microsoft Press Web site at

<http://www.microsoft.com/mspress/support>

If you have comments, questions, or ideas regarding the book, please send them to Microsoft Press via e-mail to

[MSPINPUT@MICROSOFT.COM](mailto:MSPINPUT@MICROSOFT.COM)

Or via postal mail to

Microsoft Press  
Attn: Microsoft Windows 2000 Server Administrator's Companion,  
2nd Ed. Editor  
One Microsoft Way  
Redmond, WA 98052-6399

Please note that product support is not offered through the above address. For more information about Microsoft software support options, please connect to <http://www.microsoft.com/support> or call Microsoft Support Network Sales at (800) 936-3500.

## **Footnotes**

### **Chapter 7**

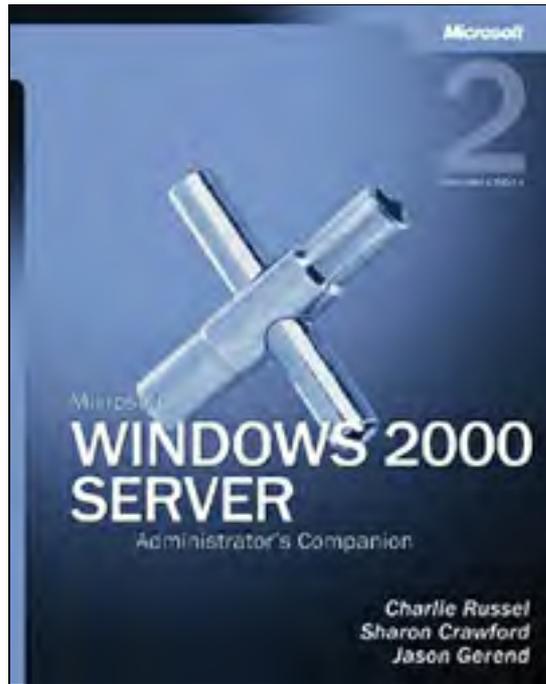

1. A one-way trust can be established in both directions.

### **Chapter 9**

1. Details about using the Microsoft Management Console (MMC) can be found in Chapter 10.

### **Chapter 36**

1. In the Number of Disks column,  $N$  refers to the number of hard disks required to hold the original copy of the data. The plus and minus symbols show relative improvement or deterioration compared to a system using no version of RAID. The scale peaks at three symbols.

## **Dedication**

To the Daves.

You know who you are.

## Acknowledgments

It's a cliché that no one produces a book alone—it's very much a team process. Clichés, however, persist because they're so often true. Many people contributed to both the composition and construction of this book. To begin at the beginning:

Thanks to acquisitions editor David Clark and our agent, David Rogelberg, for their unflagging work and support throughout this project. From the earliest discussions through the last desperate hours, they were there. We are truly grateful. Thanks also to Anne Hamilton, acquisitions manager, who rode to the rescue more than once.

We owe a debt of gratitude to the team at Microsoft Press including Anne Hamilton, Casey Doyle, and Jeff Koch. We are truly thankful for our project editor Karen Szall, who has been a remarkable oasis of calm inside the whirlwind. (Perhaps she goes home and abuses her goldfish—but we saw only unruffled professionalism on the job.) Thanks also to copy editor Teresa Horton and to technical editor Nick Cavalancia. It was their task to read and correct every page of manuscript while retaining both a broad overview and their sanity. They seem to have managed both. Needless to say, any errors that remain are the result of the authors' pigheadedness.

We also appreciate the contributions made by other talented members of the production team from nSight, Inc.: Kristen Ford, project manager; Patty Fagan, desktop publisher and artist; Jacqueline Fearer, proofreader; and Jack Lewis, indexer.

As always, Sharon and Charlie thank Dianne King and the late Dr. Rudolph S. Langer, who gave us the chance of a lifetime. And Jason would like to thank Don and Sue Gerend for encouraging him in computers and writing, as well as always believing in him.

## Contributors

In its first edition, this book required the attention of numerous true experts and specialists. Even if there had been time enough to complete such a substantial volume, the range of subjects and the degree of expertise necessary to do justice to a complex product meant that we needed help.

For this edition, all the revisions were handled by the three authors. However, we were working with splendid original material provided by the following people.

Tom Fronckowiak (LJL Enterprises) contributed two of the original chapters on security. His insights and experience were invaluable in helping explain both the concepts and implementation of protective measures in Windows 2000.

L. J. Locher was our expert on performance monitoring and tuning. She wrote about the subject in depth and with admirable clarity.

Mitch Tulloch (MTIT Enterprises, <http://www.mtit.com>) is the expert's expert on Internet services, and he provided the first edition's chapters on Internet Information Services and Internet Explorer.

Paul E. Robichaux (Robichaux & Associates, Inc.) is the computer world's Renaissance man. He is an expert on more subjects than seems fair to the rest of us. He contributed chapters on Macintosh services, Certificate Services, and managing the registry to the first book.

Craig Zacker made enormously valuable contributions on the subjects of Active Directory and Backup. His material on Active Directory was exemplary and required virtually no changes from one edition to the next.

## Introduction

When the first edition of this book was published in 2000 coinciding with the release of the Microsoft Windows 2000 family of operating systems, we were extremely gratified by the positive reception from network administrators and others interested in Windows 2000 Server. We're very proud of the book and think it's a worthwhile resource for those working to effectively manage a Windows 2000 network—and readers seem to agree. However, many months and three service packs have passed and it's time to bring the book up to date.

The entire book has been revised, but the most important modifications can be found in the following areas:

- The proxy server chapter has been written anew for Internet Security and Acceleration Server.
- In the areas of interoperability, the chapter on Macintosh Services has been revised for the Mac OS X. The interoperating with UNIX chapter is all new, reflecting the recently released Services for UNIX (SFU) version 3.
- In "Managing Software" ([Chapter 25](#)), you'll find new sections on application compatibility and deploying service packs.
- Discussion of TCP/IP administration has been greatly expanded.
- Additional security information has been included throughout the book, with particular attention given to the Internet Information Services chapters.

We've also tried to correct all the little errors and misprints that creep into even the most carefully edited book without, we hope, introducing new ones.

## **How to Use This Book**

The IT implementer can use this book in several ways. It can be read as a

- Guide to deployment
- Ready reference
- Help to making decisions about network organization and operations
- Thorough introduction to the particulars of Windows 2000 Server

We assume a fundamental understanding of networking and the Microsoft Windows family of operating systems, but we don't expect every reader to be an expert on every subject. We've tried to provide background where appropriate, as well as references to additional information.

## What's in the Book

We've divided *Microsoft Windows 2000 Server Administrator's Companion* into seven parts, roughly corresponding to each stage in the development of a Windows 2000 network:

- **Part I: Preparing for Installation** Perhaps you've heard Edison's famous quote, "Genius is one percent inspiration and ninety-nine percent perspiration." Modify that slightly and you have a good motto for network building: "A good network is one percent implementation and ninety-nine percent preparation." That's why this book begins with four chapters of planning advice. The first chapter is an overview of Windows 2000, its components, and its features. This is followed by chapters on directory services and namespace planning. The last chapter in this section covers specific issues that need to be addressed when planning your deployment.
- **Part II: Installation and Initial Configuration** This part takes you through the process of installing Windows 2000 and configuring hardware. Also included are chapters on upgrading to Windows 2000 and managing users.
- **Part III: Network Administration** Part III covers day-to-day tasks involved in running a network, including implementing Active Directory, managing storage options, and configuring security.
- **Part IV: Supporting Services and Features** This part addresses the main services that are included with Windows 2000 Server. Few networks will need all of the features Windows 2000 Server offers, but all administrators will need to be familiar with messaging and managing software and most will find reading about advanced features useful. You'll find chapters on interoperating with other operating systems plus chapters on Terminal Services and Certificate Services.
- **Part V: Internet Servers and Services** In Part V, we cover the components that connect you to the outside world—and, in turn, connect that world to you. Here you'll find chapters on Internet connectivity, Internet Security and Acceleration Server, and remote access.
- **Part VI: Tuning, Maintenance, and Repair** This section covers important material on network health. There's a chapter on the performance monitoring tools included with Windows 2000 Server and how to use them. There are also chapters on the important topics of disaster planning and prevention. If, despite your best efforts, the network falters, here's where you'll find information on troubleshooting and recovery. In addition, we include a chapter on the registry—the brains of Windows 2000 Server—and some advice if you're contemplating brain surgery.
- **Part VII: Appendixes and Glossary** At the end of the book, you'll find supplemental material that can prove useful for quick access to important information. The glossary covers terms new to Windows 2000 and familiar terms that take on new meaning. Five appendixes cover the interface changes in Windows 2000 Server, the components that are part of the package, the tools included as part of the software, and other useful information.

Within the chapters themselves, we've tried to make the material as accessible as possible. You'll find descriptive and theoretical information, as well as many step-by-step examples for how to implement or configure a particular feature. These are supplemented with graphics that make it easy to follow the written instructions.

In addition, we've made extensive use of the reader aids common to all books in the Administrator's Companion series.

Notes generally represent alternate ways to perform a task or some information that needs to be highlighted.

Methods of performing tasks more quickly or in a not-so-obvious manner show up as tips.

**More Info**

References to other books and sources of information are offered throughout the book.

Don't skip over these boxes because they contain important warnings about the subject at hand—often critical information about the safety of your system.

As we stress throughout the book, proper planning is fundamental to the smooth operation of any network. These boxes contain specific and useful hints to make that process go smoothly.

### **Real World**

Everyone benefits from the experiences of others. Real World sidebars contain elaboration on a particular theme or background based on the adventures of IT professionals just like you.

We encourage you to take advantage of other books offered by Microsoft Press. In addition to other Windows 2000 titles, the Technical Reference series will provide you with in-depth coverage of specific topics. The *Microsoft Windows 2000 Server Resource Kit* is highly recommended for every administrator.

## Talk to Us

We've done our best to make this book as accurate and complete as a single-volume reference can be. However, because Windows 2000 Server is such a large and complex product, we're sure that alert readers will find omissions and even errors (though we fervently hope not too many of those). If you have suggestions, corrections, or comments please write and let us know at [W2KAdmin2e@scribes.com](mailto:W2KAdmin2e@scribes.com). We genuinely appreciate hearing from you and sincerely hope you find *Microsoft Windows 2000 Server Administrator's Companion* enjoyable and useful.

# Chapter 1

## Overview of Windows 2000

When Windows 2000 was released it was accompanied by a great deal of hype, speculation, criticism, praise, and confusion—and it's undoubtedly worthy of some of each. It's certainly a big advance in the areas of network management, hardware support, Internet access, and more. That's not to say there aren't limitations, however. Windows 2000 has to work in the present as well as the future, and the necessity of backward compatibility results in compromises that are essential but probably not what one would hope for in a perfect world. However, the positive changes are many. Right out of the box, Windows 2000 is more reliable, easier to manage (once you get used to the changes), and faster than Microsoft Windows NT. In addition, three service packs have patched security vulnerabilities, fixed hundreds of bugs, and repaired scores of lesser faults, making Windows 2000 an even better enterprise solution.

This chapter briefly summarizes Windows 2000, including significant changes to Windows NT Workstation (now called Windows 2000 Professional). *Microsoft Windows 2000 Server* is the successor to Microsoft Windows NT 4. Based on the Active Directory service, it features Kerberos and public-key infrastructure (PKI) security, Terminal Services, COM+, Component Services, Internet Information Services, Indexing Service, and Message Queuing. It also includes up to 4 GB of physical memory and up to 4-way symmetric multiprocessing (SMP).

*Microsoft Windows 2000 Advanced Server* is the successor to Microsoft Windows NT 4 Enterprise Edition. It has all the features of Windows 2000 Server plus network load balancing, enhanced application failover clustering, up to 8 GB of physical memory, and up to 8-way SMP. *Microsoft Windows Datacenter Server* has the features of Advanced Server plus up to 32-way SMP, up to 64 GB of physical memory, and even more advanced clustering.

In this book, we make no distinctions among the servers, except that the clustering described is the Cluster service released with Windows 2000 Advanced Server. So, except for that limited case, the word *server* applies to all versions of Windows 2000 Server.

## Deploying Server and Workstation Functions Together

The deployment of Windows 2000 Server with Windows 2000 Professional and Microsoft Windows XP Professional clients provides exceptional benefits from the zero administration for Windows (ZAW) technologies. These technologies intelligently store user data, applications, system files, and administrative settings from Windows 2000 Professional and Windows XP Professional desktops onto servers running Windows 2000 Server.

For example, IntelliMirror is a distributed and highly configurable replication service that allows clients and servers to mirror and share local or distributed file system data. IntelliMirror's Remote Boot Service provides a mechanism for any authorized client computer to download all or part of an installation from a remote server—including a fully configured version of the operating system, applications, and site-specific data.

With ZAW, an application assigned to a user simply appears on the user's Start menu and is installed the first time a user clicks it. If the application isn't immediately required, the administrator can publish it so that it appears as an option in Add/Remove Programs for the user to install when needed. When an application upgrade becomes available, it is automatically applied the next time the user launches the application.

User documents and personal settings can be stored, or mirrored, on a server managed by an administrator. This provides

- **Improved access** Users can log on to any PC on the network; all of their documents and personal settings appear on any computer they use.
- **Increased availability** The information mirrored on the server is also resident on the local machine, so it is available even when users aren't connected to the network. When a user reconnects, the information on the server is synchronized with the new local information. Because laptop users' data is synchronized with the server whenever a laptop is connected to the network, network administrators can back up mobile users' data even when the laptops are not connected.
- **Better protection** All files reside on the server, which can be backed up as part of normal, centralized backup and restore procedures.

While the usual suspects—machines running Microsoft Windows 95, Windows 98, Macintosh operating systems, and UNIX—can be connected as clients for Windows 2000 Server, the full range of improvements is available only with the combination of Windows 2000 Server and Windows 2000 Professional or Windows XP Professional installed together. However, a great deal can be gained with gradual, partial upgrades. Benefits can be realized simply by upgrading a single server to Windows 2000 Server.

The primary domain controller (PDC) must be upgraded to Windows 2000 first. If you add a Windows 2000 domain controller or upgrade any domain controller other than the PDC in an existing Windows NT domain, you create a new Windows 2000 domain that looks like the existing domain but is not the same domain.

Although you can use Windows 2000 in a Windows NT 4 environment more or less indefinitely, you won't receive many of the real advantages implicit in Windows 2000 until you make the commitment to a Windows 2000 environment.

## Network Management

Admittedly, the network administrator's lot is not always a happy one, particularly when faced with big changes that could have a negative impact on the departmental budget and on what some quaintly refer to as a "personal life." There's no question that just about every improvement has its down side. There's the cost (in time) of learning about these new technologies and putting them in place. Then there's the cost (in cash) of the inevitable hardware and software upgrades needed for deploying Windows 2000 Server with Windows 2000 or Windows XP clients to reap the technological benefits, not all of which are immediately apparent (more about that later).

Nevertheless, what Microsoft taketh away with one hand, it often giveth back with the other. In the case of Windows 2000, your efforts will be rewarded with increased reliability, scalability, and security, plus administrative tools to simplify the management of large and complicated networks.

Even experienced Windows NT administrators (perhaps that should be *especially* experienced Windows NT administrators) should allow plenty of time to learn and practice the new concepts in Windows 2000. The organization of the interface will be unfamiliar, and a dedicated test network is essential for anyone coming to grips with Active Directory for the first time.

## The Microsoft Management Console

The Microsoft Management Console (MMC) hosts administrative tools displayed as consoles. These tools, composed of one or more applications, are built with modules called snap-ins. This design enables you to customize the tools so that you can delegate specific administrative tasks to users or groups. Saved as MMC files, these custom tools can be sent by e-mail, shared in a network folder, or posted on the Web. Using system policy settings, you can also assign MMC files to users, groups, or computers. A tool can be scaled up or down, integrated seamlessly into the operating system, repackaged, and customized. In fact, you can do everything with these tools short of adding pinstripes and custom upholstery. The details of creating and using MMCs are covered in [Chapter 10](#), although the use of MMCs is described in many other chapters.

## Group Policy

Group Policy is a new management technology introduced in Windows 2000, used to specify options for desktop configurations for groups of computers and users. Group policies are saved as Group Policy objects that in turn are associated with Active Directory objects such as sites, domains, or organizational units (OUs). Group policies can include security options, software installation and maintenance options, and options for scripts controlling startup and shutdown. Group Policy is covered in [Chapter 9](#).

## Zero Administration

The aim of Windows 2000 is to provide "no-touch" clients and servers. In other words, once the clients and servers are set up, hardware, software, and user changes are handled automatically, using rules and profiles to determine what happens. Administrators can control the rules for the entire network from a single central location. Although ZAW is not completely realized in Windows 2000, a good deal of progress has been made in that direction. Table 1-1 summarizes some of the centralized network management tasks in Windows 2000.

**Table 1-1.** Centralized management tasks in Windows 2000 Server

Task	What Is Done	Technologies Used
Manage user documents	Mirrors user data to the network and caches network data locally on the client	Active Directory, Group Policy, Offline Files, Synchronization Manager, disk quota, and shell enhancements
Manage user settings	Mirrors user settings to the network and applies administrator-set defaults to the user's environment	Active Directory, Group Policy, Offline Files, roaming user profile files, and shell enhancements
Perform remote OS	Installs operating system from network servers	Active Directory, Group Policy, Remote Install Server, Remote Installation-capable

installation		workstation
Manage user profiles	Allows users to "roam" among computers within the corporate network	Roaming user profiles, Group Policy
Install software	Provides just-in-time software installation (applications and operating system upgrades)	Active Directory, Group Policy, Windows Installer, Software Installation, Add/Remove Programs, Control Panel, and shell enhancements

## Terminal Services

Terminal Services allows Windows-based applications to run on desktops that can't normally run large Windows applications. All application processing and data storage takes place on the server; the client machine needs only to be able to run a "thin client," which requires very small amounts of memory and disk storage space. (Under Windows 2000, a client can simultaneously be a thin client *and* a fat client.) This permits machines that would require hardware upgrades before they were able to run Windows 2000 to have access to applications that would otherwise be unavailable. With the use of a third-party add-on, even DOS, UNIX, and Macintosh machines can be clients.

With Terminal Services, users log on and see only their own session, which is completely independent of any other client session. The application operates on the server, and the entire process is transparent to the user. The setup and use of Terminal Services and Terminal Services clients is covered in [Chapter 26](#).

## Interoperability

The typical network in a medium to large enterprise is completely heterogeneous, so interoperability between and among operating systems is imperative. For improved interoperability, Windows 2000

- Communicates natively with UNIX and NetWare 5 and later systems, using Transmission Control Protocol/Internet Protocol (TCP/IP). For Netware 3 and Netware 4, Windows 2000 uses the NWLink (IPX/SPX) protocol.
- Provides services for file and print sharing with UNIX, NetWare, Macintosh, and IBM (this last using SNA Server).
- Supports Open Database Connectivity (ODBC) software, Message Queuing Services, and Component Object Model (COM+) so that new applications can interoperate with existing software and data.

In addition, if you deploy Active Directory you can integrate multiple namespaces under various operating systems into one unified and easily manageable directory. Information on interoperating with Novell NetWare is covered in [Chapter 21](#). Specifics about UNIX interoperability are covered in [Chapter 22](#). [Chapter 23](#) describes how to use Macintosh Services on a Windows 2000 network.

## System and Network Security

Security is available in Windows 2000 for every configuration, from a simple workgroup to enterprise server systems. The emphasis on security and the fact that security mechanisms permeate every corner of Windows 2000 should not come as a surprise. Security is an increasingly critical issue in virtually every enterprise. Intranets, extranets, and dial-in access, not to mention casual user malfeasance, are all threats to both data and infrastructure. At the same time, an overly complex security apparatus tries the patience of administrators and users alike. Windows 2000 attempts to resolve these conflicting needs with a security system that is genuinely secure yet easy to administer and transparent to the user.

The Security Configuration Manager is a one-stop tool that lets an administrator configure security-sensitive registry settings, access controls on files, and registry keys all in one location. This information can be incorporated into a security template that can then be applied to multiple computers in a single operation.

Windows 2000 Server includes full support for the MIT Kerberos version 5 security protocol, providing a single logon to Windows 2000 Server-based enterprise resources. Kerberos replaces NT LAN Manager (NTLM), which is used in Windows NT 4 as the primary security protocol. For smooth integration, Windows 2000 supports both methods of authentication—NTLM when either the client or the server is running a previous version of Windows, and Kerberos for Windows 2000 servers and clients. In addition, there is built-in support for Secure Socket Layer/Transport Layer Security (SSL/TLS) for users logging on to a secure Web server.

Other security enhancements include

- An X.509-based public-key certificate server integrated with Active Directory, allowing the use of public-key certificates for authentication.
- Support for tamper-resistant smart cards to store passwords, private keys, account numbers, and other security information.
- Microsoft Internet Protocol Security (IPSec), which governs end-to-end secure communication. After IPSec is implemented, communications are secured transparently; no user training or interaction is required.

Many of the security functions in Windows 2000 are innate in Active Directory, and full implementation is available only when Active Directory is used. In addition, some security functions cannot be fully realized in a mixed environment of server domains. For example, Windows 2000 includes support for transitive trusts, which means that when a Windows 2000 domain is joined to a Windows 2000 domain forest, a two-way, transitive trust relationship is established automatically. No administrative tasks are required to establish this trust relationship. To set up a trust relationship between a Windows 2000 domain and a Windows NT domain, however, you must explicitly establish it.

Security is so firmly integrated into all aspects of Windows 2000 that it can't really be quarantined into a single section; hence you'll find security material throughout this book. However, basic security concepts are described in [Chapter 18](#). Implementation is delineated in [Chapter 19](#).

## Hardware Support

Windows 2000 includes hundreds of new printer, modem, and other hardware drivers, making hardware installation and setup more efficient. The merger of the Windows NT development and test teams with those of Windows 98 opened up the world of devices supported by Windows 98. Consequently, Windows 2000 supports device types that are difficult to use in Windows NT. A bidirectional parallel port driver lets Windows 2000 communicate with many more scanners, printers, and fax/printer/scanner devices.

Plug and Play (PnP) has finally arrived with Windows 2000, which is especially good news for laptop users. However, many older laptops need a flash BIOS upgrade or add-on software to take advantage of the power management of Windows 2000.

While adding much new hardware support, Windows 2000 retains compatibility with the Windows NT 4 video drivers. The catch is that using these video drivers disables the power management functions in Windows 2000, although all other Windows NT 4 drivers should work. Microsoft is encouraging video vendors to write new drivers for Windows 2000, and eventually all of the native Windows NT 4 drivers will be revised.

## Availability and Reliability

If you've used Windows NT Server, you no doubt noticed that practically every configuration change requires a reboot. Each time you install a scanner or a network driver or change any of a number of other configuration settings, you have to reboot—and usually right away.

There have been so many complaints about this annoying requirement that an early goal of the Windows 2000 development team was to eliminate as many required reboots as possible. Nearly 50 have been removed, and now a reboot is needed only after installing a service pack, upgrading a domain controller, changing system fonts, changing a default system locale, or adding and removing COM ports (when a change in jumpers is required). As you can see, these changes come up infrequently—a relief to the harried administrator. In addition, new tools to monitor system health can be instrumental in keeping servers up and running a higher percentage of the time.

Windows 2000 Advanced Server (the replacement for Windows NT Enterprise Edition) allows two servers to be connected into a cluster of up to 64 processors, making server resources more available and easier to manage. This cluster monitors the health of standard applications and servers and can automatically recover mission-critical data and applications from many common types of failure—usually in less than a minute. Clustering is covered in [Chapter 16](#).

## Active Directory

A directory service is a tool that connects directories across the network and acts like a big phone book for all users. Using general input (for example, "where are the printers?"), a user can receive a listing of printer resources. The directory services in Windows NT 4 provide important functions in the form of a single logon and a single point of administration and replication. Although these are critical, the Windows NT 4 directory services don't scale well enough. Active Directory is the next generation of Microsoft's directory services and offers great advances in scalability, extensibility, and security while providing a hierarchical view of the directory and multimaster replication.

Active Directory combines X.500 naming standards, the Internet's Domain Name System (DNS) as a locating device, and Lightweight Directory Access Protocol (LDAP) as the core protocol. Active Directory allows a single point of administration for all resources, including users, files, peripheral devices, host connections, databases, Web access, services, and network resources. It supports a hierarchical namespace for user, group, and machine account information and can encompass and manage other directories to reduce the administrative burdens and costs associated with maintaining multiple namespaces.

As you can see, there's a lot of good news about Active Directory—including that it paves the way for eliminating the concept of domains. The actual migration to Active Directory is not very difficult, but planning the design of your new directories can be vexatious. Design mistakes can harm the stability and efficiency of the network. Fortunately, you don't need to get rid of your existing domains to take advantage of Active Directory, and migration can be piecemeal. Servers can be upgraded from Windows NT 4 to Windows 2000 without the users being aware of any changes.

Chapters 2 and 3 explore the concepts behind Active Directory—including namespace design. Specific implementation is discussed in Chapters 11 and 12.

## Storage and File System Support

Great changes have been made in the area of storage and file system support, including a new version of NTFS—version 5—that allows disk quotas for monitoring and limiting disk space usage on NTFS volumes while drastically improving security. Administrators can establish global disk quotas that prevent users from saving or copying more data to a storage device once they have reached their quota.

### Removable Storage

Removable Storage lets you manage your online libraries, such as changers and jukeboxes, and track removable tapes and disks. It presents a common interface to robotic media changers and media libraries, and enables multiple applications to share local libraries and tape or disk drives. It also controls removable media within a single-server system.

### Remote Storage

Remote Storage makes it easy to increase disk space on the server without adding more hard disks. It automatically monitors the amount of free space available on local hard disks. When the free space on a managed hard disk goes below a specified level, Remote Storage automatically removes any local data that Removable Storage has already copied to Remote Storage (while keeping the directory and property information active), providing the free disk space you need. Working with Remote Storage, Hierarchical Storage management moves data to slower, low-cost storage devices until needed. When required, the data is automatically moved back to faster disk drives. Both Remote Storage and Removable Storage are covered in [Chapter 17](#).

### Disk Administrator

Using Windows 2000 Server Disk Administrator, system administrators can create, extend, or mirror a volume without shutting down the system or interrupting users. These tasks can be performed remotely. In addition, volume mount points make hundreds of disk volumes accessible without drive letter limitations. The details of disk administration are covered in [Chapter 15](#).

### Microsoft Distributed File System

Microsoft Distributed File System (Dfs) identifies files using a common naming scheme, making it easy to browse the network to find the data and files you need. With Dfs, you can create a single directory tree that includes multiple file servers and file shares in a group, division, or enterprise, so you can have logical views of directories and files, regardless of where those files physically reside on the network. Dfs is covered in [Chapter 17](#).

### NTFS 5

The new version of NTFS offers many performance enhancements and a host of new features. System administrators have requested many of these features for some time—most notably per-user disk quotas. Distributed link tracking is also part of the NTFS 5 package. With this tracking system, even after a file is moved or has undergone a name change, a shortcut link to the file still works. Public-key encryption is also included in NTFS 5, enabling you to protect and easily manage sensitive material in a manner that is totally transparent to the user.

The not-so-good news about NTFS 5 is that its new features make dual booting more complex. To dual boot with Windows NT 4 and have an NTFS partition, you must use Windows NT 4 with Service Pack 4 or later. The service pack makes the NTFS 5 files readable when the machine is booted into Windows NT. See [Chapter 5](#) for more on issues of dual booting.

## Communications

Communication is the lifeblood of businesses—and not just network communications, important as they are. Windows 2000 includes dozens of enhancements to make communicating easier and more reliable. For connections both inside and outside your business, Windows 2000 offers the following tools:

- Through the Internet support built into Windows 2000 Professional and Windows XP Professional, users can send e-mail, chat, and view newsgroups.
- Windows 2000 provides client support for the industry-standard virtual private network (VPN) through two protocols: the Point-to-Point Tunneling Protocol (PPTP) and the Layer Two Tunneling Protocol (L2TP). These protocols allow clients or branch offices to connect to another network (such as their corporate network) over the Internet.
- Microsoft Outlook Express, an Internet standards-based e-mail client, is built into Windows 2000 Professional and Windows XP Professional.
- Users can send, receive, monitor, and administer faxes directly from the desktop. Several easy-to-use utilities are available right from the Start menu.

## **Internet Services**

With Windows 2000, anything that can be done on a corporate network can be done in a Web environment as well. Windows 2000 incorporates a set of services that provide server-side support for the most popular application-level Internet protocols, enabling a Windows 2000 server to function as a Web server, FTP server, SMTP host, or NNTP host.

In the Microsoft Windows NT 4 operating system, these services are provided by an optional component called Internet Information Server. To obtain full support for Internet services in a Windows NT 4 environment, administrators must install Internet Information Server after applying Service Pack 3 or later for Windows NT 4 Server and the Windows NT 4 Option Pack. By contrast, basic Internet services are fully integrated into the Windows 2000 Server and Windows 2000 Advanced Server platforms. These services are now referred to as Internet Information Services 5 instead of Internet Information Server.

Because Internet Information Services are fully integrated with Windows 2000, you can do things like host multiple Web sites on a single Windows 2000 server with only one IP address. In addition, each Web site can have its own user database, which means that multiple independent user domains can coexist on a single server.

## **Defying Categories**

As you can tell from the previous sections, it's difficult to pigeonhole many of the changes in Windows 2000. The NTFS 5 file system affects disk management because it allows the setting of disk quotas for monitoring and limiting disk space usage on NTFS volumes. At the same time, it's an important security component, adding file encryption to its existing security capabilities.

As a result, neat categories aren't always possible. The discussions in this book are organized around particular tasks, thus avoiding a laundry list of tools and their menus.

## **The Need for Planning**

Whether one is designing a new network or making changes to an existing one, planning is the essential, nonglamorous, before-everything-else component. Few enjoy and many actively dislike this task, but it's important to understand that every minute, every hour spent planning will later repay you (or your heirs and assigns) a hundredfold.

Sometimes it's difficult to appreciate the benefits of careful planning—until you've had the misfortune of supporting a poorly considered installation. Windows 2000 is particularly unforgiving of an offhand approach to planning. As has been mentioned before, you can add Windows 2000 Server or Windows 2000 Professional to a Windows NT 4 network. However, unless you plan on eventually using Active Directory and other Windows 2000-specific tools, the benefits of just plugging in a couple of Windows 2000 machines are minimal. And in all cases, designing directories—not to mention applying new concepts such as forests and trees—requires considerable thought and the ability to project current experience into the future. Therefore, the wise systems person takes a longer perspective.

## Summary

This chapter has provided only the briefest overview of the Windows 2000 system and a look at just a few of the thousands of changes, large and small, that have been made. Deciding how to implement Windows 2000 on your system requires thought and planning. Although planning and design are important elements in nearly every chapter in this book, the next three chapters are devoted exclusively to the subject. [Chapter 2](#) addresses your use of Active Directory. [Chapter 3](#) covers planning namespace and domains. Finally, [Chapter 4](#) covers the matters to be considered before deploying your first copy of Windows 2000.

# Chapter 2

## **Introducing Directory Services**

Everyone uses directories—on or off the computer. After all, if it weren't for the directory of television listings in the newspaper, you'd waste hours just channel surfing, looking for something to watch. (Maybe you do that anyway.)

Another type of directory that most of us find indispensable is the telephone directory. In fact, telephone directories are the source of the analogy for two searching capabilities that are necessary in computer directories. There's the "white pages" search by attribute, in which you know a name or some other fact about the object and you search using that piece of information. The second type of search, called a "yellow pages" search, is done by category. Having both types of searches available means that you don't have to know much about an object to locate it.

The lack of coherent, accessible directories is felt acutely on a network of any size. True directory services—a global catalog of network services and resources—are missing from Microsoft Windows NT networks. The directory functions available in version 4 do provide the all-important single logon and single point of administration that corporate environments need, but they have serious deficiencies when large numbers of users are involved. Attempts to organize documents in folders and directories work up to a point, but as the number of objects scales up, management becomes both complex and onerous.

Heretofore, the best known computer directory service has been NetWare Directory Services (NDS), introduced with NetWare 4.0 in 1993. Unfortunately for Novell, NetWare 4.0 had problems of its own that kept it from becoming dominant in the networking arena.

## Understanding Directory Services

In a typical Windows NT computing environment, a user can log on to the network with a username, let's say Mperez, and a password. Assuming that permissions are correctly granted, Mperez can click Network Neighborhood or open a mapped drive and browse for needed files.

All this works very well until the scope of the network changes. The company adds e-mail, and Mperez gains another identity (maryperez@scribes.com). The additional services and databases and administrative tools—each one identifying Mary Perez slightly differently—need to be accessible by the same user. When you consider that this is just one of hundreds or even thousands of users, it isn't hard to see how errors can arise that can be very difficult to solve. As the number of objects in a network grows, directory services—a centralized place for storing administrative data that is used to manage the entire computer system—becomes essential.

Directory services differs from a directory in that it consists of both the directory information source and the services that make the information available to users. Being both a management tool and an end user tool, directory services needs to address these needs:

- Access to all of the servers, applications, and resources through a single logon. (User access is granted or blocked using permissions.)
- Multimaster replication. All information is distributed throughout the system and replicated on multiple servers.
- "White pages" searches based on attributes—for example, by filename or file type.
- "Yellow pages" searches based on classification—for example, all the printers on the third floor or all the servers in the Hartford office.
- The ability to remove dependency on physical locations for purposes of administration. That is, it should be possible to delegate administration of the directory, either partially or completely.

Although Microsoft has occasionally used the term "directory services" in connection with Windows NT (as in the Directory Service Manager for NetWare), Windows NT does not provide a true, hierarchical directory service. In Windows NT, the directory functions are divided among a host of services based on domains. The Domain Name System (DNS) Server provides the translation of names into IP numbers and is integrated with Dynamic Host Configuration Protocol (DHCP) servers used to dynamically allocate TCP/IP addresses. The Windows Internet Name Service (WINS) is used for NetBIOS name resolution and is required on Windows NT networks for file sharing and some applications. Security is implemented through access control lists (ACLs), the Security Accounts Manager (SAM) database, and other services.

In Microsoft Windows 2000 Server, Active Directory replaces the Windows NT collection of directory functions with an integrated implementation that includes DNS, DHCP, Lightweight Directory Access Protocol (LDAP), and Kerberos. (You'll learn more about these later in this chapter.)

### Real World Directory Services and X.500

X.500 is a standard for directory services established by the International Telecommunications Union (ITU). The same standard is also published by the International Organization for Standardization/International Electrotechnical Commission (ISO/IEC). The X.500 standard defines the information model used in directory services. In this model, all information in a directory is stored in entries, each of which belongs to at least one object class. The actual information in an entry is determined by attributes that are contained in that entry.

The original 1988 X.500 standard focused heavily on the protocols to be implemented. Directory Access Protocol (DAP) specifies how user applications access the directory information. Directory Service Protocol (DSP) is used to propagate user directory requests between directory servers when the local directory server cannot satisfy the request.

No extant directory service completely implements the X.500 standard, but all are modeled on the basic specifications of X.500, as is Active Directory. An excellent introduction to directories and X.500 can be found at <http://www.nlc-bnc.ca/9/1/p1-244-e.html>.

## Active Directory in Windows 2000

Active Directory has numerous advantages, not the least of which is that it can handle any size of installation, from a single server with a few hundred objects to thousands of servers and millions of objects. Active Directory also greatly simplifies the process of locating resources across a large network. The Active Directory Service Interfaces (ADSI) allows developers to "directory-enable" their applications, giving users a single point of access to multiple directories, whether those directories are based on LDAP, NDS, or NT Directory Services (NTDS).

In Windows 2000, Active Directory integrates the Internet concept of a namespace with the operating system's directory services. This combination allows the unification of multiple namespaces in, for example, the mixed software and hardware environments of corporate networks—even across operating system boundaries. The ability to subsume individual corporate directories into a general-purpose directory means that Active Directory can greatly reduce the costs of administering multiple namespaces.

Active Directory is not an X.500 directory. Instead, it uses LDAP as the access protocol and supports the X.500 information model without requiring systems to host the entire X.500 overhead. LDAP is based on TCP/IP and is considerably simpler than the X.500 DAP. Like X.500, LDAP bases its directory model on entries, where the distinguished name (see the next section) is used to refer to an entry without ambiguity. But rather than using the highly structured X.500 data encoding, LDAP adopts a simple, string-based approach for representing directory entries. LDAP uses many of the directory-access techniques specified in the X.500 DAP standard but requires fewer client resources, making it more practical for mainstream use over a TCP/IP link.

Active Directory also directly supports Hypertext Transfer Protocol (HTTP). Every object in Active Directory can be displayed as a Hypertext Markup Language (HTML) page in a Web browser. Directory support extensions to Microsoft Internet Information Services (IIS) translate HTTP requests for directory objects into HTML pages for viewing in any HTML client.

Active Directory allows a single point of administration for all published resources, which can include files, peripheral devices, host connections, databases, Web access, users, other arbitrary objects, services, and so forth. It uses the Internet DNS as its locator service, organizes objects in domains into a hierarchy of organizational units (OUs), and allows multiple domains to be connected into a tree structure. The concepts of primary domain controller (PDC) and backup domain controller (BDC) no longer exist. Active Directory uses domain controllers only, and all domain controllers are peers. An administrator can make changes to any domain controllers, and the updates are replicated on all other domain controllers.

## Terminology and Concepts in Active Directory

Some of the terms used to describe concepts in Active Directory have been around for a while in other contexts, so it's important to understand what they mean when used specifically in reference to Active Directory. This section covers these basic terms and concepts.

### Namespace and Name Resolution

"Namespace" is perhaps an unfamiliar term for a very familiar concept. Every directory service is a *namespace*—a circumscribed area in which a name can be resolved. A television listing forms a namespace in which the names of television shows can be resolved to channel numbers. A computer's file system forms a namespace in which the name of a file can be resolved to the file itself.

Active Directory forms a namespace in which the name of an object in the directory can be resolved to the object itself. *Name resolution* is the process of translating a name into some object or information that the name represents.

### Attribute

Each piece of information that describes some aspect of an entry is called an *attribute*. An attribute comprises an *attribute type* and one or more *attribute values*. An example of an attribute type might be a telephone number, and an example of a telephone number attribute value might be 345-555-0112.

### Object

An *object* is a particular set of attributes that represents something concrete, such as a user, a

printer, or an application. The attributes hold data describing the thing that is identified by the directory object. Attributes of a user might include the user's given name, surname, and e-mail address. The classification of the object defines which types of attributes are used. For example, the objects classified as users might allow the use of attribute types like common name, telephone number, and e-mail address, whereas the object class organization would allow attribute types like organization name and business category. An attribute can take one or more values, depending on its type.

## Object Identity

Every object in Active Directory has a unique *identity*. Objects can be moved or renamed, but their identity never changes. Objects are known internally by their identity, not their current name. An object's identity is a globally unique identifier (GUID), which is assigned by the Directory System Agent (DSA) when the object is created. The GUID is stored in an attribute, *objectGUID*, that is part of every object. The *objectGUID* attribute can't be modified or deleted. When storing a reference to an Active Directory object in an external store (for example, a database), you should use *objectGUID* because, unlike a name, it won't change.

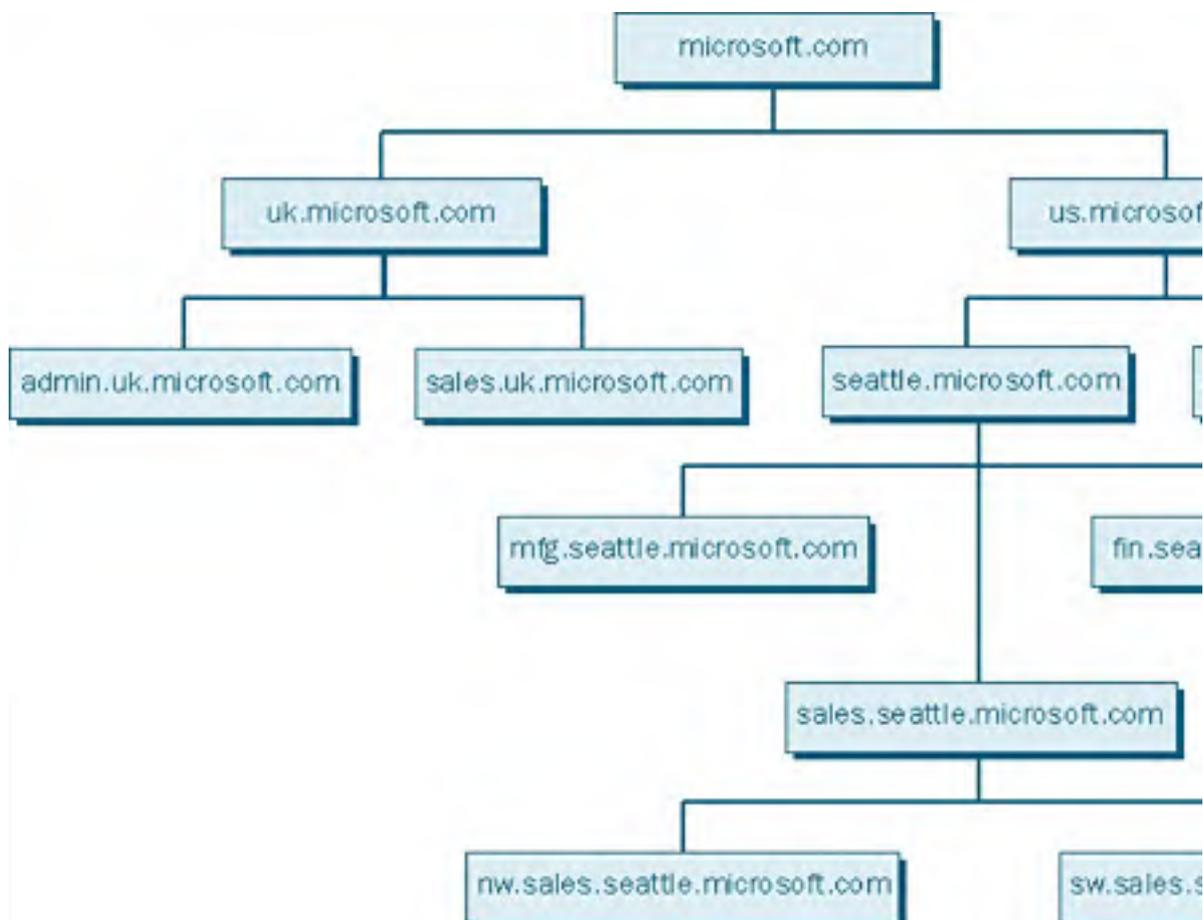

## Container

A *container* resembles an object in that it has attributes and is part of the Active Directory namespace. However, unlike an object, a container doesn't represent anything concrete. It is a holder of objects and other containers.

## Tree and Subtree

A *tree* in Active Directory is just an extension of the idea of a directory tree. It's a hierarchy of objects and containers that demonstrates how objects are connected, or the path from one object to another. Endpoints on the tree are usually objects.

A *subtree* is any unbroken path in the tree, including all of the members of any containers in that path. Figure 2-1 shows a tree structure for microsoft.com. Any of the unbroken paths (for example, from nw.sales.seattle.microsoft.com to microsoft.com) is a subtree. Trees and forests are discussed in more detail in [Chapter 3](#).

**Figure 2-1.** A tree structure with subtrees.

## Distinguished Name

Every object in Active Directory has what's called a *distinguished name* (DN). In this context, "distinguished" means the qualities that make the name distinct. The distinguished name identifies the domain that holds the object as well as the complete path through the container hierarchy used to reach the object. A typical DN might be CN=Mary Perez,OU=Research,DC=scribes,DC=com. This DN identifies the "Mary Perez" user object in the Research organizational unit, in the scribes.com domain.

CN translates as common name, OU stands for organizational unit, and DC means domain controller. Some attributes are derived from the X.500 model; an administrator can define others.

Active Directory also uses a *relative distinguished name* (RDN), which is the part of the DN that is an attribute of the object itself. In the previous example, the RDN of the user object is CN=Mary Perez. The RDN of the parent object is OU=Research.

The DC= portion of a DN allows X.500 directories to plug in to the DNS namespace, which is also what Active Directory does. The root of the global namespace for Active Directory is the DNS namespace. Thus, DNS domain names merge within the Active Directory naming scheme. For example, scribes.com is a valid DNS domain name and could be the name of an Active Directory domain as well. This DNS integration means that Active Directory fits naturally into Internet and intranet environments. Active Directory servers can be connected directly to the Internet to simplify secure communications and electronic commerce with customers and partners.

## Schema

"Schema" is a term commonly used in database work. In the context of Active Directory, the *schema* is all of the pieces that make up your Active Directory: the objects, attributes, containers, and so forth. Active Directory has a default schema that defines the most common object classes, such as users, groups, computers, OUs, security policies, and domains.

The Active Directory schema can be updated dynamically. That is, an application can extend the schema with new attributes and classes and use the extensions immediately. Schema updates are done by creating or altering the schema objects stored in the directory. ACLs protect schema objects, so that only authorized users can modify the schema.

## The Active Directory Architecture

As mentioned previously, Active Directory isn't, strictly speaking, an X.500 directory service, although like all existing directory services, it's derived from that standard. The sections that follow enumerate some of the characteristics of the Active Directory architecture.

### The Directory System Agent

The DSA is the process that provides access to the physical store of directory information located on a hard disk. The DSA is part of the Local System Authority (LSA) subsystem in Windows 2000. Clients access the directory information using one of the mechanisms in the following list:

- LDAP clients connect to the DSA using the LDAP protocol. Active Directory supports LDAP v3, defined by RFC 2251; and LDAP v2, defined by RFC 1777. Windows 2000 and Windows XP Professional clients and Microsoft Windows 95/98 clients with the Active Directory client components installed use LDAP v3 to connect to the DSA.
- Messaging Application Programming Interface (MAPI) clients such as Microsoft Exchange connect to the DSA using the MAPI Remote Procedure Call (RPC) interface.
- Windows clients that use Windows NT connect to the DSA using the SAM interface.
- Active Directory DSAs connect to each other to perform replication using a proprietary RPC interface.

### Naming Formats

Active Directory supports several name formats to accommodate both users and applications:

- **RFC 822 names**, which are familiar to most users as Internet e-mail addresses, such as maryperez@scribes.com. Active Directory provides a "friendly name" in RFC 822 form for all objects. Thus, a user can use a friendly name both as an e-mail address and as a logon name.
- **HTTP URLs**, which are familiar to most users who have Web browsers. A typical URL takes the form *http://domain/path-to-page*, where *domain* refers to a server running Active Directory services and *path-to-page* is the path through the Active Directory hierarchy to the object of interest. The URL for Mary Perez is *http://AServer.scribes.com/Division/Product/Research/MaryPerez*.
- **LDAP names**, which are more complicated than Internet names but are usually hidden within an application. LDAP names use the X.500 attributed naming convention. An LDAP URL specifies the server holding Active Directory services and the attributed name of the object—for example, *ldap://AServer.scribes.com/CN=maryperez,OU=Research,OU=Product,OU=Division,O=MegaIntl,C=US*.
- **UNC names**, the universal naming convention used in Windows NT Server-based and Windows 2000 Server-based networks to refer to shared volumes, printers, and files. For example, *\\scribes.com\Division.Product.Research.Volume\WordDocs\aprilreport.doc*.

### The Data Model

The Active Directory data model is derived from the X.500 data model. The directory holds objects that represent various items, described by attributes. The universe of objects that can be stored in the directory is defined in the schema. For each object class, the schema defines what attributes an instance of the class must have, what additional attributes it can have, and what object class can be a parent of the current object class.

### Schema Implementation

The Active Directory schema is implemented as a set of object class instances stored in the directory. This is very different from directories that have a schema but store it as a text file that is read at startup. Storing the schema in the directory has many advantages. For example, user applications can read it to discover what objects and properties are available.

### The Security Model

Active Directory is part of the Windows 2000 trusted computing base and is a full participant in the Windows 2000 security infrastructure. The distributed security model is based on the MIT Kerberos authentication protocol (version 5). Kerberos authentication accommodates both public-key and private-key security, using the same ACL support model as the underlying Windows 2000 operating system. ACLs protect all objects in Active Directory. They determine who can see the object, what attributes each user can see, and what actions each user can perform on the object. If a user is not allowed to see an object or an attribute, its existence is never made known to that user.

An ACL, in turn, is made up of access control entries (ACEs) stored with the object the ACL protects. In Windows NT and Windows 2000, an ACL is stored as a binary value called a *security descriptor*. Each ACE contains a security identifier (SID), which identifies the *principal* (user or group) to which the ACE applies and provides information on what type of access the ACE grants or denies.

ACLs on directory objects contain ACEs that apply to the object as a whole and ACEs that apply to the individual attributes of the object. This allows an administrator to control not just which users can see an object, but what properties those users can see. For example, all users might be granted Read access to the e-mail and telephone number attributes for all other users, but access to the security properties of users might be denied to all but members of a special security administrators group. Also, individual users might be granted Write access to personal attributes such as the telephone and mailing addresses on their own user objects.

Active Directory is the store for the security system, including user accounts, groups, and domains. This store replaces the registry account database and is a trusted component within the LSA.

## Delegation and Inheritance

*Delegation* is one of the most important security features of Active Directory. An administrator can authorize a user to perform a specified set of actions in some identified subtree of the directory. This is called *delegated administration*. Delegated administration allows very fine-grained control over who can do what and enables administrators to delegate authority without granting elevated privileges. This also eliminates the need for domain administrators with broad authority over large segments of the user population.

### Real World

#### Use Delegation to Protect Your Network from Yourself

Every administrator knows (or should know) that it's a bad idea to log on to the network with full administrative privileges to do ordinary day-to-day work—the risks of doing something permanent and unfortunate are very real. But convincing network administrators to use a regular user-level account on a daily basis can be a bit challenging. By delegating limited authority to do the most common administrative tasks to the network administrator's regular user accounts, you make it easier for them to get their work done while encouraging them to avoid full administrative access except when they specifically need it.

Avoid the temptation, however, to create "special" accounts that people can use for specific tasks. These accounts make it far too easy to hide who is responsible for a particular action. All administrative actions on the network should be performed by accounts assigned to a specific individual to enable a clear accountability path. No one should ever log on as simply Administrator, except when initially setting up the network and accounts.

Administrators grant rights for specific operations on specific object classes by adding ACEs to the container's ACL. For example, to allow user Mary Perez to be an administrator of the Research OU, you would add ACEs to the ACL in Research as follows:

```
"Mary Perez";Grant ;Create, Modify, Delete;Object-Class User  
"Mary Perez";Grant ;Create, Modify, Delete;Object-Class Group  
"Mary Perez";Grant ;Write;Object-Class User; Attribute Password
```

Now Mary Perez can create new users and groups in Research and set the passwords for existing users, but she can't create other object classes and she can't affect users in other containers (unless, of course, ACEs grant her that access in the other containers).

*Inheritance* allows a given ACE to be propagated from the container in which it was applied to all children of the container. Inheritance can be combined with delegation to grant administrative rights to a whole subtree of the directory in a single operation.

## Naming Contexts and Partitions

Active Directory is made up of one or more naming contexts or partitions. A *naming context* is any contiguous subtree of the directory. Naming contexts are the units of partitioning. A single server always holds at least three naming contexts:

- The schema
- The configuration (replication topology and related data)
- One or more user naming contexts (subtrees containing the actual objects in the directory)

## The Global Catalog

The DN of an object includes enough information to locate a replica of the partition that holds the object. Many times, however, the user or application does not know the DN of the target object, or which partition might contain the object. The Global Catalog (GC) allows users and applications to find objects in an Active Directory domain tree, given one or more attributes of the target object.

The Global Catalog contains a partial replica of every naming context in the directory. It contains the schema and configuration naming contexts as well. This means that the GC holds a replica of every object in Active Directory, but with only a small number of their attributes. The attributes in the GC are those most frequently used in search operations (such as a user's first and last names, logon name, and so on) and those required to find a full replica of the object. The GC allows users to quickly find objects of interest without knowing what domain holds them and without requiring a contiguous extended namespace in the enterprise.

The Global Catalog is built automatically by the Active Directory replication system. The replication topology for the GC is also generated automatically. The properties replicated into the GC include a base set defined by Microsoft. Administrators can specify additional properties to meet the needs of their installation. Specifics on the administration and deployment of Active Directory can be found in Chapters 11 and 12.

## Summary

As you've no doubt gathered, Active Directory is a very powerful tool and, like most powerful tools, it can be the source of great trouble if mishandled. Allow time for careful thought and planning before deploying Active Directory. First consider the design of a logical and efficient directory. A poor tree design can negatively affect the productivity and even the stability of the network. [Chapter 3](#) covers how to plan your namespace and domains for both maximum utility and longevity.

# Chapter 3

## **Planning Namespace and Domains**

When you spend time analyzing your organizational structure and needs and determining how best to translate those requirements into your new namespace, you'll be rewarded by reduced support costs, improved flexibility, and less reorganizing later. It's important to understand that planning the namespace of a large or even medium-sized organization or company is an iterative process. You won't get it right the first time, but you need to start somewhere. You should also understand that much of the advice you'll receive will be based on politics and agendas, making the job more difficult than it should be.

## Analyzing Naming Convention Needs

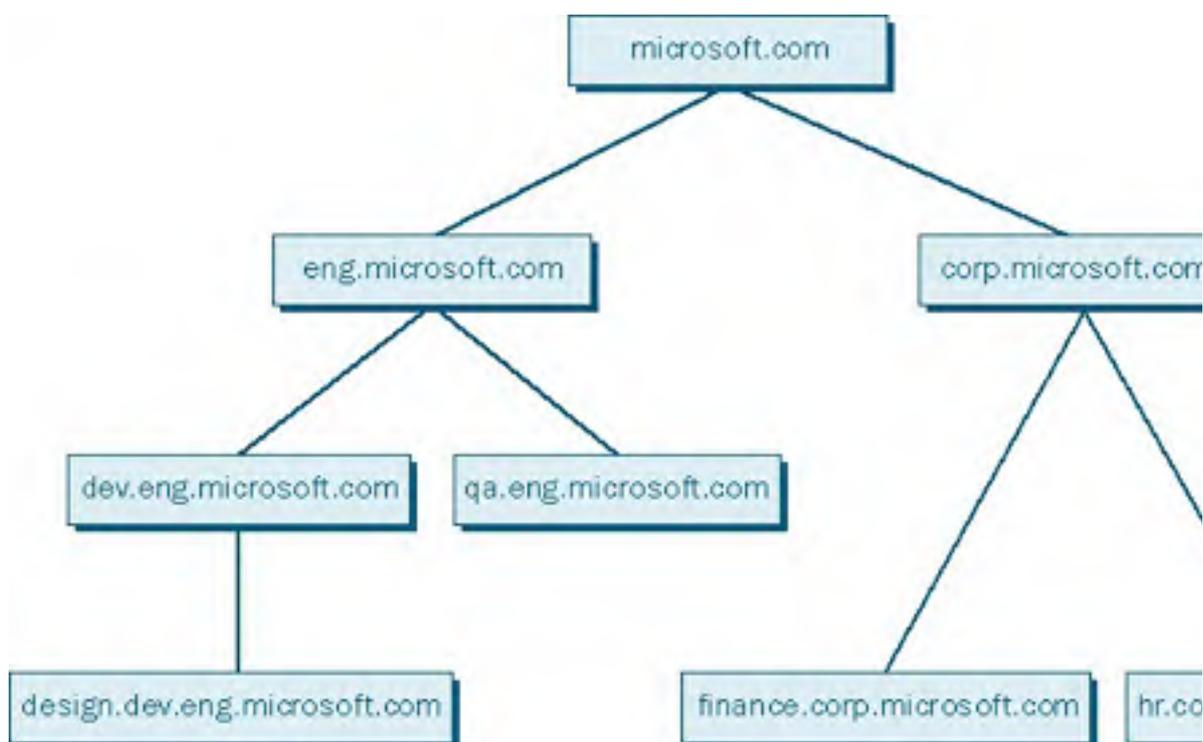

To plan what your namespace and domain structure should look like, you need to analyze your organization and attempt to understand its underlying naming needs. This process requires a thorough understanding of the type of organization you have and who the players are, as well as some educated guesses about where the organization will be going in the future.

### Trees and Forests

As a first step, you'll need to understand the differences between the two basic types of namespaces—trees and forests—to decide how they line up with your organization. You can switch models later, but not without some pain and suffering, and not without having an impact on the overall names used, so take some time here to make sure you understand what your organization really needs. What the organization needs might be different from what it thinks it wants.

#### Trees

A tree namespace, like that shown in Figure 3-1, is a single, contiguous namespace, with each name in the namespace directly descended from a single root name. This kind of straightforward naming design is appropriate for an organization that is essentially cohesive and has a single name underlying what can be many different divisions and diverse businesses. Many small to midsize businesses will fit well within this model. Even very large businesses can be a comfortable fit for a tree structure if the organization is fairly centralized and has a single recognizable name.

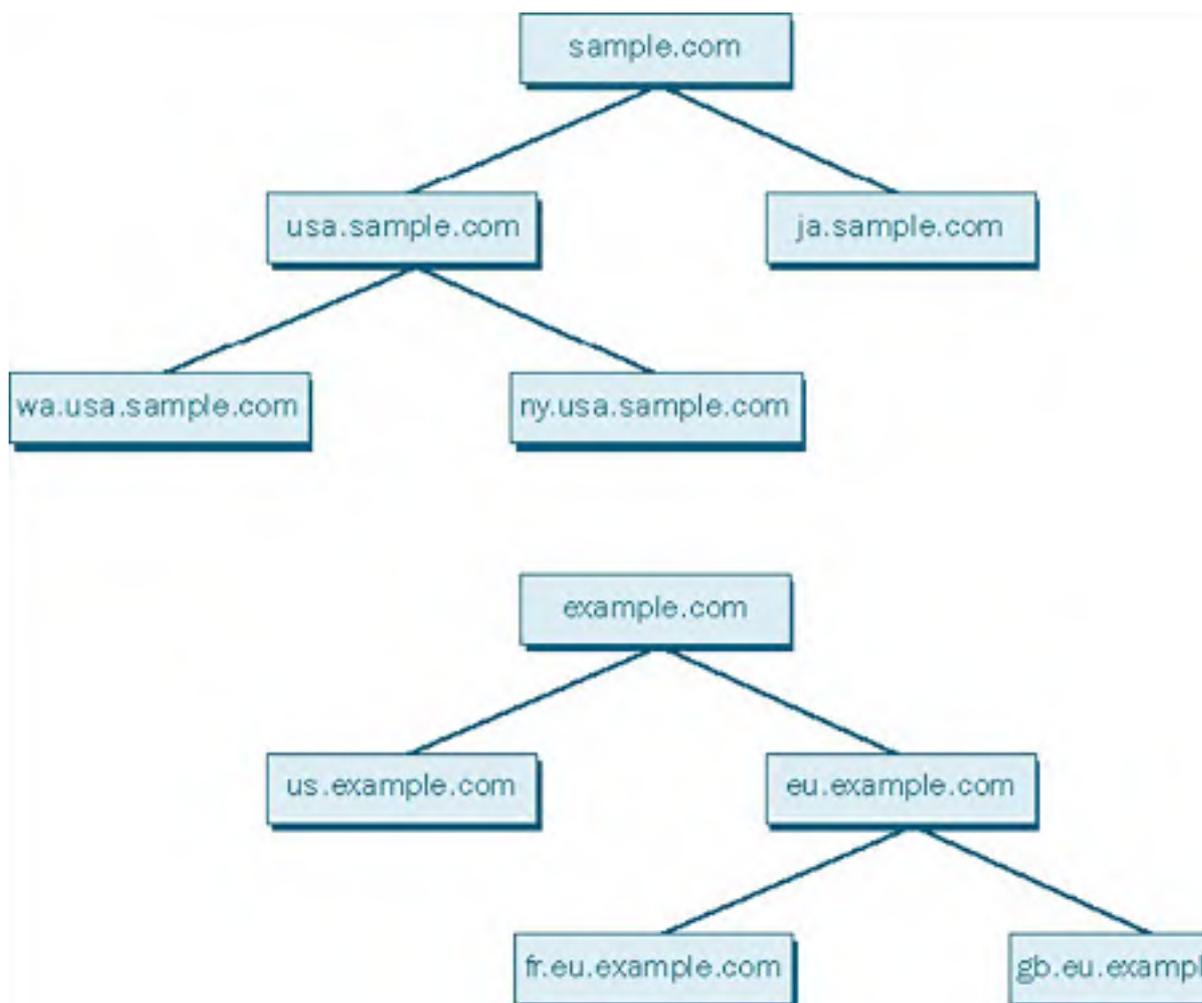

**Figure 3-1.** A tree-structured namespace.

As you can see from the figure, with a tree-structured namespace, each branch of the tree has a name that is directly descended from the root of the tree. This convention makes it easy to find any leaf or branch of the tree by tracing down the structure of its name.

#### Forests

A forest namespace, like that shown in Figure 3-2, is a collection of essentially equal trees, with no single root to the namespace. The forest namespace is appropriate for an organization that has multiple lines of business, each with its own separate and identifiable name. These are usually larger businesses, especially those that have grown by acquisition. They typically do not have a single, central information systems group that manages the entire organization, and each of the divisions generally has an essentially separate identity and infrastructure.

**Figure 3-2.** A forest-structured namespace.

As you can see from the figure, with a forest namespace you essentially have a peer group of trees, each with its own contiguous namespace, but the trees do not fit into an overall, contiguous namespace. You can't directly trace the names of all the leaves back up to a single root.

## Defining a Naming Convention

Whether you're going to have a single tree or a forest of trees for your overall namespace, you need to make some decisions about what the various branches of the tree will be called. This is easily one of the most delicate and politically sensitive decisions you'll have to make as you lay out your overall naming structure.

There are essentially two types of naming conventions—organizational and geographical. Both have their proponents, and an argument can be made for either choice. Keep in mind that people can get amazingly emotional about what their division or department is called and about its relative weight in the organization. Such political disagreements can be not only bitter but also prolonged beyond any reasonable expectation.

### The Organizational Naming Convention

Using an organizational naming convention, you would model your namespace on the way your company or organization is structured. Thus, the root of your tree might be *microsoft.com*, with the first level under that consisting of *admin.microsoft.com*, *finance.microsoft.com*, *mfg.microsoft.com*, *hr.microsoft.com*, and so forth.

The following are some advantages and disadvantages of the organizational naming convention:

#### Advantages

- Reflects company organization
- Is easily understood
- Has a natural growth path
- Permits resources to be organized by type of need

### **Disadvantages**

- Is difficult to adjust when organizational structures and names change
- Can be politically sensitive
- Can be difficult to implement if divisions of the organization have multiple site locations
- Is difficult to support as divisions split and merge

#### **Real World**

##### **Sites**

Sites, a new feature of Windows 2000 provided by the Active Directory service, can be used to reduce or eliminate the problem of implementing the organizational naming structure with divisions that have multiple locations. A company can create a site for each island of computers with LAN connectivity. For example, the main office would be a site, and a branch office another site. Any domains that span more than one site automatically adjust their replication parameters to optimize the use of the slow WAN link between the sites. Clients are also automatically directed to local domain controllers for service requests, further decreasing the use of WAN links. For more information on sites and planning your site topology, see [Chapter 7](#).

### **The Geographical Naming Convention**

Using a geographical naming convention, you would model your namespace on the geographical divisions of the organization. For example, with the same root of *microsoft.com*, you might have a first level consisting of *corp.microsoft.com*, *noram.microsoft.com*, *europa.microsoft.com*, *africa.microsoft.com*, and so on. Under this first level, you might break each entry down to the individual country/region or state/province, depending on the size and complexity of your organization.

The following are some advantages and disadvantages of the geographical naming convention:

#### **Advantages**

- Is apolitical
- Uses names that tend to be persistent
- Offers greater flexibility and granularity

#### **Disadvantages**

- Doesn't reflect the nature of the organization
- Might require more domains to meet security needs

Sites are useful for optimizing the use of slow WAN links on networks using a geographical naming convention. Although usually there aren't any domains that span multiple sites in networks using the geographical naming convention, using sites further optimizes the use of WAN links by tuning interdomain replication of Active Directory.

### **Mixed Naming Conventions**

Finally, you may opt to use a mixture of the organizational and geographical naming conventions, especially in a forest namespace where different corporate cultures have grown up and have their own agendas. The catch, of course, is that this can lead to a good deal of confusion and make any support task more difficult because there is no consistency in how things are done. In creating your first Active Directory namespaces for Windows 2000, you should consider making every effort to rationalize the structure, as it will make the overall support job easier in the long run.

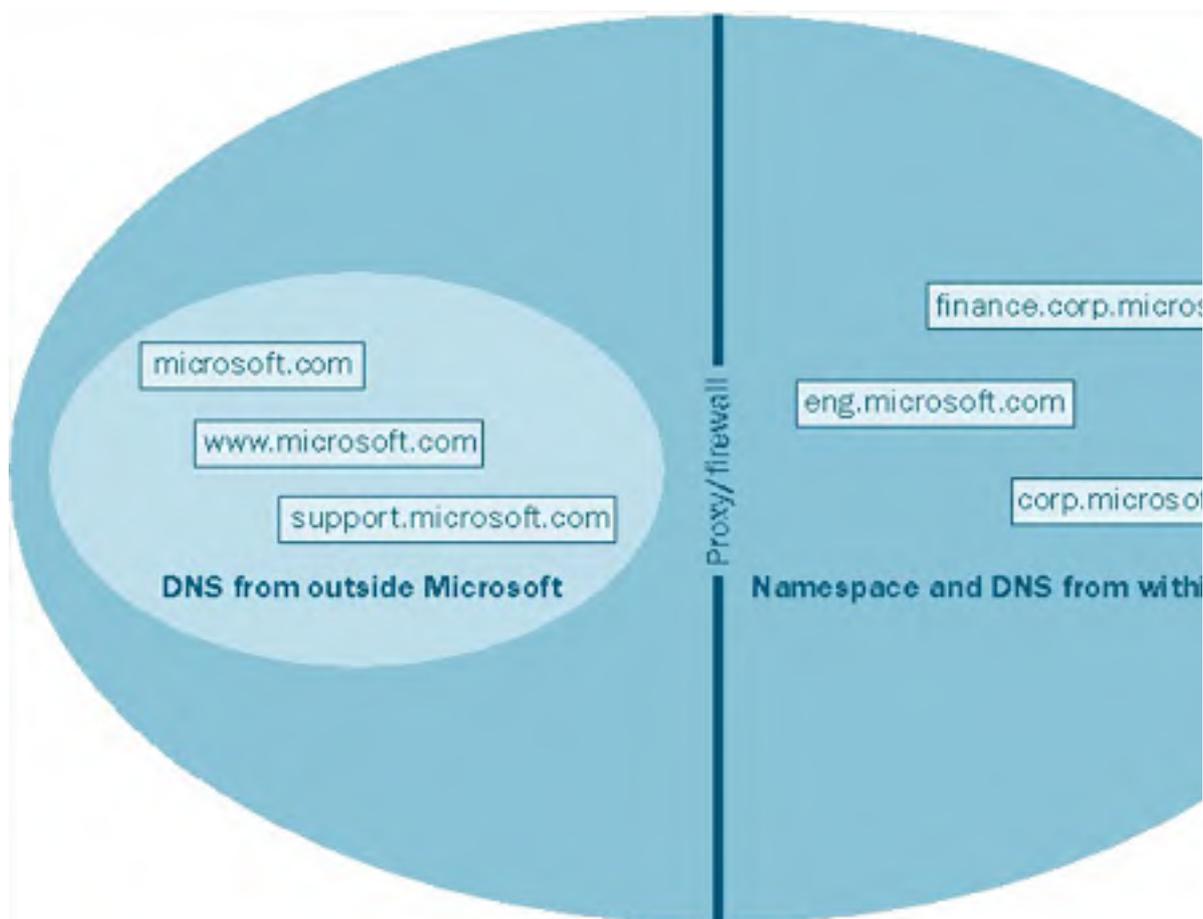

Even if you go with a purely geographical naming convention across the whole organization, chances are you'll find it advantageous at the lowest level of the tree to create organizational units or domains because groups working in similar areas or on related projects tend to need access to resources of a similar nature. The needs on the manufacturing plant floor tend to be different from those in accounting, for example. These common needs can identify natural areas of administrative support and control.

## Determining Name Resolution

A second decision that you must make is whether you want the namespace you use internally to be the same as the one that you present to the outside world. You might think that the names should be the same, but there can actually be compelling reasons to opt for different internal and external namespaces.

### Using the Same Internal and External Namespace

When you have a single namespace, you and your machines have the same names on the internal network as on the Internet. In other words, you get a single name from the appropriate Internet registration authority and you maintain a single DNS namespace, although only a subset of the names will be visible from outside the company. Your network structure will end up looking something like Figure 3-3.

**Figure 3-3.** A public/private network with a single namespace.

When you use the same name for internal and external namespaces, you must ensure that the ability to resolve names from outside your company is limited to machines outside your firewall that are supposed to be externally visible. This will require that you maintain two different DNS zones for the same domain: one visible to internal clients and one visible to external clients. In most cases, this is done on separate DNS servers, because one DNS server cannot host two zones with the same name. Make sure that no Active Directory servers reside outside the firewall. However, you'll also need to make sure that your internal machines can resolve names and access resources on both sides of the firewall.

The following are some advantages and disadvantages of using the same internal and external namespace:

### Advantages

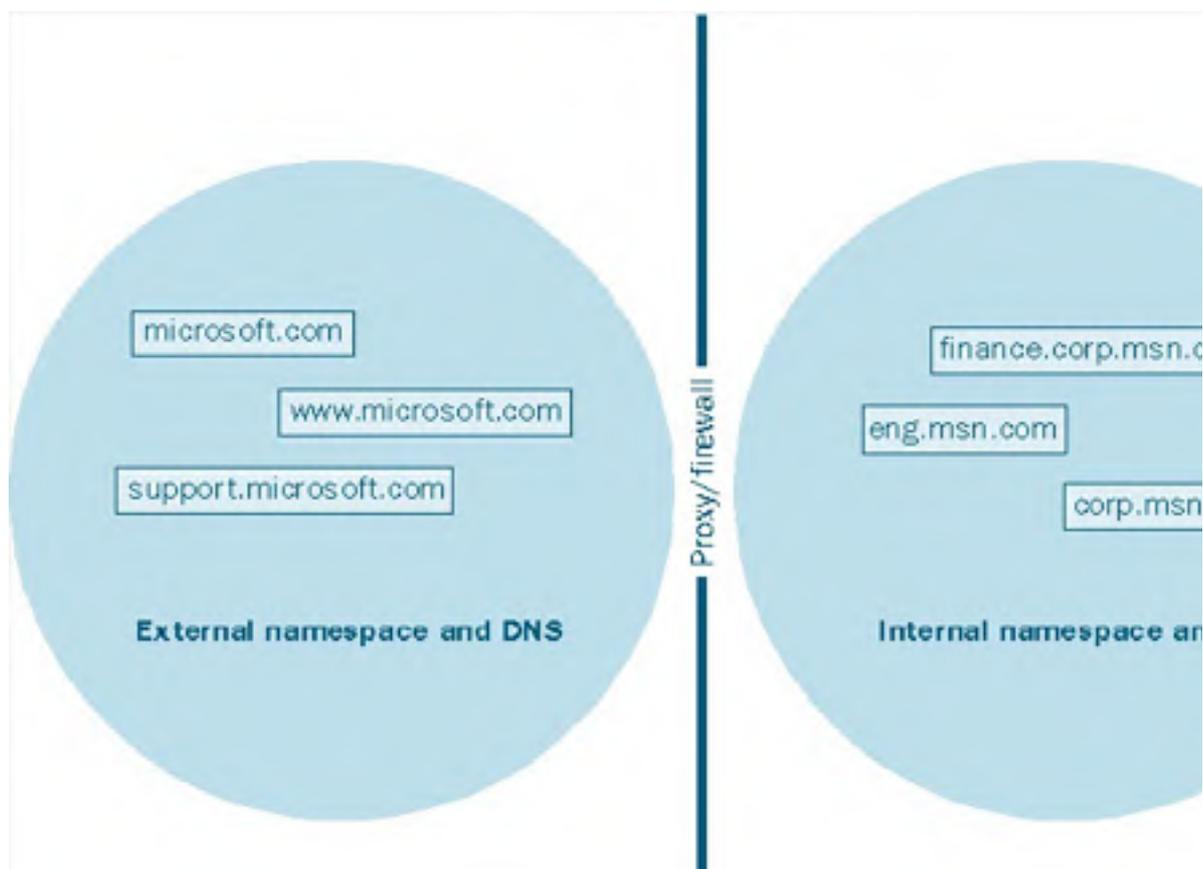

- Provides consistent naming internally and externally
- Allows single name registration
- Enables users to have a single logon identity and e-mail identity

### Disadvantages

- Needs a complex proxy server configuration
- Requires maintenance of different DNS zones that have the same names
- Requires users to work with different views of resources, depending on where they are

### Using Different Internal and External Namespaces

If you set up different internal and external namespaces, your public presence might be *microsoft.com*, while internally you would use *msn.com*. All of the resources that reside outside the company network would have names that end in *microsoft.com*, such as *www.microsoft.com*. Within the company network, however, you'd use a separate namespace that has *msn.com* as its root, as shown in Figure 3-4.

**Figure 3-4.** *Public/private network with separate namespaces.*

One consideration to remember with this scenario: you'll want to register both the public and private names with the appropriate Internet name registration authority. You might think that you don't need to worry about the internal-only name when you have no intention of exposing it to the Internet. What you're really doing, however, is making sure that no one else uses the same name as this could cause name resolution problems for your internal clients.

The following are some advantages and disadvantages of using different internal and external namespaces:

### **Advantages**

- Provides a clear distinction between what is internal and what is external
- Offers easier management and proxy configuration
- Makes it easier for users to understand the differences between the internal and external namespaces

### **Disadvantages**

- Requires that two names be registered
- Means that users' logon names are different from their e-mail names

## Planning a Domain Structure

Once you've settled on the overall design of your namespace, you need to design your domain structure to support it. Each branch of the namespace breaks down to either a domain or an organizational unit (OU). Whether a branch is a domain or an OU depends on a variety of considerations, including the need for replication, security policy, resource availability, quality of the connection, and so forth.

### Domains vs. Organizational Units

Windows 2000 network trees are made up of domains and organizational units. Each provides for administrative boundaries between branches on the tree, but they have different implications and resource requirements.

#### Domains

The core unit of the Windows 2000 Active Directory is the domain, just as it is in Windows NT 3.x and Windows NT 4. All network objects exist as part of a domain, and the security policy is uniform throughout a domain. Unlike Windows NT, Windows 2000 security is based on Kerberos version 5, and the trust relationships are *transitive*. In transitive relationships, if domain A trusts domain B and domain B trusts domain C, then domain A also trusts domain C.

One-way Windows NT 4-style trust relationships can still be set up. More important, the relationships between Windows 2000 domains and legacy Windows NT domains are based on the one-way, nontransitive trust relationships inherent in Windows NT. It is essential that you consider these relationships when planning your domain structure.

With Windows 2000, the concepts of primary domain controller and backup domain controller are finally history. Domain controllers in Windows 2000 are multiple master and peer based. Each controller of a domain has identical authority over the domain, and if any controller goes down, the others continue to administer and authenticate the domain. Any domain controller can originate a change to the domain and then propagate the change to the other domain controllers in the domain.

The domain is also the unit of replication. Changes in the domain are replicated throughout the domain, even when the domain spans multiple sites or locations. This capability allows domain controllers at distant sites to originate changes to the domain and have the changes replicated across the domain.

Whereas access rights are transitive across domain boundaries, administrative rights are, by default, limited to the domain. This allows you to grant administrative rights to a key user in a particular domain without worrying about compromising the overall security of the organization, as the administrative rights stop at the domain boundary unless explicitly granted to other domains.

#### Organizational Units

The OU concept is new to Windows 2000. It has some of the characteristics of an Active Directory domain, but without the resource overhead of one. An OU is contained within a domain and acts as a container for directory service objects. It forms a branch of the contiguous DNS namespace, and it can in turn contain other OUs. Thus, the domain *corp.microsoft.com* can contain other domains within the DNS namespace, such as *finance.corp.microsoft.com*, and it can also contain OUs such as *hr.corp.microsoft.com*. The OU provides a convenient administrative boundary, and rights and privileges for administration can be granted to users in an OU without compromising the rest of the domain. However, an OU does not require a separate domain controller, nor is it involved in replication.

The closest analogy to an OU from the Windows NT domain model is the resource domain, but without the domain controller overhead that was required under Windows NT. In cases where there is no particular need for a separate security policy for a given administrative container, the OU provides an appropriate and less resource-intensive boundary. Moreover, in case of need, an OU can be easily promoted to a domain.

## Designing a Domain Structure

Once you have designed your namespace and everyone involved has signed off on it, you're ready to start designing and implementing your domain structure. The design of your domain structure will closely match the design of your namespace, although you might make a decision that certain namespace boundaries require only OUs, not full domains. Your choice between an organizational unit and a domain should be based on whether you need a separate security policy for the entities within the namespace boundary. If a particular namespace boundary will not require a security policy that is different from that of its parent, you will probably find an OU to be an appropriate division, as it requires fewer resources to implement. As mentioned earlier, you can easily promote an OU to a domain later if that becomes necessary.

### **Designing a Tree Domain Structure**

If you'll be creating a single, contiguous namespace and therefore a pure tree domain structure, you'll want to create the domains in hierarchical order, starting at the top of the tree. The first domain will be your root domain and will, most likely, have either all of the users in it (for smaller, single-domain models) or no users at all (if you use a structural domain as the root domain). For those familiar with the Windows NT 4 domain models, this pattern very roughly corresponds to the single-master domain model, with one important difference. Users need not (and most often should not) reside in a single master domain, but should reside in their actual appropriate place in the domain structure.

As you branch down the tree of your namespace, you create domains or organizational units for each branch of the tree. The decision about whether to create an OU or a domain depends on your overall security model, the quality of the connection to the location, and a variety of other factors, including political considerations from the original namespace planning. If you're in doubt at any point, simply create an OU—it's easy to upgrade the OU to a domain later.

### **Designing a Forest Domain Structure**

The forest of trees structure is most often used to accommodate an existing namespace that is noncontiguous and can't easily be made contiguous. You'll end up with multiple root domains, all on the same level. Below each of these root domains, you'll have a contiguous namespace for that tree. Each branch of the namespace is either a domain (with its attendant requirement of one or more domain controllers) or an organizational unit. You'll generally create each tree from the top down, and each branch of the tree automatically has a transitive trust relationship with the other branches of the tree.

The trees in the forest share the same schema, configuration, and Global Catalog, with transitive Kerberos trust relationships among all members of the forest. The trust hierarchy within each tree follows the naming hierarchy. The trust hierarchy in the forest as a whole, however, follows the order in which trees are joined to the forest. This fact is transparent to the users but can be manipulated by the administrator to improve management and referrals.

### **Domain Security Guidelines**

Within each domain, the security requirements, policy, and configuration are consistent. If you need to change the security requirements and policy for a subunit within a domain, you'll need to create that subunit as a domain, not an OU. Keep this limitation in mind as you plan your overall namespace—you'll need to have a separate branch of the namespace to have a separate security policy.

What is meant by security policy? What sorts of things does it entail? Chapters 18 through 20 deal exclusively with security matters, so for the moment, we'll take a summary view. The security policy includes the following:

- Logon requirements
- Certificates
- Password aging and minimum length requirements
- Smart card or other authentication add-ons
- Machine and time-of-day restrictions

Many of these things are comfortably the same throughout your organization, but there might be certain areas that require significantly greater security than that needed in the rest of the organization. If so, plan for areas that require extra care to be in a separate domain so that their more restrictive security won't be imposed on the entire organization.

## Creating Organizational Units

In situations where you don't need to create separate domains for security reasons but do want to maintain a separate level in the namespace, you'll create a separate OU. Thus, you might have a domain called *noram.microsoft.com* that you want to divide into business units within the region. You could create separate sales, support, education, human resources, manufacturing, and finance domains under *noram.microsoft.com*. However, the overhead of separate domains (and their required controllers) for each of these units isn't necessary—especially because they all share a single security policy. Simply create OUs for each of them. If you later decide to upgrade one or more of them to a domain, you can do it easily.

Organizational units make useful boundaries for administrative purposes. Various administrative tasks and privileges can be delegated to the administrator for a specific OU, freeing up the domain administrator and giving the OU local control of its own resources.

## Planning Multiple Domains

When your organization is complex enough, or simply large enough, that you know you're going to have to create multiple domains, you should spend the extra time up front planning exactly how to implement them. Time spent on the front end will be paid back later many times over.

Draw out your planned domain structure and compare it to your planned (or existing) namespace. Decide what simply *must* be a domain and what can comfortably be an OU. Identify which servers will be your domain controllers. Keep in mind that the concepts of primary domain controller and backup domain controller from Windows NT are gone. All servers within a domain are of equal weight and importance. Changes made to any domain controller are propagated to all other controllers within the domain. If simultaneous changes are being made against multiple controllers, Active Directory uses update sequence numbers and the timestamps of the changes to resolve any conflicts.

## Planning a Contiguous Namespace

When you are planning a contiguous namespace, and thus a single tree structure, you'll initially want to create the root domain for the namespace. In this namespace, you should create the primary administrative accounts, but it is best to leave the creation of other accounts until later. User and machine accounts should reside in the leaf of the tree where they are going to do the majority of their work. This is the reverse of Windows NT, where, if you are running multiple domains, you often have to create all your user accounts at the highest level of the domain because of the nature of trust relationships.

If you're migrating from an existing Windows NT environment, you might have your users in a single- or multiple-master domain. You can continue this arrangement, and it might be the easiest way to migrate from an existing environment. See [Chapter 7](#) for a more thorough discussion about upgrading domains.

## Determining the Need for a Forest

If you have an environment in which there are already multiple root domains, or where a contiguous namespace doesn't exist, you'll need to create a forest rather than a single tree environment. The first step is to take a long, hard look at your noncontiguous namespaces. Is there any opportunity to consolidate them into fewer contiguous namespaces? Now is definitely the time to do this. It will be much harder to consolidate them later, and you'll have a harder political battle as well.

## Creating the Forest

If you've decided that there is simply no way to get down to a single, contiguous namespace, meaning that you'll need to create a forest, you should decide exactly where the root of each tree in the forest will reside. Think about the physical locations of your potential domain controllers, the layout of your network, the bandwidth of various sites, and the current existence of Windows NT 4 domains and controllers. Once you have a good physical and logical map of your network, you're in a position to plan your domain strategy.

Create your root-level domains first and then start building your trees. This isn't an absolute requirement—if you miss a tree or something changes, you can go back and add another tree to your forest. However, it's generally better to create the roots first, if only for the purpose of getting things lined up and getting your tree-to-tree trust relationships in order.

Once you've created the root of a tree, there is no easy way to rename or delete it, so don't rush into creating your domain structure. Planning it out in detail will save you a huge headache in the long run.

## Summary

Planning your namespace and domain is an essential first step to a successful implementation of Windows 2000. It is an iterative process that requires a clear understanding of the political vagaries of the organization. A Windows 2000 namespace can have either a single, contiguous, and hierarchical tree structure or a forest of trees in a noncontiguous namespace. All domain controllers have the same authority over a domain, and there can be multiple organizational units within a domain. We continue our focus on planning in [Chapter 4](#); in [Chapter 5](#), we move from planning to installing.

# Chapter 4

## Planning Deployment

Deployment involves a good deal more than merely installing an operating system, even a network operating system. The specifics of deployment—installing and configuring applications, file and print services, the Active Directory service, communications, security, and other functions—are covered in later chapters. This chapter deals with the work that must be done before the first CD-ROM is ever inserted into a drive—planning the hardware and software infrastructure on which your Microsoft Windows 2000 network will be based.

Successful deployment of Windows 2000 depends primarily on planning. Successful planning, in turn, depends on gathering and analyzing data as well as a certain amount of prophesying. The decisions made at the early stages of deployment will have your fingerprints all over them, for good or ill. Your vision of the future will prevail for years to come in the operation of the organization, and you'll undoubtedly be held accountable if the vision turns out to be a nightmare. Therefore, the more planning you devote to deployment, the better off everyone will be.

Three elements are essential for an effective information technology (IT) strategy:

- An analysis of how your business requirements and IT capabilities match up today. Where is your technological structure adequate, and where is it lacking?
- A projection of your business and IT goals. You need one-year, three-year, five-year, and ten-year plans for business needs, and the IT functionality and services to meet those needs.
- A roadmap that provides a path toward achieving the business and IT goals.

This chapter discusses all three of these elements and examines how they are interrelated.

## How Information Technology Functions

Most people would agree that the purpose of an Information Technology department is to serve current business needs as well as to advance long-term strategic goals. Unfortunately, this isn't always clear, for a variety of reasons. Sometimes communication is poor. Often no one has ever given much thought to what it takes, technically speaking, to serve business needs. Many networks appear to have sprouted like mushrooms after a rain, without the benefit of anything resembling an overall vision. Changing the situation is complicated by a number of factors:

- Legacy hardware and software
- Incompatible operating systems and applications that were adopted to solve specific divisional or departmental problems
- Rapidly changing technologies and user requirements
- Resistance to change by those who have grown comfortable with older technologies
- Too little staff, time, and money to plan and execute a network upgrade

This last item is virtually universal. However, if these factors plague your organization, it's time to start struggling against the status quo. The situation can't and won't change overnight, but a carefully thought-out plan with clear priorities can do a great deal to move things forward.

## Identifying Business Needs

Identifying business needs is a topic of such scope that it can seem overwhelming. A good place to start is with individual departments or areas. For example, consider the needs of your sales, human resources, and marketing departments. What does each area need to do now, and what services will be of benefit in the future?

Consider basic operations (such as accounts payable and inventory) that have to be taken care of daily, as well as less frequent operations (the launching of a new product). What kinds of flexibility need to be built into the IT systems? What sorts of changes must be anticipated to deal with increased Internet activity or increased access for users in remote locations?

The research you perform into the organization's business requirements can also help you overcome resistance—and there's always some resistance—to changes in the infrastructure. As people participate in your research and share your understanding of the organization's current issues and opportunities, more of them will come to have a personal stake in supporting your Windows 2000 deployment.

## Getting Specific

Start with a list, ranked in order of importance, of enterprise functions that are necessary to meet your organization's business goals. As part of that list, incorporate the following:

- A total cost of ownership (TCO) analysis identifying potential areas where upgrades to the IT infrastructure can result in cost reductions
- A return on investment (ROI) analysis identifying the financial opportunities that can result from upgrades to the IT infrastructure
- Additional business that can result from the infrastructure upgrade
- Potential risks from not updating the IT infrastructure

Information on using the Microsoft Rapid Economic Justification (REJ) framework to analyze and optimize IT investments can be found at  
<http://www.microsoft.com/business/solutions/value/valuehome.asp>.

These are complicated issues with much overlap, so you might have to construct this list more than once. Depending on the size of your operation, this list might have to be subdivided into manageable bites, each one of which constitutes a project of its own.

An estimate of the financial impact that disaster recovery in a "post-9/11" world has on your organization, and the potential costs of *not* doing this planning, should also be included.

## **Seeing into the Future**

To make your network successful, you need to undertake a high-level analysis of what your organization will look like in one, three, five, and even ten years. Will the organization become more centralized or less? Will it expand geographically, or will it contract? Will you have more knowledge workers who require the free flow of information on networks to do their jobs? Will you need to deal with "boundaryless" workers who spend time in the office but who might also telecommute, belong to virtual teams, or even work in their clients' offices? Workers with such needs can make the usual means of information distribution completely inadequate. How will these workers get what they need? How will you balance conflicting demands for access and security?

Computer networks themselves are subject to rapid change because the experience of working on a network changes users' perceptions of what is possible and therefore their view of what is needed. Once it's possible to have access to real-time sales figures or inventory counts, the demand for access grows rapidly.

Even modest changes can have a substantial impact on your IT infrastructure. By anticipating changes and planning for them, you ensure that your network can evolve to meet future needs.

## **Assessing Your Current Setup**

It's a rare company that has a complete inventory of its hardware and software. It's an even rarer company that knows the rate at which its hardware and software infrastructure changes. Grand goals for the future can't be met without knowing the facts about the present. After all, even if you're sure you want to go to Chicago, you have little hope of getting there unless you know whether you're currently in Savannah or Seattle. The sections that follow detail the steps for analyzing what you have, so you can determine what you need and how to implement changes.

## **Documenting the Network**

Knowing what hardware and software you have deployed and how that equipment is being used is vital when designing your Windows 2000 network and determining the best way to implement it. After all, you're not tearing out the entire current network and replacing it with brand new, state-of-the-art equipment. (And if you are, that's not as easy as it sounds either.)

Instead, you'll be phasing out legacy hardware and software over a period of weeks or months—perhaps even longer. During this time, the existing hardware and software still have to be supported. A careful and thorough audit of your existing network can be of great use in determining where potential problems (and opportunities) lie.

## **The Organizational and Physical Infrastructure**

Make a drawing of the physical network, including workstations, servers, routers, wiring closets, and hubs. This picture will clarify where the network can be expanded (and where it cannot), the best traffic routing, and whether servers and other hardware are optimally placed. At the same time, an organizational chart showing all members of the IT staff and the responsibilities assigned to each one can help clarify lines of communication and show where they might be lacking. Make sure that all critical tasks are assigned at every site, organizational unit, or location. You don't want to establish a server at a remote location and have no one there who can manage anything beyond a reboot.

## **Traffic Patterns**

Gather network traffic reports to determine the optimum placement of routers, hubs, and switches; bandwidth requirements for workstations and workgroups; and future needs for network management software. Network analysis utilities are available to help you determine your overhead (or background) network traffic. Traffic patterns are also important in determining appropriate wide area network (WAN) connectivity speeds or the speed to be used on risers connecting floors in a building.

## **Network Addresses**

As you upgrade the network using Active Directory, you'll probably be assigning new network names to most of the nodes on the network. Add the node addresses to the hardware drawing you made earlier so that you can analyze what addresses to assign and what steps are necessary to make the transition from the old naming system to the new one.

## **Operating System Connectivity**

Many systems already have Windows NT connected to other operating systems such as UNIX and NetWare. You'll need to determine what tools are necessary to maintain the connectivity you want. In addition, hardware placement—routers, switches, and gateways—can all be critical to optimum connectivity.

## **External Connectivity**

Just as most companies don't know what hardware they have, many networks have undocumented external connectivity. Most know about their Internet, WAN, and fax services, but often there are completely undocumented telephone lines used for dial-up networking or remote network management. Document all connections.

## **Existing Network Operating Systems**

Documenting the operating system on each server and workstation on the network, including the service pack level, is an essential ingredient to a successful operating system upgrade or migration. You'll need to determine what the upgrade or migration must support and what preparatory upgrades are needed.

### **Existing Applications and Services**

You will need an inventory of all of the software running on servers and workstations. Once you have this list, further analysis is needed to determine what resources the applications require most of the time as well as under extraordinary circumstances. For example, a particular program might generate a modest amount of traffic most of the time except for weekly downloads of 200 MB from a WAN server, and the accounting department's requirements are vastly different at year end than they are in midquarter.

In addition, the inventory of applications and services should be subdivided and classified into categories:

- **Strategic** Software and services that are essential to business operations and have the most relevance to current and future goals. This will include most infrastructure and security applications, such as firewalls, antivirus programs, and so on, assuming they are behaving optimally.
- **Tactical** Applications and services that are valuable to the business but are not providing optimal benefit.
- **Legacy** Software and services that are still used by some groups or departments but are nearing the end of their useful life. Your plan should call for removing these components before they fall into the obsolete category.
- **Obsolete** Applications and services that are not only not beneficial to the business but are a hindrance. The goal of IT should be to remove these elements as soon as possible.

Every component belongs in one of these categories, and making the assignments can clarify your thinking and help give shape to your plan.

## Making a Roadmap

A recent study commissioned by Microsoft identified six characteristics of successful IT departments. None of the conclusions is startling, but they bear repeating. Companies with successful IT departments

- **Make IT a business-driven line function, not a technology-driven staff function.** In other words, the function of the technology people must be firmly connected to business strategies and the everyday work that advances these strategies.
- **Base technology funding decisions on the same considerations as any other corporate expenditure.** Cost/benefit and ROI analyses must be as much a part of every IT investment decision as they would be in the decision to buy a new building.
- **Insist on simplicity and flexibility throughout the technology environment.** Reduce the number of technologies and platforms deployed, and aim for maximum flexibility and ease of implementation.
- **Demand near-term business results from development efforts.** Incremental project rollouts are preferred, as is packaged software over custom software wherever possible. When custom development is necessary, focus on the 20 percent of the functionality that typically adds 80 percent of the value.
- **Drive constant year-to-year operational productivity improvements.** Measure performance against internal and external benchmarks and standards, and strive for constant improvements.
- **Aim for an IT department that is smart about business and a business organization that is smart about IT.** Simply stated, in the better performing companies the IT and business organizations work together. They speak the same language, talk to each other, and understand each other's capabilities and needs.

These are all grand statements that are difficult to argue with in the abstract but hard to implement in the real world. However, we all have to start somewhere, and keeping these aims in mind and working toward implementing them can only benefit the enterprise overall.

After you've analyzed your present situation as well as the business goals you need to achieve, the next step is to design a roadmap that will take you where you want to go. The roadmap should include a definition of the goals, a risk assessment, and an implementation plan.

## Defining Goals

Your deployment goals must be specific, achievable, and measurable. Spell out the problems that have to be solved and how you will address constraints such as end user requirements, costs, schedules, and reliability.

Your plan must then address specifically what you want to accomplish at each stage and how you will measure whether you have done what you set out to do. When deploying Windows 2000 in a particular department, approach the task as a vendor to that department. As a minimum, you'll need to

- Determine who has to agree to the scope of the project and who can sign off at the end of it.
- Determine the scope of the project: what needs to be installed, what needs to be configured, and what the users will be able to do at the end of the project. Involve as many people in the department as possible.
- Get agreement as to what will constitute completion of the project. For example, a project might be considered complete when all workstations are connected to the network with specified software installed, all users can log on, and data can be retrieved under all conditions in  $n$  seconds or less. Again, be specific.
- Define a method that will test all areas of the project. Get a sign-off on the method. Allow ample time for testing. Regular, short-loop testing as you go will save much time and aggravation later.

- When the project is complete, get a sign-off that it is in fact complete. Additions and changes that are not in the original scope should be addressed as a new project—a different phase of the deployment. It's very important that every stage have a point of closure.

Some of these steps seem obvious, but it's surprising how often people have no idea whether their upgrade to the system has actually accomplished anything and, if it has, whether the results are what was wanted and needed. All too often the IT people go away dusting their hands and congratulating themselves, while the actual "customers" are far from satisfied.

## Assessing Risk

It's not possible to predict everything that can go wrong in a deployment, but you can be sure that something will. Typical problems include sudden changes in business needs or user requirements, cost overruns, and the almost inevitable schedule slippage.

Risks can be managed proactively or reactively. Preventing difficulty is obviously better than reacting to trouble after it pops up, although (just as obviously) this is not always possible. Nevertheless, it's feasible to draw up a risk assessment and risk management plan. Such a plan would include the kinds of problems that might occur, an appropriate response to each problem, and ways to minimize the potential loss in case of a problem.

Few things can hurt you more during deployment than a poorly thought-out schedule. At the same time, a schedule that considers risks can go a long way toward minimizing the likelihood of serious problems. The following precautions will help you minimize schedule-related perils:

- **Develop high-risk components first.** Any areas that are already an ongoing tangle—such as messaging or your Web server—should be developed first and independently. New components that haven't been part of your network before should also be tested separately and understood completely before you install them where they can affect critical operations.
- **Include a fudge factor for unforeseen circumstances.** Nothing ever works exactly as you expect. The "five-minute install" turns out to require a change in hardware to work correctly. The quick change of hardware requires an unexpected half-hour of configuration. Estimate how much time each stage of deployment will take, and then double it.
- **Update the project plan and schedule.** When circumstances change and milestones are reached, notify everyone involved in the project by updating and distributing the plan and schedule. If you find yourself two days behind after the first stage of the deployment, don't just plan on working faster to catch up. Instead, update the plan and determine whether the delay is due to a defect in the plan (and therefore likely to multiply over time) or merely a one-time failing. Optimism is a fine quality, but it's more important to be realistic.
- **Communicate problems *and* successes.** Keeping everyone involved up to date on where you stand and what you've accomplished or where you've had problems will make everything go smoother. When you establish a pattern of communicating both success and problems, you help all your customers keep the problems in the appropriate perspective.

## **Summary**

These first chapters have no doubt given you lots to think about—and certainly plenty to do. Nevertheless, no matter how much groundwork you lay, you must eventually put some of your plans into practice—if only to see where they can be improved. Part II starts with the next chapter; there you begin the process of actually installing and configuring Windows 2000 Server, Windows 2000 Advanced Server, Windows 2000 Professional, and Windows XP Professional.

# Part II

## **Installation and Initial Configuration**

### [Chapter 5](#)

Getting Started

### [Chapter 6](#)

Configuring New Windows 2000 Server Installations

### [Chapter 7](#)

Upgrading to Windows 2000

### [Chapter 8](#)

Installing and Managing Printers

### [Chapter 9](#)

Managing Users and Groups

# Chapter 5

## Getting Started

The first four chapters of the book have dealt with fairly abstract planning. In this chapter, we get down to the matter of actually installing the operating system. There are five ways to install Microsoft Windows:

- Manual installation from a CD-ROM or network share
- Unattended installation using an answer file in conjunction with a CD-ROM or network share
- Using SysPrep and a third-party disk imaging program to make an "image" of a Windows installation, which can then rapidly be deployed by CD or network share
- Automated installation by booting from the network and installing from a Remote Installation Services (RIS) server
- Centrally managed operating system upgrade using either Group Policy's Software Installation and Maintenance feature (IntelliMirror), or using Microsoft Systems Management Server (SMS)

The first three methods are covered in this chapter; using RIS servers and performing upgrades using Group Policy are discussed in [Chapter 25](#) (consult Microsoft's Web site for information on using SMS to upgrade Windows).

## Windows Installation Considerations

Before you deploy Windows, yes!—*more* planning. Advance preparation might not reduce by much the total time it takes to bring the server online, but it will reduce the number of procedures that you have to do, redo, and then do again. Before installing Windows on any computer there are a number of things to consider, such as the system requirements, how you want to partition your hard disks, what licensing modes will be used, and so forth.

### Reviewing System Requirements

Before installing Microsoft Windows 2000, check that you have appropriate and adequate hardware. This involves both meeting the minimum system requirements (hopefully exceeding them if you want the server to do any real work) and checking the Microsoft Hardware Compatibility List (HCL) to be sure that the computer and peripherals are supported.

Table 5-1 lists the minimum system requirements for Windows 2000 Advanced Server, along with some more practical recommendations for the minimum necessary hardware.

The late Duchess of Windsor was fond of saying that you can never be too rich or too thin. Now you can add the axiom that without a doubt, you can never have too much processing power or too much RAM on a domain controller, or on any server for that matter. The only restriction is economic. Get the most server you can afford.

**Table 5-1.** *Minimum requirements for achieving adequate performance*

Minimum	Recommended Minimum
Intel Pentium 166	One or more Intel Pentium II 300 or faster microprocessors (or compatible processors—check the HCL)
64 MB RAM minimum, 128 MB recommended, 8 GB maximum	128 MB RAM minimum, 256 MB or more recommended
VGA monitor resolution	Super VGA monitor capable of at least 800-by-600
Keyboard and mouse or other pointing device	Keyboard and mouse or other pointing device
850 MB partition with 650 MB free disk space	2 GB free disk space on a 7200 rpm or faster hard disk
Bootable CD-ROM	Bootable 12x or faster CD-ROM or DVD-ROM drive (El Torito-compatible)
1.44 MB floppy	1.44 MB floppy
One or more network adapters	One or more PCI-based Fast Ethernet network adapters with Preboot Execution Environment (PXE) support

Yes, the name of the specification is indeed El Torito. The engineers who developed the standard named it after the restaurant where they had held many, presumably happy, collaborative meetings.

Before buying server hardware, check the HCL in the \Support folder on the Windows 2000 installation CD. If updated drivers are available for the hardware, download and copy them to a floppy disk or available local disk so that you can use them during installation, if necessary (they can also be added to unattended installations, as discussed later).

If a component in the system isn't listed in the HCL, visit the manufacturer's Web site or contact the manufacturer of the device to see whether updated drivers are available. In general, though, the rule is this: don't use a server that isn't 100 percent compatible and certified.

Although having a fast processor is important for some server applications, older systems can be made to work extremely well by adding more RAM. Even Pentium 100 systems can perform reasonably well as servers if you increase their installed RAM to 256 MB or more.

### **Real World**

#### **Hardware Compatibility**

Although it's true that many devices not in the HCL will work most of the time, servers are needed all the time. Inevitably, some traceable-to-the-hardware fault will show up, and you'll have no recourse. Microsoft will justifiably point out that you should be using hardware from the HCL. And the manufacturer will shrug and say that they're "working on" drivers. Neither is a good position to be in.

If you have machines that aren't 100 percent compatible, try them out as clients. Often, Windows 2000 Professional or Microsoft Windows XP works perfectly well on a machine that's not in the HCL.

## **Planning Partitions**

Before installing Windows, determine how you want to partition the hard drives. We recommend that you use a single partition for client installations. Although a single partition is the simplest option for servers, you gain flexibility (and security) by creating a 2- to 4-GB partition for the operating system, and another partition with the remaining space. In this way the operating system is separate from applications and data (especially the Inetpub folder belonging to Internet Information Services) and permits the use of such services as Remote Installation Services (RIS) on the server, which must be installed on a nonsystem partition.

If you plan to create multiple partitions, we recommend that you create the partitions in Windows after the installation is finished.

Servers with multiple disks should take this strategy as well, more or less. If the first hard disk is small, make it into a single partition for Windows and use other drives for data and applications that can't be installed on the same drive as Windows (such as RIS). Otherwise, split the first disk into two partitions (one being a 4-GB partition for Windows) and create full-size partitions on subsequent disks.

Of course, most serious servers will make use of some form of redundant array of independent disks (RAID). Hardware RAID can be treated simply as a single drive: if the RAID is used for the system drive, create a 4-GB partition on it for Windows and leave the rest for data and applications.

Although hardware RAID is the highest performance and simplest RAID solution, Windows also supports software-based RAIDs that don't require a special RAID disk controller, thereby saving money. However, software-based RAID (as well as software-based disk spanning, mirroring, and striping) can create problems with Windows Setup, because Setup has difficulty handling dynamic volumes. Although most upgrades should work fine, you can't perform a clean install on a dynamic volume unless the dynamic volume is "hard-linked." (Only dynamic volumes that were upgraded from basic volumes are hard-linked.) Problems do occur. One of our computers now relies on a floppy disk to boot into Windows 2000 and can't be upgraded to a newer version of Windows precisely for that reason. Therefore, if you use the software RAID feature of Windows, leave the first hard disk as a basic disk and use software RAID only for applications and data.

### **Real World**

#### **Just Say NTFS**

Although the Windows 2000 Server family supports three different file systems for hard drives—FAT(16), FAT32, and NTFS—the file system choice is simple: NTFS.

Although FAT16 and FAT32 had their places in the past, notably for dual-booting with Windows 95/98 and for their ability to be accessed from boot floppy disks, there is no place for them anymore on the hard drives of today's Windows clients and servers. Simply put, NTFS is more reliable, secure, and efficient than FAT and FAT32. You can also use the Safe Mode and Recovery Console features to gain access to a nonbooting NTFS system without compromising the system's security. Additionally, many Windows Server features or services require an NTFS partition. For example, to use a server as a domain controller or Active Directory server, an NTFS partition must be available.

The bottom line is that unless you need to keep a legacy version of Microsoft Windows 95, Windows 98, or Windows Me installed on the machine for compatibility reasons, use NTFS. Servers should always use NTFS.

## Gathering Network Information

After determining how you want to partition the drives, locate all the drivers for the hardware. Then record (or create) the following settings:

- **Domain Name System (DNS) name of the computer** This name can contain both uppercase and lowercase letters, numbers, and the hyphen character. Keep any DNS host names shorter than 15 characters if you want the NetBIOS name to be the same as the DNS name (a good idea for compatibility with Windows 95, Windows 98, and Windows NT systems).
- **Name of domain or workgroup to join (if on a network)** If the computer is currently on a Windows domain, note the domain name. On a peer-to-peer network, note the name of the workgroup to which the computer belongs.
- **IP address of the computer** This is required unless the network has a Dynamic Host Configuration Protocol (DHCP) server.

If you don't have a DHCP server and don't assign an IP address to the computer, Windows assigns the computer a restricted IP address. This IP address will work on a simple network with only one IP subnet, but it won't work on more complex networks, nor will it work as an Internet-accessible IP address. For more complex networks, install a DHCP server on the network or assign IP addresses manually. To acquire valid Internet IP addresses, you need to register with your Internet service provider for a scope of IP addresses.

- **Optional Windows Server components** For a full listing of the components available for installation, see [Appendix B](#).
- **Client licensing mode and the concurrent number of clients (if the licensing mode is Per Server)** The Windows 2000 Server family supports Per Server and Per Seat licensing. If you're unsure which licensing mode to use, choose Per Server. You can switch from Per Server to Per Seat once (without additional cost) but not from Per Seat to Per Server.

Internet Information Services (IIS) is installed by default in Windows 2000, and unless it's been patched to the latest service pack, it could easily expose the server to a virus or other security risk as soon as the system is joined to a network. Therefore, disable the installation of Internet Information Services (IIS) during Windows setup, unless the server must run IIS and you're installing from an installation source that has the latest service pack and integrated hot fixes. You can install IIS after the system has been patched.

**Real World**

**Licensing**

There are two types of licensing modes for Windows servers, Per Server and Per Seat licensing. With Per Seat licensing, each client that accesses the server needs its own Client Access License (CAL). Clients with a CAL can connect to any number of servers, making this method the most common licensing method for companies with more than one Windows server. You would also commonly choose it when using Terminal Services/Remote Desktop Connection (unless you're using the Terminal Services Internet Connector License, in which case you would use Per Server).

Per Server licensing requires the server to have a CAL for each concurrent connection. For example, if you choose the Per Server licensing mode with 50 concurrent connections, the server can support a maximum of 50 simultaneous client connections. This licensing mode works well for companies using only a single Windows server or for Internet or remote access servers where the client computers might not be licensed as Windows network clients.

If you're unsure which licensing mode to use, choose Per Server. You can switch from Per Server to Per Seat once (without additional cost) but not from Per Seat to Per Server. You can use License Manager, located in the Administrative Tools folder on the Start menu, to keep track of the license purchases and holdings.

## Physical Preparation

After you've recorded all of these settings, several physical tasks remain:

- Back up any existing data on all the drives for which the server is responsible.
- Disable any disk mirroring for the duration of the setup process.
- Disconnect any serial connections to an uninterruptible power supply (UPS). UPS equipment can interfere with the setup program's ability to detect devices connected to serial ports.
- Upgrade the system BIOS to the latest version available. If the BIOS doesn't meet Windows Advanced Configuration Power Interface (ACPI) standards, set the PNP OS setting to NO.
- Locate any mass storage drivers or custom hardware abstraction layer (HAL) files necessary for the system.

## Dual-Boot Considerations

Under most circumstances, a server won't have two operating systems, but sometimes such an approach is appropriate. For example, you might want to keep an existing installation of Windows NT 4 in case you find specific incompatibilities with the software or hardware. For more information on upgrading your server from Windows NT to Windows 2000, see [Chapter 7](#).

You must have a different computer name for each operating system installation on a network. A unique security identifier (SID) is generated for each Windows installation on a domain, and each SID is associated with one particular computer name. So, you can boot several operating systems, but in each system the computer is known to the network by a different name.

## Multiple Copies of Windows 2000, Windows XP, or Windows .NET Server

If for some reason you need to use multiple recent versions of Windows, keep the following things in mind:

- Each operating system needs to have its own unique computer name.
- You can't install two operating systems on a dynamic disk (discussed in [Chapter 15](#)).
- To access files encrypted with the Encrypting File System (EFS) feature, you need to ensure that both installations are in the same domain, and that the user has a roaming profile. You should also export the user's file encryption certificate and private key from one installation and import it into the other installation.

If you need to run multiple operating systems on a computer, we suggest that you look into purchasing VMware Workstation, or Connectix Virtual PC. Both programs create one or more virtual machines in which you can install any operating system you like (including MS-DOS 4). The virtual machine runs as a Windows program and doesn't need a disk partition—just a chunk of hard disk space. This can be an excellent way to evaluate an operating system or provide a legacy operating system environment for testing or old applications.

## Dual Boots with Windows NT

Rather than upgrading the server, you can perform a clean install of Windows 2000. A clean install allows you to preserve the existing installation for use in case you encounter trouble setting up the server with Windows 2000. Performing a clean install is also the only option if the server is running a version of Windows earlier than 3.51 and you don't want to upgrade to Windows 3.51 or 4.0. However, when you perform a clean install, Windows 2000 doesn't migrate the existing programs and settings as it would if you upgraded the server.

The following list shows the issues involved when using Windows NT with newer versions of the Windows NT family (Windows 2000, Windows XP, and the Microsoft Windows .NET Server family) on computers with NTFS drives:

- Windows NT should be installed on its own separate FAT (16) partition to ensure that it can access all the necessary files at boot. Windows NT cannot be installed on a dynamic volume.
- Install Windows NT first, and the newest version of Windows last.
- Only Windows NT 4 with Service Pack 4 or later can access NTFS drives and volumes on a system that contains Windows 2000, Windows XP, or Windows .NET Server. However, you should install Service Pack 6 (SP6) and post-SP6 hot fixes to ensure the greatest compatibility.
- Each operating system needs to have its own unique computer name.
- Any drives formatted with the FAT32 file system can't be read by Windows NT 4.
- NTFS 5 features such as disk quotas and encryption don't work in Windows NT 4. (Encrypted files can't be read in Windows NT 4.)
- Don't install applications in the same location. If you need an application in both operating systems, install them separately onto separate partitions.
- Windows NT 4 disk utilities such as Chkdsk won't work with NTFS drives. You must use the versions of these utilities included with the newest version of Windows on the computer.
- Windows NT 4 emergency repair disks can no longer be used.
- Files you save or create in newer versions of Windows might not be accessible in Windows NT 4 (if they make use of new file system features such as EFS).
- Removable media that is formatted with NTFS is automatically converted to NTFS 5 when inserted or used with a newer version of Windows.

## Dual Boots with Other Operating Systems

Dual booting with MS-DOS, Windows 95, Windows 98, Windows Me, or other personal operating systems should be performed on desktop computers and not on the server. Performing a dual boot with UNIX or another server operating system is perhaps more useful, but you should avoid it if possible.

If you do choose to perform a dual boot with another operating system, use the backup utility provided with the newest installed version of Windows or another supported backup program to perform a full backup of the system including system state information. Also, you should create an emergency recovery disk by using the Windows Backup utility (just for good measure). When installing or configuring the operating systems, be careful with the master boot record (MBR). Table 5-2 shows a list of additional factors you should consider when working with different operating systems.

**Table 5-2.** *Dual boot issues*

<b>Operating System</b>	<b>Issue</b>
Windows 95/98/Me	Install and boot before installing newer versions of Windows to keep Windows 95/98/Me from overwriting the MBR and preventing the newer version of Windows from booting.
All operating systems	Programs must be installed separately in each operating system.
All operating systems	Windows Servers can't be installed on drives that have been compressed with any program other than the NTFS File Compression utility.
MS-DOS, OS/2	If you install Windows on a computer that was previously performing dual boots between MS-DOS and OS/2 using the Boot command, at startup you can choose to boot only either Windows or the operating system you most recently booted.

## Installing Windows 2000

How you choose to install Windows depends on what is already on the server, where the installation files are, and how many installations you have to do.

If you only need to perform a few installations, you can manually install Windows, either from within an existing copy of Windows or by booting from the Windows CD-ROM.

If you need to perform multiple installations, you can create unattended answer files to automate the setup process, use SysPrep to clone a computer with Windows and applications already installed, or use Remote Installation Services (RIS) to perform automated installations from across the network (RIS is discussed in [Chapter 25](#)).

### Manually Installing Windows

The most basic way of installing Windows is to manually go through each Setup screen (instead of automating the process). This is fine when doing a few installations or when you're familiarizing yourself with the installation process. However, it's a tedious and slow method of deploying systems en masse, so for multiple installations, automate the process using answer files, SysPrep, or RIS.

#### The Phases of Setup

The Windows setup process consists of several phases that vary somewhat depending on how you initiate the installation.

If you install from Windows, Setup gathers information and copies the files that are necessary for the computer to boot into text-mode setup, which it then reboots into. You then (optionally) select the appropriate partition, after which Setup installs a minimal version of Windows to the hard disk and reboots into the graphical user interface (GUI)-based Windows Setup Wizard, which collects more information, configures the devices, and finishes copying files. After this, Setup is complete, and the computer reboots into Windows proper.

If you boot the system from the Windows CD-ROM, Setup launches straight into text-mode setup, where you select the partition on which you want to install Windows. Setup then installs Windows to the hard disk and then boots into the GUI-based Windows Setup Wizard. The Setup Wizard then collects information, configures devices, and finishes installing files to the computer. Setup reboots the computer when it's finished.

If you boot the system with a Windows 98 boot disk and then run Setup, Setup copies the necessary files to the hard disk to boot into text-mode setup and then reboots into text-mode setup. Setup then performs the same process it would perform if you booted from a Windows CD-ROM or (or setup boot disks).

If you already have a copy of Windows 2000, Windows NT 4, or Windows 98 installed on the server, the easiest way to install Windows is to run the 32-bit version of setup (Winnt32.exe). To do so, follow these steps (if there isn't already a copy of Windows on the computer, see the sidebar "Installing Windows on a Blank Disk"):

1. Disconnect the server from the Internet, even if it's destined to become a Web server (you can leave the server connected to the local network, as it is presumably placed securely behind a firewall).
2. From within Windows, insert the CD-ROM for the version of Windows you're installing (Windows 2000 Professional, Windows 2000 Server, and so on) and click Install Windows as shown in Figure 5-1. If this screen doesn't appear, launch Setup.exe from the Windows CD-ROM, or Winnt32.exe from the \i386 folder on the CD-ROM.

**Figure 5-1.** *The Windows AutoPlay window.*

3. To install Windows from across a network, launch the Winnt32.exe program on the network drive containing the Windows setup files, and then proceed with Setup normally (see the section [Creating a Distribution Folder](#) later in this chapter for advanced tips on network installations).
4. Choose Install A New Copy Of Windows 2000 (Clean Install), as shown in Figure 5-2, and then click Next to perform a clean install of Windows. This installs Windows into a new folder on the hard disk. (For information on upgrading Windows, see [Chapter 7](#).)

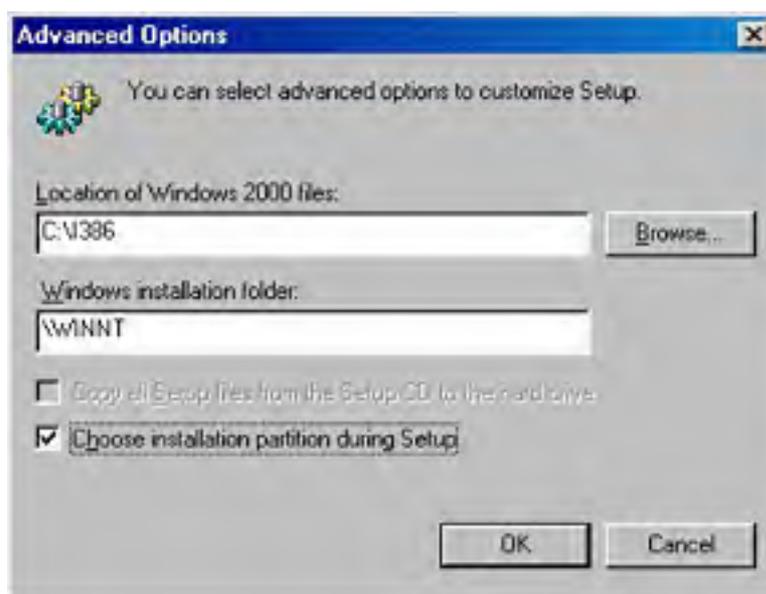

**Figure 5-2.** *Windows Setup.*

5. Read through the licensing agreement, choose the I Accept This Agreement option, and then click Next.
6. Enter the product key from the Windows CD-ROM packaging and then click Next.

7. In the Select Special Options window shown in Figure 5-3, optionally click Advanced Options to change the file copying behavior of Windows Setup. Then use the Advanced Options dialog box shown in Figure 5-4 to change the following settings and click OK when finished:
  - The source for the Windows Setup files (a CD-ROM or network location).
  - The name of the folder into which you want to install Windows.
  - Whether or not to copy all installation files onto the hard disk before restarting Setup (so that the files remain available even if the network source of the setup files becomes unavailable during setup, such as if the network adapter is unsupported by Windows 2000 Server).
  - Whether or not you want to specify the hard disk partition used for Windows.

**Figure 5-3.** The Select Special Options window.

**Figure 5-4.** The Advanced Options dialog box.

8. Click Accessibility Options to optionally enable the use of Microsoft Magnifier and/or Microsoft Narrator during setup for visually impaired users.
9. Click Language Options to optionally install additional character sets. Select the desired languages, click OK, and then click Next.

You can change the language options after installation by using Control Panel.

10. Click Next in the Directory Of Applications For Windows 2000 screen.
11. If prompted, select Yes to upgrade the drive to NTFS and then click Next.
12. Setup then copies the installation files to the computer. After Setup finishes copying files, it restarts the computer and boots for the text-based part of Setup (you might need to temporarily remove the CD-ROM to properly boot into Setup).
13. If you need to load special mass storage drivers (such as drivers for a Small Computer System Interface [SCSI] or RAID controller) or a custom HAL, press F6 when the computer reboots into the text-based part of Setup. To manually specify a different HAL, press F5.

### Real World

#### Installing Windows on a Blank Disk

If you don't have a copy of Windows already installed on the server, you need to boot the system with the Windows CD-ROM. To boot from the Windows CD-ROM, insert the CD into the drive and reboot the system. When prompted, press the any key (just teasing—press a key) to boot from the CD. If Setup doesn't launch automatically, you might need to configure the BIOS boot order to tell the system to use the CD-ROM drive before the hard disk drive.

If you are unable to boot from the CD-ROM or you need to install from a network share, you can use the Windows 2000 Setup boot disks, or you can use a boot disk created with Windows 98—the only solution if you want to install from a network source (although Windows XP and the Windows .NET Server family can create bootable floppy disks, these disks don't contain SmartDrive, making the installation process hours longer than it should be). After booting from the floppy, launch the Winnt.exe program from the \i386 folder on the Windows CD-ROM or network source (the floppy disk needs to have appropriate network drivers loaded to access network shares).

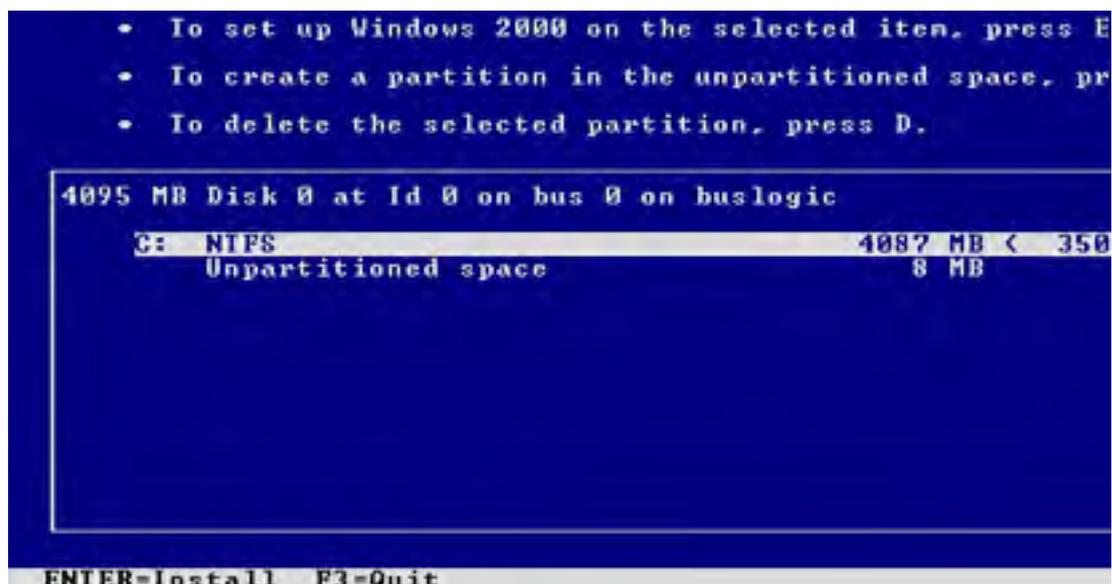

After booting from the Setup boot disks or launching the Winnt.exe program the computer reboots into the text-based phase of Windows Setup, as described in the next section (make sure to eject the floppy disk before the reboot).

14. When the Welcome To Windows Setup screen appears, press Enter to continue with Setup.
15. Read the licensing agreement and then press F8 to continue, if this screen appears.
16. In the next screen (shown in Figure 5-5), you're asked to choose the disk and partition on which you want to install Windows (this screen only shows up if you selected the I Want To Choose The Installation Partition During Setup option in step 6 of this section, or if you booted from the Windows CD-ROM or boot disks). All recognized drives and partitions on the system are displayed, organized by SCSI or Integrated Device Electronics (IDE) ID, and bus number. Select a partition or unpartitioned space by using the arrow keys on the keyboard.

#### Windows 2000 Server Setup

The following list shows the existing partitions and unpartitioned space on this computer.

Use the UP and DOWN ARROW keys to select an item in the li

**Figure 5-5.** Choosing a disk partition for Windows 2000.

If you have a removable drive with a capacity of 829 MB or more, you can install Windows onto a removable disk. This step is recommended only for parallel installations for recovery or testing purposes, not for the primary installation of Windows.

17. To delete the selected partition, press D; to create a new partition, select some unpartitioned free space and press C. If you choose to create a new partition, you are prompted to format the partition using either the NTFS or FAT file system, using either a quick format or a full format. Choose the NTFS Quick format if you know the disk has no bad sectors or history of file corruption, otherwise choose NTFS Full Format and press Enter.

Deleting a partition erases all information on that partition. Don't delete a partition unless all data on the partition is reliably backed up.

18. After you finish modifying the partitions, select the partition on which you want to install Windows, and press Enter.
19. Setup confirms the choice of partitions (and warns you if there's an existing operating system on the partition) and gives you the option of converting the partition to the NTFS file system if it's not an NTFS partition already. If you want to reformat the hard drive, choose the Format With NTFS option and press Enter (this erases all data on the selected partition).
20. Setup checks the hard disks for errors and then copies the appropriate files into the newly created Windows folder (named \Winnt by default). After Setup finishes copying files, it prompts you to remove any floppy disks or CD-ROMs, and then it reboots the system and starts the Windows 2000 Setup Wizard.
21. The Setup Wizard detects and configures the devices installed on the computer. If Setup can't properly detect a device, it displays a Device Configuration dialog box for manual configuration of the device.

The hardware detection part of the setup process is where problems occur most frequently. If the system becomes unresponsive or doesn't progress for a long time (give it 30 minutes to an hour if possible), press the Reset button on the computer to restart the computer. Setup automatically resumes where it left off, and usually completes Setup successfully.

22. After the hardware is detected, you are prompted to configure the regional settings, if you haven't already. These settings affect such factors as keyboard layout and how dates and currency values are displayed. Configure these options as appropriate and then click Next.

You can use the Regional Options tool in Control Panel to change regional settings after you install Windows, so you probably don't need to linger over these dialog boxes.

23. Enter the name of the person the computer will be registered under (if you haven't already), as well as the organization.
24. Enter the product key if you haven't already, and then click Next.
25. Choose the licensing mode in the next window (shown in Figure 5-6), either Per Server or Per Seat. If you choose Per Server, specify how many CALs you purchased. See the sidebar "Licensing" earlier in this chapter for more information on licensing.

**Figure 5-6.** Per Server and Per Seat licensing modes.

You can use the Licensing Control Panel tool after installing Windows to modify the licensing options.

26. Enter the name for the computer in the Computer Name text box. The computer name can contain the numbers zero to nine, uppercase and lowercase letters, and the hyphen character, but no spaces, underscores, or periods. The name should be DNS-compatible and can be a maximum of 63 characters in length, but in the interest of compatibility with pre-Windows 2000 clients, it should be 15 characters or shorter. See the sidebar "Naming Computers" later in this chapter for advice on naming schemes.

27. After entering the computer name, enter an administrator account password up to 14 characters long in the Administrator Password text box, and type it again in the Confirm Password text box. Click Next.

Press Shift+F10 at any time during the Windows Setup Wizard to open a command prompt from which you can do devious things, such as inspect log files or launch a screen capture program.

### Real World

#### Password Security

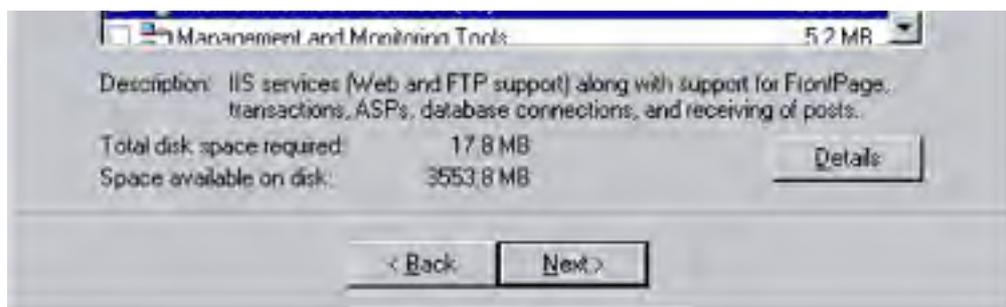

To make the system as secure as possible, always assign a password to the administrator account, preferably a password at least seven characters long and consisting of mixed letters and special characters, uppercase and lowercase. We like to use acronyms for phrases that are meaningful to us, easy to remember, and unlikely to be meaningful or memorable to anyone else, such as Uk,Ur?Ue! (You know, you are what you eat!)

You should also clear the logon history after installing Windows so that would-be hackers must figure out both the password and the user name. Another good precaution after installation is to use the built-in Administrator account to make a second account with full administrative privileges. This account can have a generic name, or you can call it something descriptive. Use it for all the day-to-day administrative work. Assign a special secure password to the built-in Administrator account and rename it from the default. Stash the password and name somewhere safe and relegate that account to semiretirement. Because it's possible to disable any administrator account, including the built-in Administrator account, it's wise to have a backup account. That way, you'll always have an uncontaminated known-to-be-good administrator account to which you can resort, just in case.

28. Use the next window to select the components to install at this time (Figure 5-7), such as Terminal Services (which allows you to remotely administer the service; this is identical to the Windows XP Remote Desktop feature). To install an option, select the check box to the left of the option, or select the option and click Details to modify the subcomponents that you want installed. (For a list of components and their descriptions, see [Appendix B](#).)

Internet Information Services (IIS) is installed by default and opens the server to viruses and security exploitation (although this isn't as big a deal on a private network, there's still no point in opening up more security risks). We recommend that you not install IIS during Windows setup, even if the server is destined to become a Web server, unless the Windows installation files already have the latest service pack applied.

**Figure 5-7.** The Windows 2000 Components window.

29. Review the date, time, and time zone information, make any necessary corrections, and then click Next to configure the network settings.
30. In the Dialing Location window that is displayed if Setup detects a modem, select the country, enter the area code of the phone line (if any), enter any codes needed to get an outside line, and then click Next. (You can choose additional locations or modify the current location by using the Phone And Modem Options tool in Control Panel after you've finished Setup.)
31. If you checked Windows Terminal Services, choose the appropriate mode operation—most likely Remote Administration Mode—and then click Next.
32. Choose the Typical Settings option to install the following commonly used network protocols and services: Client for MS Networks, File and Printer Sharing for MS Networks, and TCP/IP configured to use DHCP (or Automatic Private IP Addressing [APIPA] if no DHCP server is available).
33. To specify your own network settings, choose the Custom option and click Next. Otherwise, click Next and then skip to step 36. Setup displays the default list of networking components, as shown in Figure 58, which you can modify to suit your needs.

**Figure 5-8.** The Networking Components window.

Don't disable NetBIOS over TCP/IP, as doing so disables browsing and causes problems logging onto Windows NT 4 domains. If Windows Internet Name Service (WINS) is used on the network, make sure to enable it if TCP/IP settings aren't obtained from a DHCP server.

34. To install additional components, click Install, select Client, Service, or Protocol, click Add, select the desired component, and click OK.
35. To turn off an installed component, clear the check box next to the component, or select the component and click Uninstall to remove it from the system.
36. To join or create a workgroup, choose the first option in the Domain Membership window shown in Figure 5-9, and type the workgroup name in the Computer Domain text box.

**Figure 5-9.** *The Domain Membership window.*

37. To join an existing domain, click the second option and enter the domain name you want to join in the Computer Domain text box. If you are setting up a new domain, join a workgroup or an existing domain (you'll create the new domain later, as discussed in [Chapter 6](#) and [Chapter 11](#)).
38. Click Next when you're finished configuring the domain or workgroup settings. If you chose to join a domain, a dialog box appears and asks you to enter a user name and password for a user with sufficient permissions to create a new computer account for the server. Enter your user name and password, and then click OK. Setup then logs on to the domain and configures a computer account for the server. See [Chapter 3](#) for more information on domains and workgroups.
39. Setup then installs the components you specified and configures Windows. After Setup finishes this process, it deletes any temporary installation files and then prompts you to remove any CD-ROMs or floppy disks you have in your drives. Click Finish to restart the computer.
40. If any errors occurred during the installation process, Setup displays an error message and asks you if you want to view the Setuplog.txt log file it created. Click OK to do so. Review the file, and then click Close to restart the system.
41. After Setup restarts the computer, the Network Identification Wizard appears. Click Next.
42. Select Users Must Enter A User Name And Password To Use This Computer and then click Next (choosing the other option results in a system that is not secure, at least until this option is turned off), and then click Finish.
43. Lock down the server's security settings, apply the latest service pack and hot fixes, and update Microsoft Internet Explorer before reconnecting the server to the network, if possible. See [Chapter 6](#) for more information on configuring a newly installed server.

## Real World

### Naming Computers

Take a few moments to think about naming conventions before you commit yourself. Many ways exist to create names on the network, from the cute to the whimsical to the sensible. Sometimes system administrators devise arbitrary schemes based on algorithms known only to them. Or they attempt to insert charm into the process of computer naming. Block those impulses!

It's easy for *you* to keep a map of what and where the different clients and servers are on the network, but if you make life hard on users, you pay in the long run. So naming all the domain controllers after Shakespearean characters and naming the client machines after characters in Greek mythology might make sense to you. And it does, of course, have a certain poetic grandeur. But it isn't going to help users figure out that "Cordelia" is the server in Legal and "Goneril" is the one in Production. On the other hand, using "legal\_srv" for the server in the Legal department tells everyone immediately which machine it is.

Try to resist the desire to be cute with your machine names. And at all costs, avoid arbitrary names based on some formula that only you know how to crack.

## Automating Windows Installations

Installing Windows 2000, like installing any operating system, takes a lot of time. Setting up multiple servers can wipe out entire days if you set up each server manually. The time you can save by automating installations for a large number of similar servers far outweighs the occasional hiccups you might encounter.

Before automating installations, run through a couple of manual installations to get a better feel for the installation process. Review the earlier parts of this chapter and pay attention during the installations. Then try using the command-line switches to partially automate Setup. Following that, use the Setup Manager Wizard to create and test the fully or partially automated setup scripts.

Don't feel that you must fully automate all setups. Using automated answer files (setup scripts) can provide significant time savings, but it's important to choose the appropriate level of automation for the particular job. That might involve creating a single answer file that you'll use to deploy hundreds of servers, or it might mean using just one or two command-line parameters to speed up the installation of a single server.

## Using Setup Command-Line Parameters

You can streamline the setup process on a single machine by launching Setup using command-line parameters; you also use command-line parameters to specify an answer file to completely automate Setup.

To use a command-line parameter on a computer with Windows, boot the computer into Windows and open a command prompt window. Then type `[path]\winnt32.exe[parameter]`, substituting `[path]` with the location of the Windows setup files and replacing `[parameter]` with the appropriate parameter or parameters you want to use. Table 5-3 shows the available parameters and what they do. (These are for use with only Winnt32.exe, the 32-bit version of Setup.)

**Table 5-3.** Parameters for Winnt32.exe

Parameter	Function
<code>/checkupgradeonly</code>	Runs a compatibility test on the computer to see whether it has any problems that would interfere with upgrading the OS. Saves a Winnt32.log report in the installation folder for NT upgrades, or an Upgrade.txt report in the Windows folder for Windows 95/98 upgrades.
<code>/cmd:[command]</code>	Runs the command following the <code>/cmd:</code> parameter after the Windows 2000 Setup Wizard completes.
<code>/cmdcons</code>	Enables the use of the Recovery Console at boot time for repairing

	failed installations. Can only be used after Windows 2000 is installed.
<i>/copydir:[folder name]</i>	Names an additional folder to be copied into the folder in which you install Windows 2000 (\Winnt). The folder remains after Setup completes, and additional folders can be copied by using the parameter multiple times. The folder might contain drivers or other files needed after setup.
<i>/copysource:[folder name]</i>	Names an additional folder to be copied into the folder in which you install Windows 2000. The folder is deleted after Setup completes.
<i>/debug[level:filename]</i>	Creates a debug log file with the specified level. The default creates a log file named C:\Winnt32.log with the level set to 2 (Warning).
<i>/m:[folder name]</i>	Specifies the location of a folder containing system file replacements. Setup checks this folder first for files to copy and then checks the installation folder.
<i>/makelocalsource</i>	Tells Setup to copy all installation files to the local hard disk so the files will be available later during the installation if the Windows 2000 CD-ROM or network share is inaccessible.
<i>/noreboot</i>	Tells Setup not to reboot after the initial Windows NT/95/98/2000 file copy phase of Setup is complete. This allows you to run additional commands before continuing.
<i>/s:[sourcepath]</i>	Specifies the location of the Windows 2000 Setup files. (The default is the current folder.) This must be a full path; for example, X:\path or \\server\share\path. To specify multiple paths in which Setup should search for needed files, use multiple /s: parameters. (You can also sometimes speed transfers from a server by specifying the same source more than once.) Setup fails if the first server isn't available.
<i>/syspart:[drive letter]</i>	Specifies a hard disk to which you want to copy the Setup startup files. This disk drive is then made active and Setup stops, allowing you to remove the disk and insert it in another computer. When you boot the new computer, the next phase of Setup automatically starts. You have to use the <i>/tempdrive</i> parameter in addition to the <i>/syspart</i> parameter (both pointing to the same drive).
<i>/tempdrive:[drive letter]</i>	Specifies the drive to which you want Setup to copy its temporary files and install Windows 2000 on. By default, Setup uses the partition with the largest amount of free space.
<i>/unattend</i>	Upgrades the previous version of Windows in unattended mode, taking all settings from the previous installation. The unattend switch may not be used by original equipment manufacturers (OEMs) selling to end users because it explicitly acknowledges understanding and acceptance of the End-User License Agreement (EULA).
<i>/unattend: [num:answer file]</i>	Launches Setup in unattended mode by using the answer file you provide. The <i>num</i> parameter specifies the number of seconds to wait after copying files before restarting the computer, and it works only when running Setup from Windows 2000. You must use the /s: switch to specify the location of the answer file.
<i>/udf:[id,UDF file]</i>	Specifies a uniqueness database file (UDF) to be used to modify an answer file. The ID identifies data in the UDF that should be used in a corresponding section of the answer file. For example, /df:ComputerName,our_company.udf would take the Computer Name from the UDF instead of the answer file. If you don't specify a UDF, you're prompted to insert a disk that contains the \$Unique\$.udf file.

As you can see, many of these parameters piggyback onto other parameters, and pretty soon you can find yourself typing (and sometimes retyping) in long strings at the command prompt. If you end up doing this a lot, create a batch file (a text file with the .BAT extension) containing the setup command and parameters. Then simply launch the batch file instead of typing all the parameters.

To use a command-line parameter on a computer without an existing copy of Windows, boot the computer with a Windows 98 boot disk. Then, at the command prompt, type `[path]\winnt.exe[parameter]`, substituting the location of the Windows Setup files for `[path]`. Table 5-4 shows the available parameters for use only with Winnt.exe, the 16-bit version of Setup.

**Table 5-4.** Parameters for Winnt.exe

Parameter	Function
<code>/a</code>	Turns on Accessibility features during Setup.
<code>/e: [command]</code>	Runs the command following the <code>/e:</code> parameter after the Windows 2000 Setup Wizard completes.
<code>/i:[inf file]</code>	Specifies the filename of the information (.INF) file used for Setup (the default is Dosnet.inf). Do not include the path to the file.
<code>/r:[folder]</code>	Names an additional folder to be copied into the folder in which you install Windows 2000. The folder remains after Setup completes, and additional folders can be copied by using multiple <code>/r:</code> parameters.
<code>/rx:[folder]</code>	Names an additional folder to be copied into the folder in which you install Windows 2000. The folder is deleted after Setup completes.
<code>/s: [sourcepath]</code>	Specifies the location of the Windows 2000 Setup files. (The default is the current folder.) This must be a full path, <code>X:\path</code> , or <code>\\server\share\path</code> . To specify multiple paths for Setup to search for needed files, use multiple <code>/s:</code> parameters.
<code>/t:[drive letter]</code>	Specifies the drive to which you want Setup to copy its temporary files. By default, Setup uses the partition with the most free space.
<code>/u:[answer file]</code>	Launches Setup in unattended mode using the answer file you provide. You must use the <code>/s:</code> switch to specify the location of the answer file.
<code>/udf:[id,UDF file]</code>	Specifies a uniqueness database file (UDF) to be used to modify an answer file. The ID identifies data in the UDF that should be used in a corresponding section of the answer file. For example, <code>/udf:ComputerName,our_company.udf</code> would take the Computer Name from the UDF instead of the answer file. If you don't specify a UDF, you're prompted to insert a disk that contains the <code>\$Unique\$.udf</code> file.

## Creating a Distribution Folder

A distribution folder (sometimes called a source directory) is a shared folder on a server that contains the `\i386` folder (or `\ia64` folder for Intel Itanium installations) from the CD-ROM and any device drivers or other files that you add to support the specific systems.

You can create this folder manually, or you can do it while creating an answer file using the Windows Setup Manager (discussed in the next section). To create a distribution folder manually, follow these steps:

1. Connect to the volume where you want to create the distribution folder. Copy the `\i386` folder from the Windows 2000 CD-ROM to the volume on which you want to create the distribution folder.
2. Create a subfolder named `$OEM$` in the `\i386` folder for any additional drivers or programs that will be preinstalled on the systems. All files and folders in this folder are copied into the temporary setup folder during installation.
3. Create any additional subfolders needed for the installations. Table 5-5 describes the special folders that you can create for use by Setup.

With Windows 2000, Windows XP, and the Windows .NET Server family, you can apply service packs to distribution folders. This not only eliminates the service pack step of the setup process, but it also ensures that any time a computer needs original Windows files from the distribution folder, it receives up-to-date files. (So service packs no longer have to be reapplied after changing the system configuration.) To upgrade a distribution folder, see the next section.

**Table 5-5.** Subfolders you can create to store extra files

Folder	Description
\\$OEM\$\textmode	<p>The folder in which you place any hardware-dependent files for use while loading Windows 2000 Setup and during the text-mode phase of Setup. These files include any OEM HALs you might use, as well as updated SCSI, keyboard, video, and pointing device drivers.</p> <p>Also include the Txtsetup.oem file in this folder to control the loading and installation of these files. To create the Txtsetup.oem file, create a normal text file and list the filenames of all files in this folder. (Be sure to include this file and all files mentioned in the Unattend.txt file, under the [OEMBootFiles] section.)</p>
\\$OEM\$\\$\$	<p>The folder that holds any new system files or files that replace existing system files. These files are copied into the various sub-directories that are created in the Windows 2000 system folder (\Winnt).</p> <p>This folder must match exactly the structure of the Windows 2000 system subfolders for those folders in which you want to add or replace system files. For example, to copy new or replacement into files the %windir%\System32 folder, create an \\$OEM\$\\$\$\System32 folder.</p>
\\$OEM\$\\$1	<p>The folder in which you place files that you want copied to the drive where Windows 2000 will be installed. Equivalent to the %systemdrive% environment variable and can be used to permit drive letters to be changed without causing problems for applications that point to a hard-coded driver letter. You can also create subfolders here for the files and the entire folder structure will be copied to the system drive.</p>
\\$OEM\$\drive_letter	<p>The folder that specifies additional files and folders to be copied into the root folder of the named drive. You will have one entry for each drive having additional files. For example, the files located in the \\$OEM\$\C folder are copied into the root folder of the C drive during the text-mode phase of Setup. Any subfolders of the \\$OEM\$\C folder are also copied.</p> <p>All files must use short (8.3) filenames, but you can rename them after installation by including them in the \$\$Rename.txt file.</p>

The \Display and \Net folders that were used in the \\$OEM\$ folder in Windows NT 4 are no longer used in Windows 2000. You can also place the \\$OEM\$ folder outside of the distribution folder if you place the path (file or Uniform Naming Convention [UNC]) to the \\$OEM\$ folder after the OEMFILES\_PATH key in the answer file.

## Applying Service Packs to a Distribution Folder

To update a Windows distribution folder to the latest service pack, allowing Windows to be installed with the latest service pack already applied, use the following procedure (you can also integrate hot fixes and security updates into the distribution folder, but it's a nuisance; instead add the hot fixes to an answer file, as described later in this chapter):

1. Extract the service pack to the hard disk. For example, to extract Windows 2000 Service Pack 3, open a command prompt, switch to the folder storing the service pack, and then type the following command: `w2ksp3.exe -x`.
2. When prompted, enter the path of the folder in which you want to temporarily store the extracted service pack (for example, `e:\w2ksp3`).

3. Type the command `e:\w2ksp3\i386\update\update.exe -s:e:\Win2000`, substituting `e:\w2ksp3` with the folder storing the extracted service pack, and `e:\Win2000` with the path of the Windows distribution folder you want to update. (Make sure that the Windows install files are located in the `\i386` folder; if they're not, create an `\i386` folder and move them there.)

Don't update your existing Windows installation share if there are users currently performing installations of Windows using the network share. Bad things might happen, such as failed or corrupted installs that create unstable or nonworking systems.

You can't apply a Windows 2000 service pack to Remote Installation Services CD-based images. To work around this, copy the original Windows CD files to the RemoteInstall folder, apply the service pack, and then add the image to the RIS Server. See Microsoft Knowledge Base article Q258868 for updated information on this issue.

When you run the Update.exe file to update a Windows distribution share with the latest service pack, it creates a Svcpack.log file in the systemroot of the computer you ran Update.exe from. If you want to perform more service pack installations from the same computer, you should rename this log file before performing them.

### Adding Hot Fixes to a Distribution Folder

Microsoft makes operating system hot fixes and security updates available in between service packs. Although hot fixes and security updates are technically different beasts, the way they are deployed is the same, so we'll cover them at the same time. With that said, you should only apply hot fixes on an as-needed basis because they're not regression tested and might introduce system instabilities (make sure you test them out in a nonproduction environment). Security updates should be applied more liberally, although you should still take the time to verify that the update applies to the environment, and test them out before deploying them.

You can download hot fixes and security updates from Microsoft's Security Web site (<http://www.microsoft.com/security/>), or from Microsoft Corporate Windows Update (<http://corporate.windowsupdate.microsoft.com>). We recommend that you register with Microsoft to automatically receive security bulletins by e-mail so that you'll be on top of new patches when they come out.

Most companies deploy hot fixes and security updates using Microsoft Systems Management Server (SMS), Group Policy's Software Management And Installation feature (discussed in [Chapter 25](#)), or the new Corporate Windows Update service (or the standard Windows Update if you don't mind manually installing on each system). Although you can also integrate hot fixes and security updates into a distribution folder that is integrated with the latest service pack, it's a nuisance (see the Spdeploy.doc file included with the service pack for the procedure). An easier solution is to use the following steps to copy the hot fixes into the distribution folder and add them to an answer file:

1. Add the following line to the [Commands] section of the Cmdlines.txt file, either using the Setup Manager Wizard (using the Additional Commands screen, which lists commands to be run at the end of an unattended setup), or manually in the [Commands] section, where Q123456.exe is the name of the hot fix or security update (named after its associated Knowledge Base article):

```
Q123456.exe -q -m
```

2. Rename the hot fix into 8.3 file format, and copy the hot fix executable file into the `i386\%OEM%` folder, along with the Unattend.txt and Cmdlines.txt files. If you're using the Setup Manager Wizard, you can use the Copy Additional Files And Folders screen to add the hot fix to the Temporary Files folder of the distribution folder (`\i386\%OEM%`).

Hot fix chaining (installing multiple hot fixes with a single reboot) is supported in Service Pack 3 and later. Previously you had to reboot after each hot fix installation, or run the Qchain.exe tool after installing the hot fixes before rebooting. We should caution you, though, that Microsoft's official recommendation is still to reboot after every hot fix installation, even if you're using post-SP3 hot fixes or Qchain.exe.

Only install hot fixes released after the service pack version you're deploying. For example, if you're deploying Service Pack 3 using an integrated install, only add hot fixes that are labeled sp4 (which means that they're post-Service Pack 3). Installing hot fixes that are included with the service pack breaks the distribution folder.

## Installing Plug and Play Drivers in the Distribution Folder

To configure the distribution folder with additional Plug and Play (PnP) drivers, follow these steps:

1. Create a subfolder in the `\$OEM$\$1` folder with a name containing no more than eight characters.
2. Inside the subfolder you created, you can make additional subfolders to categorize the devices; for example, you might have the following directories:

```
\$OEM$\$1\Company\Net
```

```
\$OEM$\$1\Company\Video
```

```
\$OEM$\$1\Company\Sound
```

3. Copy the drivers and .INF files into the appropriate subfolder.
4. Add the appropriate lines to the answer files:
  - **Standard answer file users** If you placed all the drivers in the single folder (for example, `\$OEM$\$1\Drivers`), add the following line to the [Unattended] section of the answer file (Unattend.txt or Sysprep.inf):

```
OEMPnPDriversPath = \Drivers.
```

If you created multiple subfolders for the drivers, add them to the answer file in the following format, each folder reference separated by a semicolon:

```
OEMPnPDriversPath = Drivers\Nic;Drivers\Video;Drivers\Sound
```

- **Remote Installation Services (RIS) users** Add or modify the following lines to the [Unattended] section of the default template for the desired image (Ristndrd.sif):

```
OemPreinstall = Yes
```

```
OEMPnPDriversPath = Drivers\Nic;Drivers\Video;Drivers\Sound
```

Leave the drive letter out of the paths. The system drive is automatically added to the paths.

5. If you're installing new drivers for a RIS-based operating system image, restart the BINL service on the RIS server after copying the files into the distribution folder. To do so, enter the following commands at a command prompt:

```
net Stop "boot information negotiation layer"
```

```
net Start "boot information negotiation layer"
```

SysPrep and RIS installations postpone installing devices with unsigned drivers until an administrator logs onto the computer. To avert this (something we don't usually recommend), add the `DriverSigningPolicy = Ignore` line to the [Unattended] section of the answer file. Newer versions of drivers that ship with Windows are installed only if they're signed.

## Installing OEM Drivers in Remote Installation Preparation Images

Although it's tempting to add OEM drives to a Remote Installation Preparation (RIPrep)-based image by installing them on the source computer before running the RIPrep program on it, this doesn't work because RIPrep images need to be able to adapt to a wide variety of hardware. Therefore, we recommend that you use the following procedure to add drivers to RIPrep-based images:

1. Before running the RIPrep process (described in [Chapter 25](#)), create a folder named SysPrep on the C drive of the source computer.
2. Create a C:\Drivers folder to hold OEM drivers, and create any necessary subfolders, such as C:\Drivers\Video or C:\Drivers\Sound.
3. Create a Sysprep.inf file and place it in the SysPrep folder.
4. Add the following lines to the Sysprep.inf file:

```
[Unattended]
```

```
OEMPnPDiversPath = Drivers\Nic;Drivers\Video;Drivers\Sound
```

5. Use Device Manager to remove any devices for which you're installing updated or new drivers. Also remove any unknown devices.
6. Run Riprep.exe from the RIS server's network share, as described in [Chapter 25](#).
7. Stop and restart the BINL service on the RIS server by typing the following commands:

```
net Stop "boot information negotiation layer"
```

```
net Start "boot information negotiation layer"
```

## Installing Mass Storage Drivers

If the hard drive or installation source is attached to a device for which Windows doesn't have drivers, such as a new SCSI adapter or network card, you've got a problem. When performing a manual installation, you can always press F6 at the beginning of text-mode setup to install new mass storage drivers, but this option isn't available with unattended installations. To get around this, you need to copy the mass storage drivers to the distribution folder using the following technique:

1. Open the \i386 folder of the distribution folder.
2. Create a subfolder named \Textmode.
3. Copy the storage drivers into the \Textmode folder. These files should include at least one .SYS file and the Txtsetup.oem file.
4. Edit the Txtsetup.oem file using Notepad, and in the [disks] section, replace any floppy drive references, backslashes (\) or other path references with periods. For example, change the following line:

```
d1 = "Windows 2000 Driver Set 1.01", \win2kdisk1, \win2k\ultra160\
```

to read as follows (the path is replaced with a period):

```
d1 = "Windows 2000 Driver Set 1.01", \win2kdisk1, .
```

5. In the answer file, add the following lines:

```
[MassStorageDrivers]
```

```
"scsi controller string from txtsetup.oem" = "OEM"
```

For example:

```
[MassStorageDrivers]
```

```
"Adaptec Ultra160 Family PCI SCSI Controller (29160, 39160, etc.)" = "OEM"
```

6. Add or modify the [Unattended] section of the answer file to include the following line:

```
OemPreinstall = Yes
```

## Converting Short Filenames Back to Long Filenames

The Windows 2000 text-mode setup requires the use of MS-DOS 8.3 file formats because the program is based on a 16-bit MS-DOS implementation. Thus, all files that are included in the distribution folder need to have MS-DOS-compliant short names. However, Setup converts them to long names with the use of a renaming file. To create a renaming file, follow these steps:

1. Open Notepad.
2. Using brackets, type in the path to the subfolder containing the files you want to rename (leave blank or use the backslash character [\] for the root folder).
3. Underneath the bracketed heading, enter each short filename you want to rename (not enclosed in quotes) followed by an equals sign and then the long filename in quotes.
4. Repeat step 3 with any additional subfolders in which you have files or folders that need to be renamed. A sample renaming file is shown:

```
[media]
filenm1.txt = "Your long filename here.txt"
ding.wav = "Really loud and annoying ding.wav"
whiz.drv = "Whizbang Deluxe Video.drv"
[images]
desktpl.bmp = "corporate logo.bmp"
desktpl2.bmp = "division logo.bmp"
```

5. Save the file as \$\$rename.txt in the distribution folder prior to running Setup.

## Creating Answer Files Using the Setup Manager Wizard

When Windows is installed, the setup program pauses several times along the way, waiting for input from the user. Answer files are simple text files that supply the information a user would normally enter, thus automating most of the installation process.

Windows 2000 ships with a handy tool, Setup Manager, which graphically walks you through the creation of answer files. To use this tool, follow these steps:

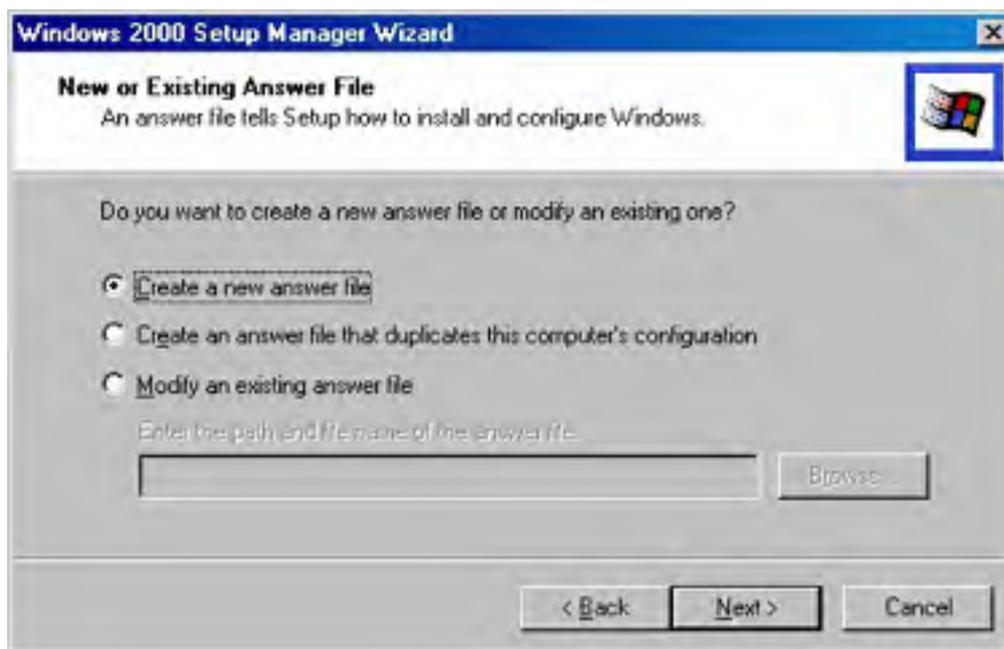

For real labor savings, set up a typical server or client and then let the Setup Manager Wizard build an answer file that duplicates the configuration of the machine. Then use the answer file to set up multiple versions of the typical machine.

### More Info

The Windows Setup Manager walks you through the most important parameters in an answer file, but there are other parameters that might be useful to you. For detailed information on each parameter, open the Deploy.chm file (help file) located in the same Deploy.cab file in which Setup Manager is located.

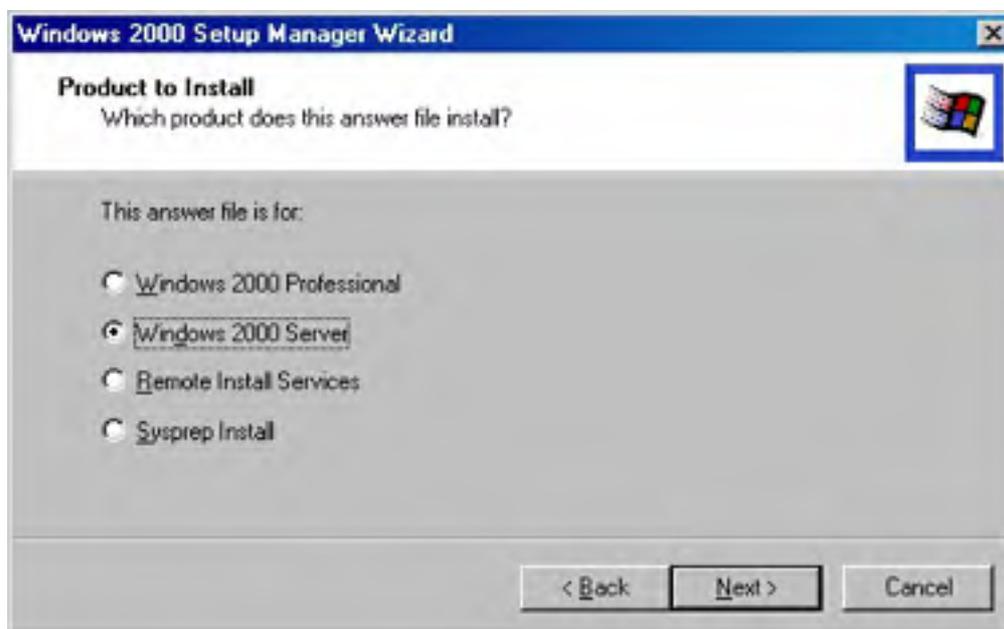

1. Insert a Windows 2000 CD-ROM in the computer and navigate to the \Support\Tools folder.
2. Extract the contents of the Deploy.cab file to a location on the hard drive.
3. Launch the Setupmgr.exe file from the location on the hard drive to which you copied the contents of the Deploy.cab file.

4. Click Next to begin using the wizard, and then choose the option to create a new answer file (Figure 5-10). The Windows 2000 Setup Manager Wizard walks you through creating or modifying answer files you can use to automate the installations.

**Figure 5-10.** The Windows 2000 Setup Manager Wizard's New Or Existing Answer File screen.

5. Choose the type of installation for which you want to create an answer file by choosing the appropriate installation type, as shown in Figure 511. Click Next.
6. Select the product for which you are creating an answer file.

**Figure 5-11.** The Windows 2000 Setup Manager Wizard's Product To Install screen.

7. Choose the level of interaction that will be available during Setup (see Figure 5-12), and then click Next (see the sidebar "Choosing and Interaction Level" for more information).

Figure 5-12. The Setup Manager Wizard's User Interaction Level screen.

## Real World

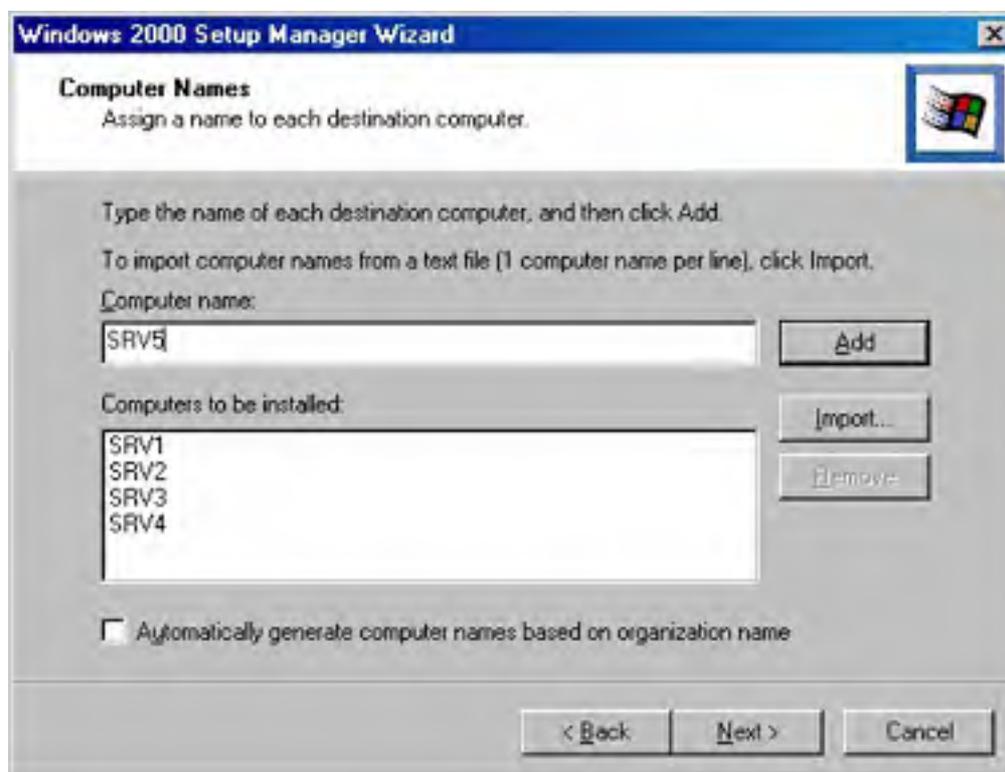

### Choosing an Interaction Level

When determining the level of user interaction you want to require, you have several choices, and the choice you make determines how much the person running the installation will need to attend to the process. Here's a more detailed explanation of the interaction levels:

- **Provide Defaults** Uses the information in the answer file as default answers during the Windows 2000 installation. The user still has to confirm the defaults or make changes as the installation progresses.
- **Fully Automated** Completely automates Setup by using the settings you specify in the provided answer file. This option is best for quickly setting up multiple systems with identical configurations. If any settings don't work properly (such as might happen if the answer file provides a computer name that's already in use), the installation will fail.
- **Hide Pages** Automates the parts of Setup that you provide information for, but it requires the user to supply any information you didn't include in the answer file. Use this option to set up a system in a specific way, while still allowing the user some limited customization options. (The user sees only the parts of Setup that aren't covered in the answer file.)
- **Read Only** Hides the parts of Setup you provide information for, just like the Hide Pages option. However, if a window with only partial answers is supplied in the answer file (and therefore not hidden from the user), the user can complete only the unanswered portion of the window. Settings provided in the answer file can't be changed during installation.
- **GUI Attended** Automates the text-based portion of Setup. The person running Setup supplies answers for the Windows 2000 Setup Wizard. Use this level when you want to automate the text-based portion of Setup and allow the person running the installation to provide the settings during the GUI portion.

8. Supply the name and organization you want to use, and then click Next. (The dialog box says that if you leave the boxes blank, no name or organization will be specified in the answer file—but for a fully automated answer file, a name and organization are required.)
9. Specify the Licensing mode the servers will use, and, if necessary, how many concurrent connections you have licenses for; then click Next. See the section entitled [Gathering Network Information](#) earlier in this chapter for more information about licensing modes or any other setting in the Windows 2000 Setup Manager.
10. Create a list of computer names to use for the systems, as shown in Figure 5-13. Enter a computer name in the Computer Name text box, and then click Add. The Windows 2000 Setup Manager Wizard takes the names (if you have two or more) and creates a UDF that the setup program then queries for computer names, using each name only once. Make sure that the computer names are both DNS-compatible and NetBIOS-compatible if you want to maintain compatibility with pre-Windows 2000 clients.

Continue entering all the computer names necessary for the number of systems you plan to set up by using this answer file. To remove a name from the list, select the name, and then click Remove. To import a list of names from a text file, click Import. You can select Automatically Generate Computer Names Based On Organization Name to have Setup do it for you—the names will include a few letters from the organization's name but will be otherwise random and unhelpful. When you have finished, click Next.

**Figure 5-13.** The Setup Manager Wizard's Computer Names screen.

11. Use the next screen to specify how administrator account passwords for the systems are to be chosen.

The answer file that the Windows 2000 Setup Manager Wizard creates is an unencrypted text file. If you specify an administrator account password in the answer file, make sure that after installation, you change the administrator account password to something more secure.

12. Select the display settings for the computer to use during Setup in the next screen and then click Next.

Although Windows' default 640 by 480, 60 Hz, 16-color display is pretty horrific, you should use extreme caution here. If you set the screen area (resolution), colors, or refresh frequency too high for some systems, you could damage their monitor or leave them (temporarily) inoperable. We find that 800 by 600, 72 Hz and High Color (16 bit) is a safe setting that's also usable for end users, although if you're sure the hardware is up to it, you might increase the color depth to Full Color (24 bit).

13. Choose the Typical Settings option to install TCP/IP, enable DHCP, and install the Client for Microsoft Networks and File and Printer Sharing for Microsoft Networks on the systems, or choose the Custom Settings option to specify how you want to configure the systems' network settings. Click Next.
14. In this screen you have the option to join the computer or computers to a domain or a workgroup. If the systems are going to be joining a workgroup, choose the Workgroup option and type in the appropriate workgroup name.

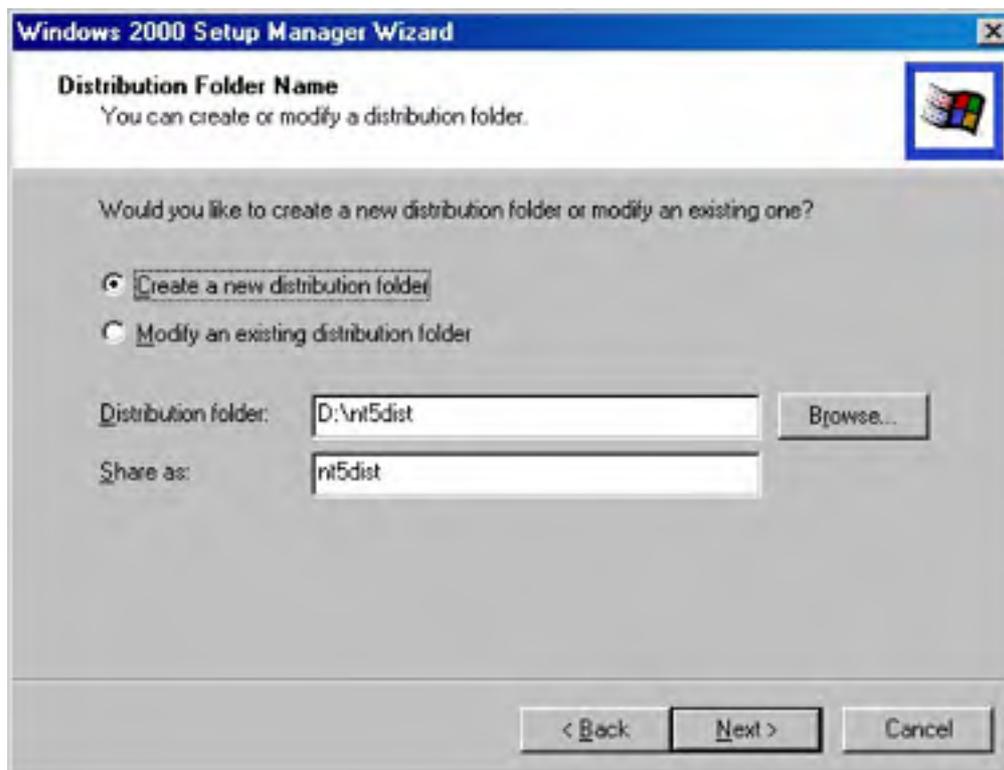

If the systems are going to be joining a domain, choose the Windows Server Domain option. Type the Windows Server domain name in the text box provided. To create an account for the computer in the domain, click the Create Computer Account In The Domain check box and supply a user name and password. The user name and password must be for a user account that has sufficient administrative privileges to authorize the creation of a computer account. Click Next to continue.

If you enter a user name and password with sufficient privileges to create a computer account in the domain for the new systems, you are introducing a security risk because the answer file stores all passwords in a plain text file with no encryption. The best solution is not to include administrative account passwords in an answer file, but if you feel you must, guard the file carefully and make sure you delete it after installation is completed.

15. In the next screen, specify the time zone the systems will use. Click Next.
16. At this point, sufficient information has been garnered to create the answer file, but you can specify additional settings as well. If you choose to not edit the additional settings, skip ahead to step 23. Otherwise, select Yes, Edit The Additional Settings and click Next.
17. Choose Regional Settings, where you specify (or decline to specify) the character set for the language and region where the computer will be used. This setting determines default views for times, date, currency, and other characters specific to a region.
18. In the Languages screen, select any additional language groups you want to use. Click Next.
19. In the Browser And Shell Settings screen, select the customization method for Internet Explorer. You can accept the defaults, use a custom autoconfiguration script created with the Internet Explorer Administration Kit, or specify the individual proxy and default home page settings.
20. In the Installation Folder screen, choose the folder into which you want to install Windows 2000. Use the default folder and install into a folder named \Winnt unless you have a specific reason to do otherwise.
21. Specify any network printers to install and then click Next.
22. Specify any commands to run the first time a user logs on and then click Next.
23. Choose Yes in the Distribution Folder screen to create a distribution folder, otherwise choose No. Click Next to move on.

24. If you choose to create a distribution folder from which the system will install Windows 2000, you'll be asked to specify whether a new folder should be created or an existing one modified (Figure 5-14). If you're going to install Windows 2000 from a CD-ROM, you won't need a distribution folder, so choose No.

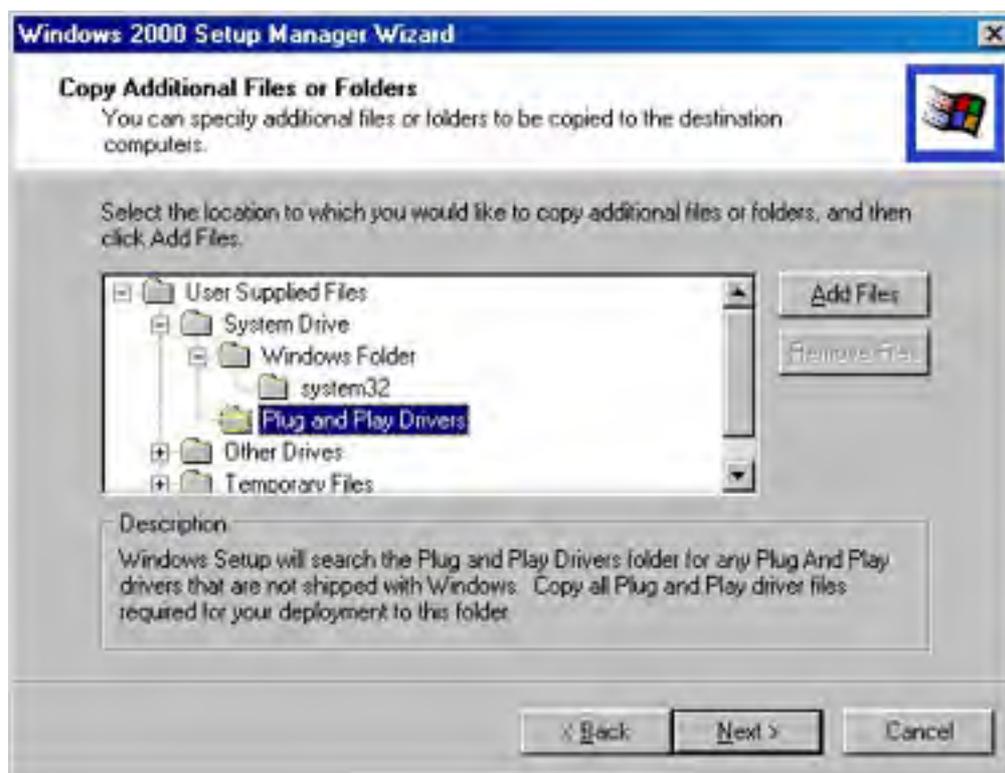

**Figure 5-14.** The Setup Manager Wizard's Distribution Folder Name screen.

Setup Manager, by default, creates a distribution folder named \Win2000dist. Unfortunately, it doesn't create an \i386 subfolder, which causes integrated service pack installations to fail. Therefore, we recommend that you create an \i386 folder inside the distribution folder, and then move the contents of the distribution folder into the new \i386 folder.

25. To install mass storage drivers (typically drivers for newer SCSI adapters or Fibre Channel controllers), click Browse in the Provide Additional Mass Storage Drivers screen. You'll be prompted for the location of the drivers.
26. Specify a replacement HAL if one is needed. Click Browse and locate the HAL that the system manufacturer provided.
27. Enter any commands to run at the end of Setup in the Commands To Run text box, clicking Add after typing each command. Note that you can't run commands that require a user to be logged in. You can remove a command from the list by selecting the command and clicking Remove.
28. To customize the installation, you can include a logo or background to display during setup. A logo bitmap can be specified to run in the corner during the GUI portion of the installation. A background bitmap must be 640 by 480 with 16 colors and will display as the background during installation.
29. In the Copy Additional Files Or Folders screen, you can select files or folders to be automatically copied to the destination computer. The list can be expanded to a variety of folders. Select a folder and click Add Files. Then browse for the file or folder to add. Figure 5-15 shows the expanded list after a file has been selected for the \Windows folder on the destination computer.

If you have additional drivers for Plug and Play devices that aren't included with Windows 2000, copy them to the \Plug and Play Drivers folder on the system drive. Windows 2000 Setup searches this folder for drivers it couldn't locate.

**Figure 5-15.** The Setup Manager Wizard's Copy Additional Files Or Folders screen.

30. Type in the name and location for the answer file, and then click Next. Click Finish to end the wizard. The Setup Manager Wizard creates a batch file (with the same name as the answer file) that, when launched, starts Setup and uses the contents of the answer file. You can use this batch file or launch Setup with the appropriate parameters, including the parameter pointing to the answer file. (See Tables 5-3 and 5-4.)

If you created an answer file automating a CD-based installation, rename the Unattend.txt file Winnt.sif, place it on a floppy disk, and insert the floppy disk right after the computer boots from the Windows 2000 CD.

The batch files that Windows 2000 Setup Manager Wizard creates use the 32-bit version of Setup. If you don't have a 32-bit version of Windows on the machine where you're planning to install Windows 2000, modify the batch file to use the 16-bit Setup file by deleting the 32 from the third to the last line of the file. Also change the `/unattend:` parameter in the second to last line to `/u:`.

## Using SysPrep to Clone Your Computer

Although creating answer files for running Windows 2000 Setup in an automated fashion is very convenient and can save a lot of time for administrators, you can go a step or two further than that under the right circumstances.

One way to further automate the setup process for a new machine is to "clone" an existing system. (One can also use Remote Installation Services in combination with IntelliMirror to achieve similar results, as discussed in [Chapter 25](#).) The primary advantage of cloning a system is installation speed: a SysPrep-created disk image can usually be installed 45 to 60 minutes quicker than a normal installation.

Cloning works like this: First, install Windows and all of the applications you need on a single machine that is identical or very similar to the many machines on which you want to deploy Windows. Then prepare this system for cloning using SysPrep (which is available on the Windows CD) to clear out the SID and other computer identity information. Clone the configuration using a third-party disk-imaging program, such as PowerQuest's Drive Image or Norton Ghost, which copies and compresses the disk image to a network share. You can then boot up a blank system using the floppy disk created by the disk-imaging program, copy and uncompress the cloned disk image onto the new system, and be up and running in far less time than would be required to perform even a fully automated operating system and application installation.

However, this solution has some problems. First, the systems need to be fairly similar for the disk images to work on them. The computers don't have to be exactly the same because Windows leverages Plug and Play to detect changes to most system components. However, the systems do need to have identical mass storage controllers (SCSI controller or IDE chipset), as well as share the same HAL—no mixing ACPI systems with non-ACPI systems or uniprocessor systems with multiprocessor systems. Also, this process doesn't work for domain controllers, unless you script the DCPROMO process into the disk image.

Covering in detail how to use SysPrep and disk-imaging tools to mass deploy preconfigured computers is outside the scope of this book, but we can give you a taste of how it works. Thoroughly investigate these tools and experiment with them in a test environment before installing Windows throughout your organization using this procedure. The following steps summarize how to clone a system:

1. Install and configure Windows 2000 on the sample system.

Because a SysPrep-created operating system image can't be installed on a disk partition smaller than that on which the image was created, we recommend that you install Windows into a partition just large enough for Windows and any necessary applications. The destination computer's hard disk will be partitioned to the same size as the source computer's partition, but you can use the ExtendOemPartition entry in the Sysprep.inf file to extend the destination computer's system partition to fill the hard disk.

2. Install and configure any applications you want to deploy to *all* systems using this drive image.
3. Run the SysPrep program to remove all identity information from the system.
4. Clone the system using a third-party disk-imaging program, and save the disk image to the desired network share. The system you clone will need to be rebooted and run through the mini-Setup Wizard (see step 6) before it can be used again as a normal system. Use a floppy disk to boot the system you want to install the drive image onto and connect to the network share containing the drive image.
5. Use the drive image's client tools to expand the image file onto the new system's hard drive.
6. Reboot the system. A Windows 2000 mini-Setup Wizard runs, detecting any additional Plug and Play devices and hiding any missing devices. The wizard generates a new SID, and the system is then fully functional. (To force the mini-Setup Wizard to perform a full PnP detection process to eliminate rather than hide any missing devices, run SysPrep with the /PnP switch.)

You can optionally provide an answer file to modify individual machines' system configurations without re-creating the disk image. To do this, create an Unattend.txt file as you would normally, rename it Sysprep.inf, place it on a floppy disk, and insert the floppy disk right before the mini-Setup Wizard is launched.

## Troubleshooting Installations

In most cases, installing Windows 2000 is a relatively painless process; however, when Setup fails for some reason or another, life gets more difficult. Fortunately, most installation problems are easily solved. The most common problems are covered here. Additional troubleshooting procedures can be found in [Chapter 38](#).

### More Info

You can find additional troubleshooting help either in the Windows 2000 Help System's troubleshooters (admittedly not much good unless you have access to a functioning Windows 2000 machine) or in the Microsoft Knowledge Base, available online through <http://support.microsoft.com>.

## Setup Freezes or Locks Up

Sometimes Windows 2000 Setup inexplicably locks up during the installation process. If you receive a Stop Error message, write it down and consult either the Stop Errors troubleshooter in Windows 2000 Help or Microsoft technical support.

In general, these failures are intermittent and don't come with anything as helpful as an error message. First reboot the system by pressing Ctrl+Alt+Del. Do this repeatedly, if necessary. If you get no response, press the Reset button on the computer or turn the system off, wait 10 seconds, and then turn it back on. If you see a Boot menu, choose the Windows 2000 Server Setup option to allow Windows 2000 Setup to attempt to continue with its installation. If no Boot menu appears, launch Setup again. In either case, don't choose to repair the installation, but instead choose to continue with Setup.

Setup usually detects that an error occurred with its last attempt to install Windows 2000 and compensates by using a safer method of installation. If Setup hangs or stops responding again, repeat this process. Sometimes, Setup hangs multiple times before it finishes installing Windows 2000, so be persistent. If installation freezes at a particular part of Setup, try choosing simpler setup options, if applicable. For example, leave out optional Windows components.

Other procedures you can use to fix setup problems are as follows:

- Disable the system cache (processor cache) in the BIOS, and then run Setup again. Consult the hardware documentation for information on the correct procedure to do this. After Setup is complete, enable the cache again to avoid a significant performance loss.
- Try adding a wait state to the RAM in the system BIOS. This can help with partially faulty RAM chips. (However, if this server is important—and what server isn't?—plan on replacing that iffy RAM before doing any critical work on the machine.)
- Verify that the RAM modules are manufactured by the same company and are of the same speed and type. Although this isn't a necessity, it can often eliminate problems.
- Switch the order of the RAM modules, or remove some modules and try installing them again.
- Test the RAM modules for faulty RAM chips with a third-party software program. Replace any faulty modules and run Setup again.
- Check the computer for an MBR virus by booting it from a floppy disk that has been checked for viruses, and then run a virus-checking program and scan the drives for any viruses. If you find any viruses, clean them from the system and run Setup again.

### Real World

#### ACPI BIOS Compatibility Problems

If Setup consistently freezes during the Windows-based Setup Wizard and the system has an older ACPI-compatible BIOS (dated January 1, 2000 or earlier), the BIOS may not function in ACPI mode with Windows. The freezes might happen at any time during the Setup Wizard, although they most frequently happen during the device detection phase. If you suspect the BIOS isn't working properly with Windows, download the latest version from the system vendor.

If you still have trouble, or if no updated BIOS is available, try disabling ACPI during Setup by pressing F5 at the beginning of the text-mode phase of Setup, right after it prompts you to press F6 to install third-party storage drivers. If this doesn't solve the setup problems, you don't have a problem with the ACPI support in the BIOS (ACPI support can only be added back by reinstalling Windows, usually by a same-version upgrade).

You can also manually enable or disable ACPI support after the file copy phase of Setup completes, right before the computer reboots into the Windows Setup Wizard. (Sometimes you can do this after the system freezes during the Setup Wizard.) To force Windows to enable or disable ACPI support, follow these steps:

1. After the text-mode phase of Setup completes but before Windows reboots into the Setup Wizard, go to a command prompt.
2. Type `attrib -r -s -h c:\txtsetup.sif` at the command prompt.
3. Open the `c:\Txtsetup.sif` file using the edit command or another text editor and search for "ACPIEnable=".
4. To force ACPI support to be enabled, which sometimes fixes setup problems, change the "ACPIEnable=" value to 1.
5. To disable ACPI support, change the "ACPIEnable=" value to 0.
6. Save the file and reboot into the Windows Setup Wizard.

Again, if any of the steps you take reveal questionable hardware, replace the hardware before you rely on the computer to store important data or provide critical functions to users.

## Setup Stops During File Copying

If Setup locks up while copying files, you might have a problem with IDE drive configuration. Try one of these solutions:

- Reboot the machine using Ctrl+Alt+Del or Reset, and go into the system BIOS. Verify that the IDE controllers are enabled and configured properly. Make sure that any IDE hard disks or CD-ROMs are detected properly. (You might have to reboot the system and watch the display to verify this because often the drives aren't displayed inside the BIOS.)
- Check the physical jumper settings on the drives to make sure that they are properly configured to have one master and a maximum of one slave per IDE channel.
- If the CD-ROM drive is on the same channel as the hard disk, move it to the secondary channel and configure it to master.
- Try lowering the data transfer rate for the drives; for example, configure the drives to use PIO mode 2 instead of Ultra DMA mode or Ultra 66 transfer mode.
- Check to make sure that the drives are cabled correctly and that the cables aren't faulty.
- Check the hardware settings to make sure that the hard disk controller isn't conflicting with another device. Try removing all cards from the computer except for the display card and SCSI adapter (if you're using a SCSI drive), and run Setup again. If Setup succeeds, add the cards one by one after installation, and use the Hardware Wizard in Windows 2000 to configure the devices and troubleshoot any hardware conflicts you encounter.

Windows 2000 provides a variety of tools you can use to boot a system that doesn't want to start, including the Safe Mode and Last Known Good Boot options, as well as the Recovery Console, which allows you command-line access to an NTFS or FAT drive that won't boot (see [Chapter 38](#) for more information).

---

If none of this helps, try the recommendations in the previous section or consult the Windows 2000 Knowledge Base.

## Previous OS Will Not Boot

When you install Windows 2000 on a computer that's already using an operating system and you choose not to upgrade, Setup creates a dual boot so that you can select which operating system you'd like to use at boot time.

If the computer never displays the Windows 2000 Loader menu that allows you to choose the previous operating system, the problem is most likely one of two issues: either the Boot.ini file has a timeout set to 0 (and thus doesn't display the Boot menu), or the MBR was overwritten during Setup, preventing you from booting the previous operating system even if you have the proper entry in the Boot.ini file.

## Changing the Default Operating System and Boot Times

To change which operating system Windows boots by default, as well as to control how long Windows displays a choice of operating systems at boot time, follow these steps:

1. Double-click the System icon in the Windows Control Panel.
2. Click the Advanced tab, and then click Startup And Recovery.
3. Select the operating system you want to boot by default from the Default Operating System list box.
4. Select the Display List Of Operating Systems For check box and specify the number of seconds you want the Boot menu displayed.

You can also do this by manually changing the *timeout* value in the Boot.ini file to a value higher than 0. To do so, follow these steps (for more information on the Boot.ini file, see [Chapter 38](#)):

1. At a command prompt either in the Recovery Console or Windows 2000 proper, type the command  

```
attrib -r -s -h c:\boot.ini
```

```
edit c:\boot.ini
```
2. Change the timeout value from 0 to the number of seconds that you want the system to display the Windows 2000 Loader screen before automatically booting. (The default is 30 seconds.)
3. Save and exit Edit, and then type the following command:  

```
attrib +r +s +h c:\boot.ini
```
4. Reboot the computer normally.

You can force the Windows 2000 Boot menu to display at startup by holding down the Spacebar after the BIOS screens are displayed. This displays the Hardware Profile/Configuration Recovery screen. Press F3 to display the Windows 2000 Loader screen with no timeout value.

## Restoring the MBR of the Previous OS

If the previous operating system still doesn't boot properly, you might need to re-create the MBR for the operating system that you had previously installed. This is risky business, so make sure that you have the time to reinstall the operating system and restore a backup if you run into trouble.

To re-create the MBR for a version of Windows 95, Windows 98, or Windows Me, use the following steps:

1. Boot the computer with a boot disk for the operating system you are unable to boot. (Make sure the disk contains the Sys.com file.)
2. Type `A:\sys c:` at the command prompt to transfer the system files from the floppy disk to the hard disk.

If this step doesn't work on your operating system, transfer the system files the way the operating system allows, or try using any MBR repair utilities bundled with the operating system.

3. Remove the floppy disk and reboot your computer. Verify that the operating system you wanted to repair boots properly before performing the next step.
4. Boot Windows 2000 using the Windows 2000 CD-ROM or Setup boot disks.
5. In the Welcome To Setup screen press F10, or type `R` followed by `C`.
6. Choose the Windows installation to log on to and then enter the administrator password.
7. Type `fixmbr` to write a valid MBR for the system.
8. Reboot the computer and choose the appropriate operating system from the Windows 2000 Loader menu.

## Summary

To successfully install Windows, it is very important that you assess the system, document it, plan the installation, and then methodically follow through with your plan. When documenting the system configuration, it's crucial that you ensure that the system is powerful enough to run the desired version of Windows and that all components are in the HCL. It's also important to thoroughly record all the information you can about the computer, including the network and hardware settings for the system. Also, you can save time as well as a very large headache if you plan ahead by deciding such things as what file format to use on the partitions, whether to perform a dual boot, and whether to automate the installation.

When it comes time to perform the Windows installation, there are a number of different phases of the setup process, including the optional Windows-based phase (if you're installing from Windows), the text-based phase, and the GUI-based Setup Wizard. If you have any trouble during the setup process or immediately after Setup completes (such as not being able to boot into a previous operating system), you can try a number of things to solve the problem, from updating the BIOS to refreshing the Master Boot Record with a previous operating system's boot information. In the next chapter, we move on to the steps you'll want to take after installing Windows.

# Chapter 6

## Configuring New Windows 2000 Server Installations

After installing Microsoft Windows 2000 Server, it's important to check for installation errors or problems. Also, add (and possibly troubleshoot) any other devices, review the server's network settings, and use the Configure Your Server Wizard to set up the server for its desired network role, such as Dynamic Host Configuration Protocol (DHCP) server or Active Directory service domain controller. Now is also the time to partition and format any additional disk drives and tune the server's performance and memory options to best suit its desired role. You should also implement the appropriate security measures for the server's desired role.

The goal of this chapter is to help get your system in basic working order, with information on fine-tuning to come in later chapters. For example, [Chapter 14](#) has more information on the management of DHCP, Domain Name System (DNS), and Windows Internet Name Service (WINS). If you need to configure disks, see [Chapter 15](#).

In addition to the tasks covered in this chapter, you might want to set up security auditing (covered in [Chapter 9](#) and [Chapter 18](#)) and remote administration using the Terminal Services feature (covered in [Chapter 26](#)).

## Checking for Setup Problems

After your Windows installation is complete, you should check the system for setup errors or device problems. Check the following items:

- Check Event Viewer for errors (Event Viewer is discussed in [Chapter 10](#)).
- Review setup errors. To do so, open the \Winnt\setuperr.log file, if it exists. If it doesn't, there were no errors.

## Configuring Devices

Immediately after finishing an installation of Windows 2000, or any operating system for that matter, check to make sure devices are recognized and properly configured. Although Windows 2000 Setup generally does a good job of detecting and configuring, Setup isn't able to resolve resource conflicts or overcome a lack of drivers. You'll also need to enable devices, such as an uninterruptible power supply (UPS), that were disconnected or disabled before starting the installation.

Microsoft Windows NT 4 isn't the best operating system for finding and troubleshooting device problems because it lacks Plug and Play (PnP) functions and supports a somewhat limited hardware base. In contrast, Windows 2000 handles these issues well, integrating PnP support along with a more centralized method of managing hardware devices, using Device Manager and the Add/Remove Hardware Wizard, and generally improving device driver support. Check the list of devices in Device Manager for conflicts and for devices that weren't installed during setup, and then use the Add/Remove Hardware Wizard to make the necessary changes. You can use Device Manager if you prefer a more hands-on approach.

## Using the Add/Remove Hardware Wizard

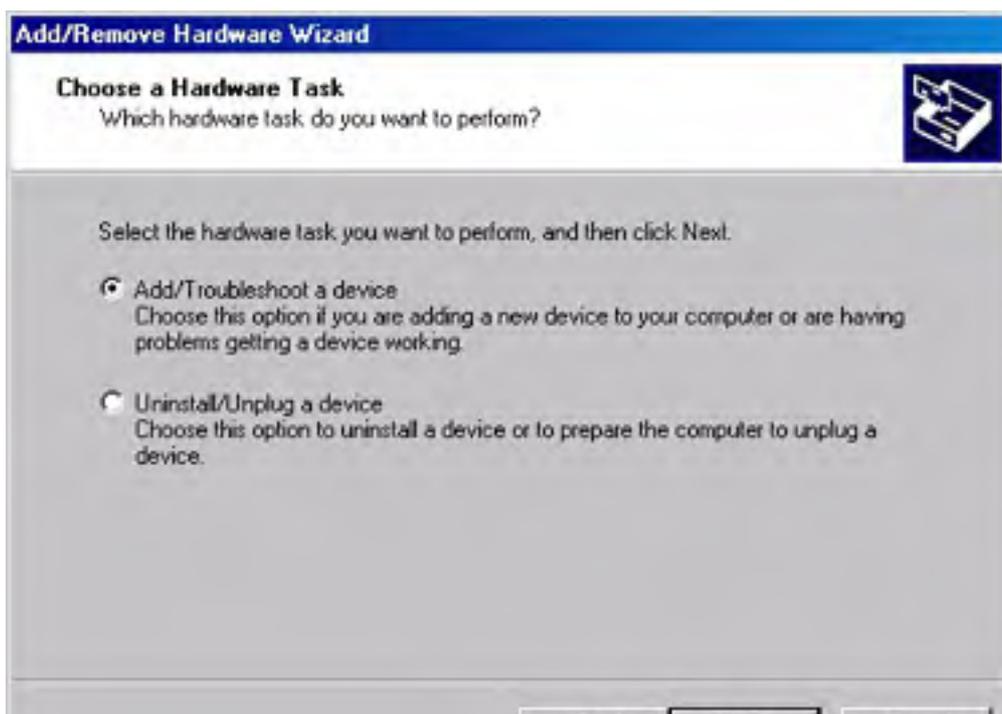

Although you can use Device Manager instead of the Add/Remove Hardware Wizard to handle most of the wizard's functions, you do need to use the Add/Remove Hardware Wizard to add a device that Windows 2000 can't recognize or to unplug or eject a device.

### Removing and Adding a Device

To remove a device, select the Uninstall/Unplug A Device option in the Add/Remove Hardware Wizard, and then use the screens that follow either to temporarily unplug a hot-pluggable device or to permanently uninstall a device from your system. You can always add the device back later by using this same wizard or by using autodetection of PnP devices in Windows 2000.

To add a device to your system, make sure the device is physically connected and, if appropriate, turned on. Then double-click the Add/Remove Hardware icon in Control Panel, and when the Welcome screen appears, click Next to begin the wizard.

Select the Add/Troubleshoot A Device option, shown in Figure 6-1, and then click Next. Windows 2000 scans your system for PnP hardware and displays a list of detected hardware. If new PnP hardware is detected, Windows 2000 installs drivers, if it can locate them, and displays a list of devices that it installed. Click Finish to end the installation process.

**Figure 6-1.** The Choose A Hardware Task screen of the Add/Remove Hardware Wizard.

## Troubleshooting a Device

If, after you add a device, Windows 2000 doesn't detect it or detects it incorrectly, you can troubleshoot the problem using the Add/Remove Hardware Wizard. When no new devices are found, Windows 2000 displays all the devices on your system—listing any disabled devices or devices with problems first (Figure 6-2).

**Figure 6-2.** The Choose A Hardware Device screen of the Add/Remove Hardware Wizard.

When troubleshooting a problem device, select the device from the list, and then click Next to see the status of the device and to start a troubleshooter. To add a device that Windows 2000 couldn't detect, select Add A New Device from the list in the Choose A Hardware Device screen, and then follow these steps:

1. Choose whether you want Windows 2000 to search for your hardware or whether you want to select the device manually from a list.
2. Select from the list of devices detected, or select a type of hardware you want to install from the provided list, and click Next.
3. If you chose to select your device manually, select the manufacturer and device, or click Have Disk to supply your own drivers, and then click Next. Windows 2000 installs the drivers for your device and then displays a summary of its actions.
4. Click Finish to complete the wizard.

## Using Device Manager

Device Manager is a central repository for device information in Windows 2000. If you've used Device Manager in Microsoft Windows 95/98, you'll be at home with the Windows 2000 Device Manager. Use it to view or print the configuration and drivers loaded for any device on your system as well as to disable, uninstall, or change the configuration for a device.

## Opening Device Manager

You can access Device Manager in one of several ways. Perhaps the most useful way is to launch Computer Management (Compmgmt.msc) from the Administrative Tools folder on the Programs menu. Click the plus sign next to System Tools to expand the tree, and then click Device Manager.

You can also access Device Manager by opening the System tool in Control Panel. Click the Hardware tab and then click Device Manager. The Hardware tab also contains the Hardware Wizard and the Driver Signing tool that you can use to specify whether you want to permit the use of unsigned device drivers.

To use the Computer Management snap-in to remotely administer another computer running Windows 2000, select Computer Management in the console tree, and then choose Connect To Another Computer from the Action menu. Select the computer you want to manage, click OK, and you're there.

## Working with Device Manager

After opening Device Manager, you'll see a list of all the devices that Windows 2000 has detected on your system (Figure 6-3). Any nonfunctioning devices are displayed with an exclamation point, indicating that a problem exists with the device; disabled devices are displayed with a small red "x" over the icon.

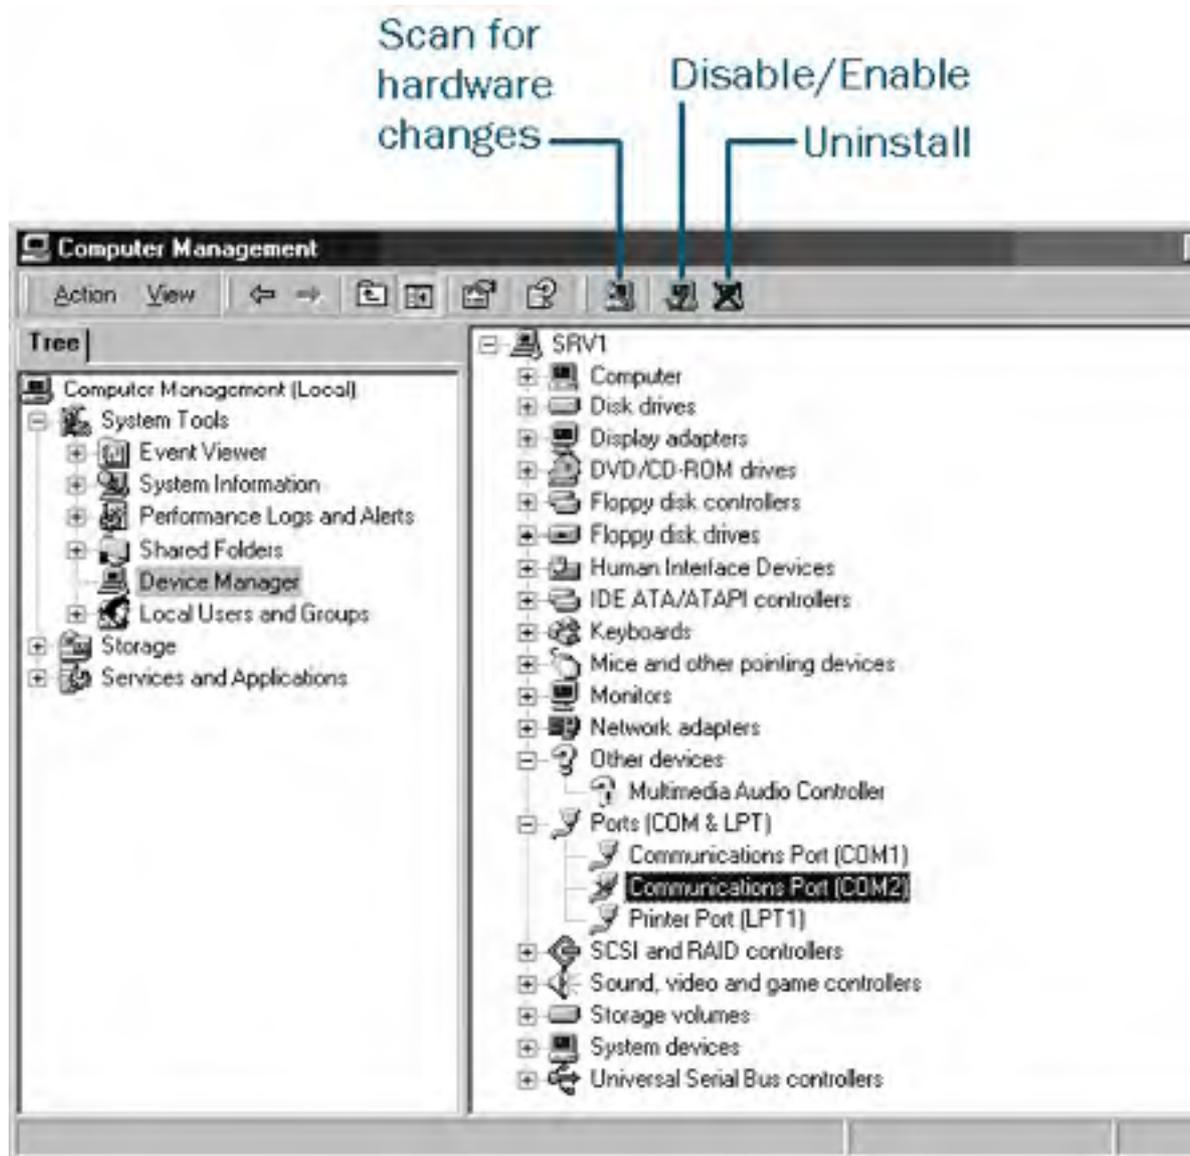

Figure 6-3. The Device Manager snap-in.

On the far right side of the toolbar, icons are available according to the device you've selected. In Figure 6-3, they are the following buttons (reading from left to right):

- **Scan For Hardware Changes** Click this button to tell the system to look for changes in hardware. Use this button after adding new PnP devices or after swapping hardware.
- **Disable/Enable** Select a device and click this button to disable it or enable it, depending on its current status. When a device is disabled, its resources are freed and its drivers remain but are not loaded during startup. Take care not to disable something you need to start the machine.
- **Uninstall** Select a device and click this button to uninstall it. This should only be necessary for non-PnP devices. You can uninstall a PnP device by simply removing it from the computer. Uninstalling a device doesn't remove its drivers from the hard disk.

To change the Device Manager display, choose a setting from the View menu (see Table 6-1). Use the different view settings for Device Manager to organize your system's devices in a way that makes it easy to find the information you need.

**Table 6-1.** View settings

Setting	Description
Devices By Type	Shows devices categorized by device type; usually the most useful view (also the default)
Devices By Connection	Shows all devices in relation to how they're connected to other devices
Resources By Type	Shows all system resources, organized by type of resource
Resources By Connection	Shows all system resources, organized and grouped by the device to which they're connected
Show Hidden Devices	Includes devices that are not PnP plus devices that might have been physically removed but still have their drivers installed

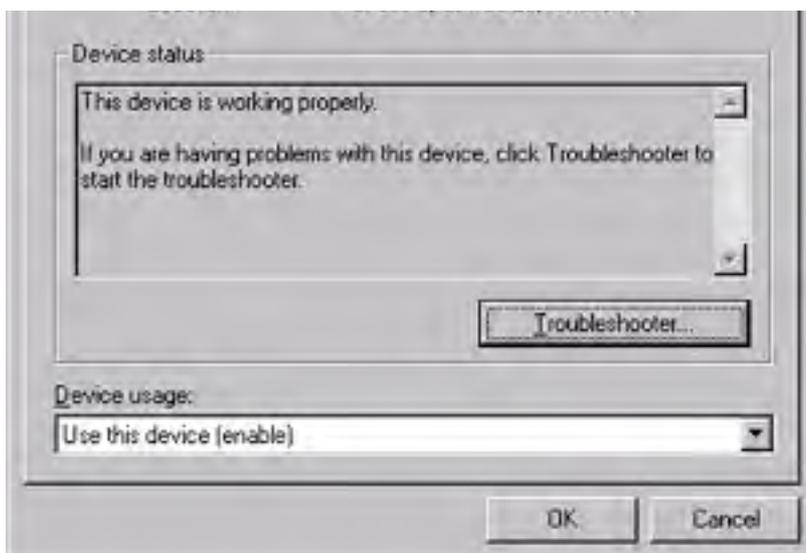

## Working with Device Properties

To display a device's properties (Figure 6-4), select the device, and then click the Properties toolbar button or double-click the device. In the Device Properties dialog box, there might be several tabs. You can view the status and configuration information, as well as the device manufacturer, device type, and location, in the upper portion of the General tab.

The device name shown in Device Manager is the name of the driver that Windows 2000 is using for the device and can actually be incorrect if the wrong driver is loaded for the device.

The Device Status box in the middle of the General tab displays the status of the device, including any errors. If the device has any problems, the Device Status box briefly describes the problem, and usually it also describes the appropriate course of action to correct the problem. Click Troubleshooter to use the built-in mechanisms for detecting the nature of the problem.

**Figure 6-4.** The General tab of the Device Properties dialog box.

#### More Info

If you need additional information about a message displayed in the Device Status box, check Microsoft support at <http://support.microsoft.com>.

Other tabs include the Driver tab, which displays the details of the driver being used. This tab also lets you update or uninstall the driver. The Resources tab displays the hardware resources being used. This tab allows you to see and resolve any conflicts caused by non-PnP devices. Along with these tabs, some devices have additional advanced settings or tabs for device-specific settings.

Device Manager works on remote computers in read-only mode. You can use Device Manager to diagnose problems, but you must make changes locally.

## Troubleshooting Devices

Troubleshooting devices is not an exact science. Devices in Windows 2000 usually work with minimal installation headaches. If they don't, it's often difficult to make them work. With that said, here are some of the troubleshooting techniques we've learned from our many years of device-induced headaches:

- Open the properties for the device and see if the cause of the problem is listed in the General tab or the Resources tab. If there are any conflicts, remove or disable the conflicting device, or plug the device into a different slot (if possible).
- Select the device in Device Manager and click the Uninstall toolbar button. Click Scan For Changes and let Windows redetect the device. Hopefully it will install properly. You can also uninstall the device and then reboot Windows for a more thorough but time-consuming attempt.
- Try plugging external devices into a different port, or directly into the computer instead of through a hub. Only connect high-power, bus-powered Universal Serial Bus (USB) or Firewire devices such as scanners without external power supplies to self-powered hubs (hubs with external power supplies). To check the power consumption of USB devices, open the device properties for the USB hub and click the Power tab.
- If the problem is persistent, remove all unnecessary devices from the system and see if the device works. If not, you've got real problems (try the device in another system to see if it's faulty or if there is a conflict unique to your system). If the device works, add the removed devices back one by one until something doesn't work, and then assess the situation (you might need to leave some cards or devices unplugged).

If you disable something essential—like the mouse or keyboard—you can return to the previous hardware profile by rebooting. When the Loader menu appears, press F8, and choose Last Known Good Configuration. Then choose the version of Windows you have installed from the Loader menu and press Enter. This action enables the last good hardware profile.

**More Info**

For more in-depth troubleshooting advice, consult Windows Help, or perform a search on the Microsoft Knowledge Base, accessible from Help or from <http://support.microsoft.com>.

## Configuring Networking Settings

Although most computers will be properly set up for network access during Windows Setup, you might need to change these settings at some point—possibly immediately if the specified settings were wrong or incomplete. This section explains how to get a server running properly on a network.

### Changing Your Network Identity

Change is sometimes necessary—although with a server, it's better to spend your time planning first than to have to make changes later. However, as Robbie Burns might have said while reconfiguring his server, "The best laid schemes o' mice and men gang aft a-gley." So even with careful planning, you can discover that a machine needs to have a different name or needs to be joined to a different domain.

To change the identity of a server that isn't a domain controller, log on using an administrator's account and follow these steps:

1. Open the System tool in Control Panel, and then click the Network Identification tab.
2. To change your computer name and domain or workgroup membership, select Properties. Then enter the new name for your computer in the New Computer Name text box in the Identification Changes dialog box, as shown in Figure 6-5.

**Figure 6-5.** *The Identification Changes dialog box.*

3. To change the domain or workgroup you belong to, choose either the Domain option or the Workgroup option, and then type the domain or workgroup name in the text box.
4. Click More to manually specify the domain name for your computer and to preview the NetBIOS name for your system. Click OK when you're finished.

Changing the identity of a domain controller is a multistep process. First you must demote the domain controller by running DCPROMO. Then you can change the identity, and finally you can promote the domain controller again. The steps for this process are detailed in [Chapter 11](#).

## Real World

### Naming Computers

It's a good idea to use a computer name that is both DNS-compatible and NetBIOS-compatible so that all types of clients see the same name for your computer. To do this, make the name 15 characters or fewer and don't use asterisks or periods. To obtain the best application compatibility, try to avoid using spaces, underscores, and hyphens.

## Configuring Network Components

To add or change the settings for core network components such as clients, services, and protocols, open the Network and Dial-Up Connections folder, right-click the Local Area Connection icon, and choose Properties from the shortcut menu. This procedure opens the Local Area Connection Properties dialog box shown in Figure 6-6, which you can use to view and change your server's networking components.

**Figure 6-6.** The Local Area Connection Properties dialog box.

The top of the dialog box shows the network adapter to which you are binding networking services. Beneath that is the media access control (MAC) address for the network interface card, the unique identifier of your network card that is used for communications with other hosts in your subnet.

To install a network component, select Install, choose the type of component you want to install (Client, Service, or Protocol), and then click Add. Select the component from the list presented and click OK. To configure the component (if the component has a configurable option), select the component and click Properties.

If you have a multihomed server (a server with more than one network adapter), give your local area connections a name indicating to which network the adapters are connected. To do so, right-click the connections in the Network and Dial-Up Connections folder and choose Rename from the shortcut menu.

## Configuring TCP/IP

TCP/IP is the most important protocol in today's networks, and it's the backbone for Microsoft's vision of networking in Windows 2000 and beyond. The protocol is well suited to enterprise networking, and it's required for accessing the Internet. If you're unfamiliar with TCP/IP, see [Chapter 13](#) for an introduction.

Before installing and configuring protocols on your network, review the checklists in the Windows 2000 Help files. Once you understand the following three areas, you can install all the necessary interlocking pieces.

- TCP/IP concepts such as IP addressing, subnet masks, and gateways
- Whether your network supports DHCP to configure TCP/IP dynamically
- How computers on your network will handle name resolution

## Installing TCP/IP

TCP/IP is installed as the default network protocol if a network adapter was detected during installation. If the default was overridden during installation, you can add TCP/IP by following these steps:

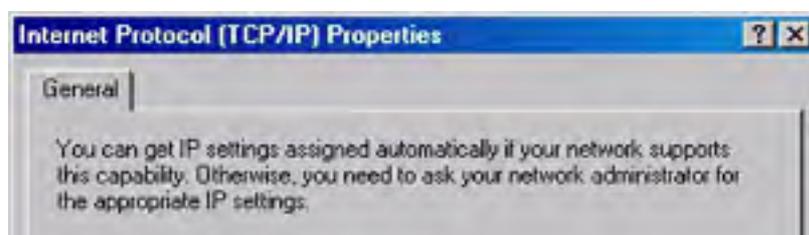

1. Click Start, select Settings, and then choose Network And Dial-Up Connections.
2. Right-click the connection for which you want to install TCP/IP, and choose Properties from the shortcut menu.
3. If TCP/IP isn't in the list of components used, as shown in Figure 6-6, click Install.
4. Select Protocol, and click Add.
5. In the Select Network Protocol box, select Internet Protocol (TCP/IP) and click OK.
6. Verify that the Internet Protocol (TCP/IP) check box is selected, and then click OK.

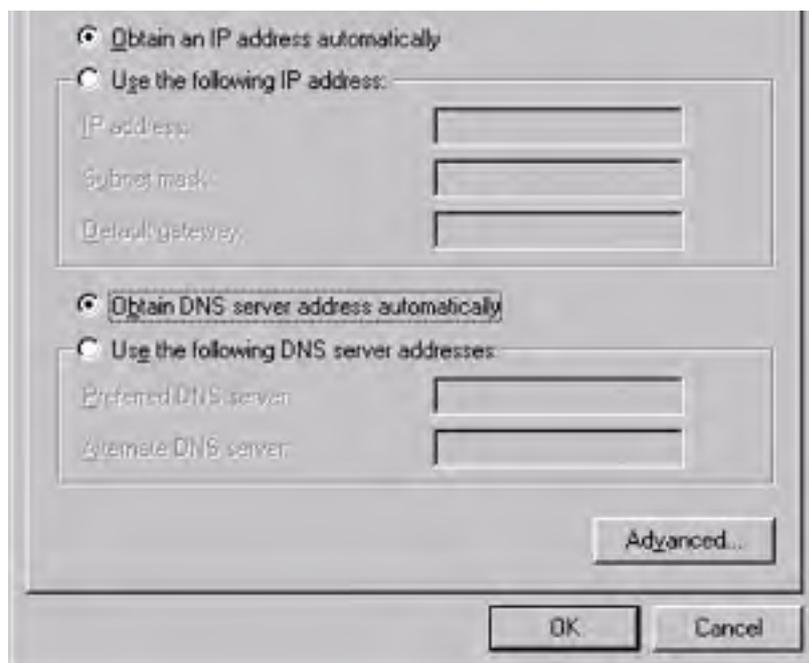

## Using Dynamic Addressing

The easiest and most reliable way to configure machines on a network running the TCP/IP suite is to use a DHCP server to automatically distribute IP addresses. DHCP can also inform clients of the appropriate DNS servers and gateways to use. A DHCP server not only simplifies client configuration, but it also saves headaches for the poor soul who would otherwise have to track the use of IP addresses, because it manages the database of available IP addresses dynamically and automatically.

Dynamic addressing using DHCP is the Windows 2000 default setting. If you need to check this or change a statically assigned host to a dynamically configured host, follow these steps:

1. Select the Internet Protocol (TCP/IP) component in your Local Area Connection Properties dialog box, and click Properties (Figure 6-7).

**Figure 6-7.** The General tab of the Internet Protocol (TCP/IP) Properties dialog box.

2. Select the Obtain An IP Address Automatically option. However, don't select this option on a machine that is to act as a DHCP server. A DHCP server must have a fixed, static IP address.
3. Select the Obtain DNS Server Address Automatically option if your DHCP server is set up to provide the DNS server addresses to clients; otherwise, select the Use The Following DNS Server Addresses option, and enter the IP addresses for the DNS servers you want to use.

### **Real World**

#### **Assigning IP Addresses for DNS and WINS Servers**

When setting up a DNS or WINS server, it's tempting to use a static IP address. Although this is an acceptable use of static IP addresses, a better method for many networks is to allow the server to obtain an address from the DHCP server and then create an IP reservation for the server with an unlimited lease duration on the DHCP server. This step gives the server a permanent lease on the IP address it was assigned, ensuring that the IP address of the DNS server won't change, at the same time allowing the DHCP administrator to easily take back the address if the server is moved or decommissioned. See [Chapter 14](#) for information on creating reservations on a DHCP server.

### **Using Static Addressing**

If your network doesn't have a DHCP server or if you're setting up a DHCP server, you need to manually configure TCP/IP to use a static IP address and DNS information. To do this, obtain an IP address from the person who maintains the database of IP addresses that your organization can use. If using DHCP, all DHCP servers also need to be updated to exclude your static IP address.

To set up a system with a static IP address, follow these steps:

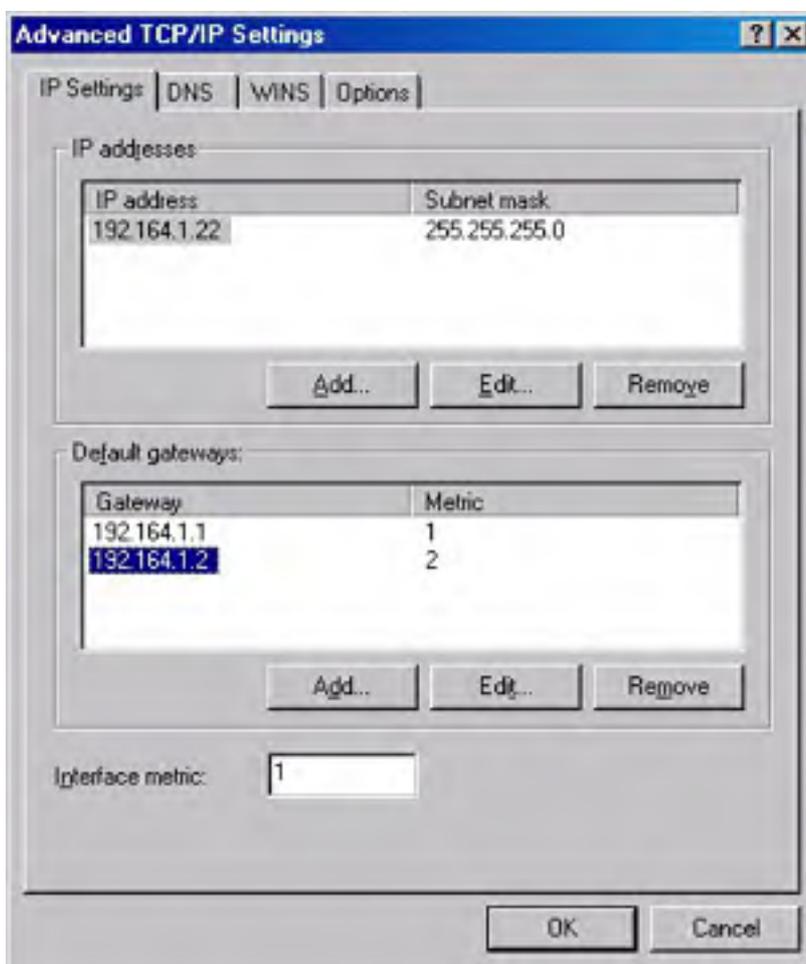

1. Select the Internet Protocol (TCP/IP) component in the Local Area Connection Properties dialog box, and click Properties.
2. Select the Use The Following IP Address option, enter the address you obtain in the IP Address text box, and then press Tab to automatically fill in the default subnet mask. Most likely, you'll be able to use the default subnet mask, but if your network is using a specific subnet mask, you need to find the proper mask and enter it in the Subnet Mask text box.

3. Enter the IP address for your default gateway or router in the Default Gateway text box. The default gateway forwards, or routes, any traffic destined for hosts outside your local subnet, possibly to another portion of your wide area network (WAN) or to the Internet.
4. Choose the Use The Following DNS Server Addresses option to specify the IP addresses for your DNS servers. Enter the primary and secondary DNS server addresses in the text boxes provided.

The DNS service is critical for resolving host names such as <http://www.microsoft.com> into IP addresses that your computer can access. Without the DNS service, users could access resources only by typing in their IP addresses directly or by broadcasting their NetBIOS names (which only works on local subnets and consumes lots of network bandwidth).

## Setting Advanced TCP/IP Options

If you aren't using a DHCP server to configure your server's IP address and associated settings and you need to enter other settings besides just your server's IP address and DNS servers, select Advanced in the TCP/IP Properties dialog box. This opens the Advanced TCP/IP Settings dialog box, shown in Figure 6-8, which you use to specify additional settings, including WINS servers, NetBIOS over TCP/IP, and optional TCP/IP parameters. [Chapter 13](#) contains more information about configuring TCP/IP.

**Figure 6-8.** The IP Settings tab of the Advanced TCP/IP Settings dialog box.

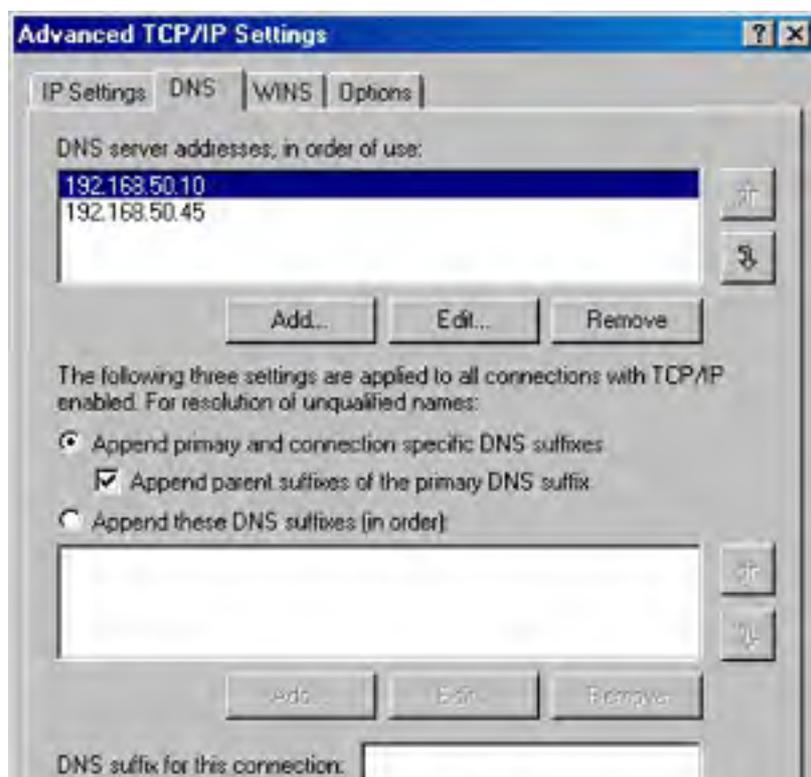

**Configuring IP Settings** The Advanced TCP/IP Settings dialog box contains four tabs, the first of which is the IP Settings tab. You use this tab to add the IP address and subnet mask for your network connection and the gateways your server should use. To change the options on this tab, follow these steps:

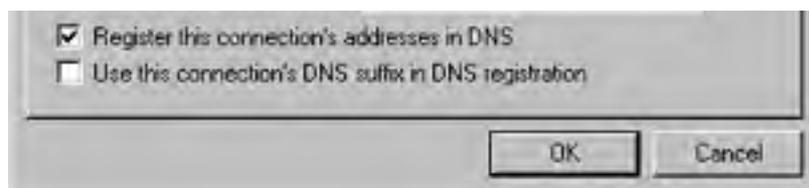

1. Use the Add, Edit, and Remove buttons in the IP Addresses box to modify your IP address and subnet mask settings.

2. To add a default gateway or router, click Add and enter the IP address for the router.
3. Now add the interface metric for the connection. The interface metric assigns a relative cost to using a particular router to access a particular IP address. Assign lower interface metrics with routers connecting to fast networks, such as another section of a local network; assign higher numbers to slower connections, such as an Integrated Services Digital Network (ISDN) or a slow digital subscriber line (DSL) connection to the Internet.

**Configuring DNS Settings** Click the DNS tab to access the advanced DNS settings for your network connection, as shown in Figure 6-9. Then use the following procedure to configure your DNS settings:

1. Use the Add, Edit, and Remove buttons in the DNS Addresses box to add or modify the DNS servers you want to use for this connection. Use the up and down arrows next to the box to change the order in which your server queries the DNS servers.
2. Select the appropriate options for unqualified names:
  - **Append Primary And Connection Specific DNS Suffixes** Limits the resolution for unqualified names to the domain suffixes and connection-specific suffixes. If your primary DNS suffix is `eng.scribes.com` and you type `ping srv4` at a command prompt, DNS looks for `srv4.eng.scribes.com`. If you also specify a connection-specific name (under DNS Suffix For This Connection), such as `dev.scribes.com`, DNS queries `srv4.eng.scribes.com` and `srv4.dev.scribes.com`.
  - **Append Parent Suffixes Of The Primary DNS Suffix** Includes parent suffixes up to the second-level domain in the resolution of unqualified names. So if the primary DNS suffix is `eng.uk.corp.scribes.com` and you type `ping srv4` at a command prompt, DNS queries for the following:
    - `srv4.eng.uk.corp.scribes.com`
    - `srv4.uk.corp.scribes.com`
    - `srv4.corp.scribes.com`
    - `srv4.scribes.com`
  - **Append These DNS Suffixes (In Order)** Specifies the only domain suffixes to be appended to unqualified domain names during the name resolution process. If you specify domain suffixes here, the primary and connection-specific suffixes are not used.

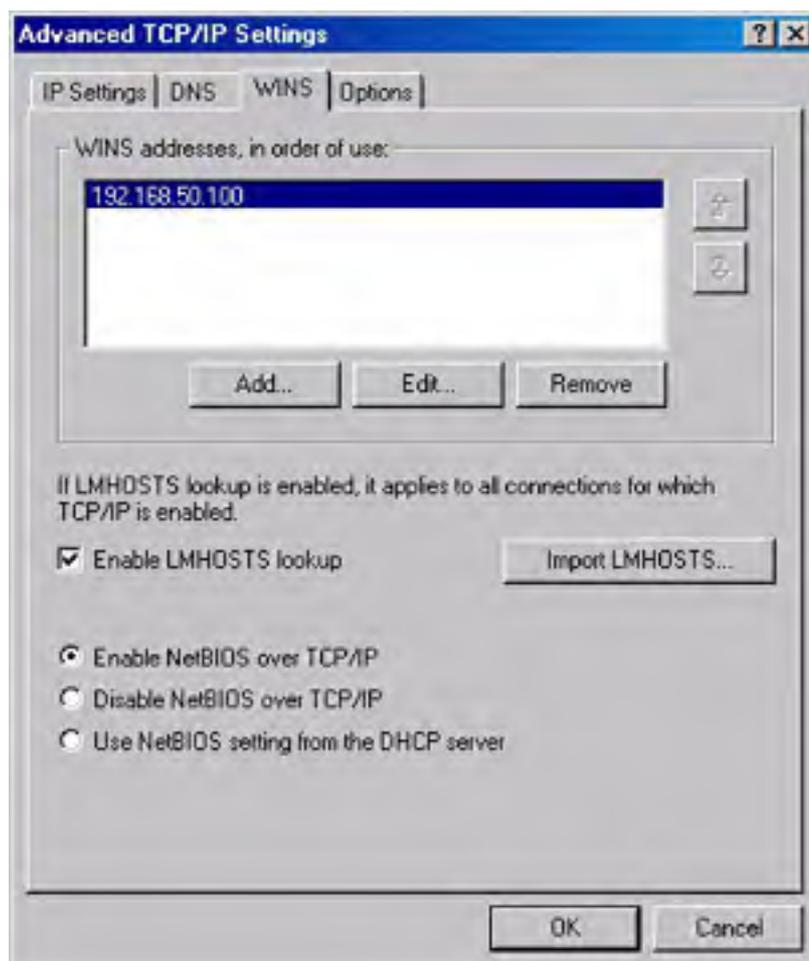

**Figure 6-9.** The DNS tab of the Advanced TCP/IP Settings dialog box.

3. To override the parent DNS domain name specified for your computer in the Network Identification tab of the System Properties Control Panel tool, type the DNS domain name you want to use in the DNS Suffix For This Connection text box.
4. To prevent the full DNS name of your server's IP address from being registered with the DNS server, clear the Register This Connection's Addresses In DNS check box.
5. To register the IP addresses of your network connections in DNS based on the domain name of the connections as well as by the fully qualified domain name (FQDN) for your server, select the Register This Connection's DNS Suffix In DNS Registration check box. The domain name of the connection is entered in the DNS Suffix For This Connection text box or assigned by the DHCP server.

**Configuring WINS Settings** To configure the WINS settings for your computer, click the WINS tab in the Advanced TCP/IP Settings dialog box (Figure 6-10). If WINS servers are operating on your network, you should add their addresses here. Doing so gives you the best results when communicating with hosts that are running Microsoft operating systems earlier than Windows 2000. As with the other tabs in the Advanced TCP/IP Settings dialog box, use the Add, Edit, and Remove buttons to modify your WINS server list. For a more thorough discussion of when to use WINS servers on your network, see [Chapter 14](#).

**Figure 6-10.** The WINS tab of the Advanced TCP/IP Settings dialog box.

To enable the use of an Lmhosts file for resolving NetBIOS names to IP addresses, select the Enable LMHOSTS Lookup check box, and click Import LMHOSTS to import an Lmhosts file. We recommend using Lmhosts files only when absolutely necessary because trying to keep them up-to-date can be tricky—the minuscule reduction of network traffic that Lmhosts files offer isn't worth it.

When you configure a WINS server, use the Ipconfig command at a command prompt to obtain your current IP address, and then enter that address in the WINS Addresses field. Don't enter any other WINS server in this field; you don't want your WINS server registering its NetBIOS name with another WINS server if WINS hasn't started in time to respond at bootup.

In all likelihood, you'll need to communicate with clients that are running Microsoft operating systems earlier than Windows 2000, so make sure the Enable NetBIOS Over TCP/IP option is selected. Disable this only if you communicate exclusively with other computers running Windows 2000 or computers that rely solely on DNS for name resolution services (for example, UNIX). Also, note that any applications that use NetBIOS won't work if you disable NetBIOS Over TCP/IP.

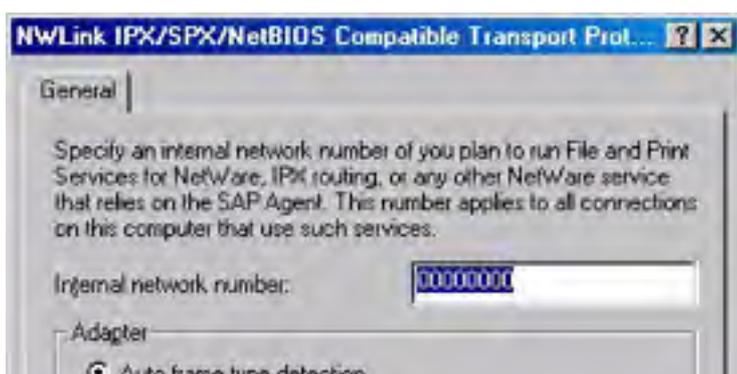

**Configuring TCP/IP Options** If you need to configure any TCP/IP options, click the Options tab in the Advanced TCP/IP Settings dialog box. Select an option you want to configure, and then click Properties. For more information about TCP/IP properties and secure TCP/IP connections, see [Chapter 13](#).

## Configuring NWLink IPX/SPX

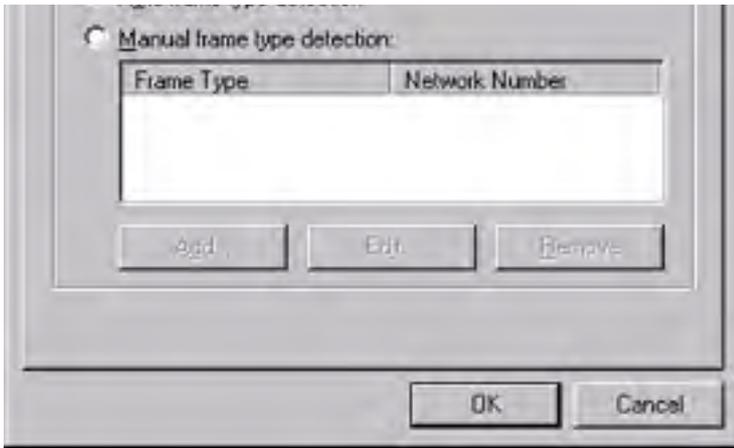

The NWLink IPX/SPX protocol was designed as an easy-to-use-and-configure, routable protocol that is compatible with NetWare's IPX/SPX protocol. As such, it used to be a popular protocol in many companies and can still be useful in maintaining interoperability with older network environments. For detailed information about interoperating with NetWare, see [Chapter 21](#).

Fortunately, configuring the NWLink IPX/SPX protocol is easy. Just follow these steps:

1. Install the protocol in the Local Area Connection Properties dialog box, which can be accessed by right-clicking the Local Area Connection icon in the Network and Dial-Up Connections folder and then selecting Properties.
2. Select the protocol and click Properties.
3. To advertise the services running on your server (such as File and Print Services For NetWare or IPX routing) to native NetWare clients, enter a unique eight-digit hexadecimal number in the Internal Network Number text box (Figure 6-11) to identify your server.
4. In most cases, you can also let Windows 2000 handle your frame type detection by selecting the Auto Frame Type Detection option. Windows 2000 then detects the proper frame type by sending out a Routing Information Protocol (RIP) request for all frame types and then waiting for a response. The frame type for which Windows 2000 received a response then becomes the default. If responses are received for multiple frame types, Windows 2000 sets the default frame types for which the responses were received in this order: Ethernet 802.2, Ethernet 802.3, Ethernet II, Sub-Network Access Protocol (SNAP).
5. If you want to specify the frame type manually or add multiple frame types, select the Manual Frame Type Detection option, select Add, and then choose a frame type and enter the network number for that frame type.

**Figure 6-11.** The General tab of the NWLink IPX/SPX/NetBIOS-Compatible Transport dialog box.

## Configuring Storage

Microsoft recommends that you partition and format only the system partition during Windows installation, and that you exclusively use the NTFS file system (no FAT), and we back them up on this recommendation. The Disk Management snap-in is a much more elegant and efficient way of partitioning and formatting disks and volumes than is Windows Setup, and we recommend that you do as many of your disk management chores as possible after Setup completes.

The chores that you will likely need to perform include partitioning and formatting the rest of the computer's hard disk(s), as well as possibly setting up software-based redundant arrays of independent disks (RAIDs), stripe sets, or mirror sets. In the interest of reducing redundancy (in this book), we refer you to [Chapter 17](#), where these tasks (and others) are covered in detail.

## Using the Windows 2000 Configure Your Server Tool

The Windows 2000 Configure Your Server tool provides a central location that you can use to install and manage most of the important server tools, such as Microsoft Active Directory, DHCP, DNS, and WINS. However, given the sometimes bewildering number of administrative tools and Microsoft Management Console (MMC) snap-ins available, having an organized and central location from which to access all of these tools is crucial. You don't actually use the Configure Your Server tool to perform many actions, but it serves as an interface for launching the various MMC snap-ins that you use to accomplish your tasks.

The Windows 2000 Configure Your Server tool appears when you first boot your server after completing Setup. If it doesn't appear, set up any additional devices and prepare any additional drives you need for your server programs and data, and then launch the Windows 2000 Configure Your Server tool from the Administrative Tools folder on the Programs menu.

In the Configure Your Server tool, use the topics on the left to choose the services you want to configure, and click the hyperlinks and buttons to set up and configure these services. The Configure Your Server tool launches any necessary wizards to walk you through installing the services you select.

## Choosing Whether to Set Up a Domain Controller

The first screen in the Windows 2000 Configure Your Server tool asks whether your server is the only one on your network (Figure 6-12). When you create a new network and this is the first server on the network, choose the This Is The Only Server In My Network option. (See the [Configuring the First Server on Your Network](#) section later in this chapter for more information.) This selection sets up your server as a domain controller and installs Active Directory, DHCP, and DNS on your server. Otherwise, choose the One Or More Servers Are Already Running In My Network option. Choosing this option allows you to pick exactly which services you want to install on your system. After choosing an option, click Next to continue.

**Figure 6-12.** The first screen of the Configure Your Server tool.

You should be extremely careful about adding a domain controller to an existing Windows NT 4 network. Before you can add any Windows 2000 domain controllers to an existing Windows NT 4 domain, you must upgrade the primary domain controller (PDC) to Windows 2000. This upgrade is required because Windows NT domains are single-master networks where the PDC contains the master records for the domain. Windows 2000 servers use full, multimaster replication, and each

domain controller acts as a master repository for domain information. If you add a Windows 2000 server or upgrade any machine other than the PDC on an existing Windows NT domain, you'll create a new Windows 2000 domain that looks like the existing domain but is not the same domain. The Windows 2000 domain controller that will work as the PDC for the network won't have the same security identifier (SID) as the PDC of the Windows NT 4 domain you were trying to upgrade. The result is a "network" that doesn't work. Therefore, you must upgrade the PDC on a Windows NT domain to Windows 2000 before attempting to install any other iterations of Windows 2000 Server as domain controllers (member servers can be added at any point).

When upgrading a PDC to Windows 2000, be sure the server's hardware is capable of handling the upgrade. If there's any doubt about whether your existing PDC can function with the additional load, you can do a little juggling by promoting a backup domain controller (BDC) that you're sure of to be the PDC. Then upgrade the new PDC to Windows 2000. See [Chapter 7](#) for more information on upgrading servers.

## Configuring the First Server on Your Network

If you're creating a new network or domain and you're setting up the first server in the domain, the Windows 2000 Configure Your Server tool can guide you through the configuration process. Just follow these steps:

1. In the first window of the Windows 2000 Configure Your Server tool, choose the This Is The Only Server In My Network option, and click Next (as discussed in the previous section). Choosing this option helps you configure your server as a domain controller running Active Directory, DHCP, and DNS.
2. Click the Show More Details link to view information about how your server's TCP/IP services will be configured, and then click Back.
3. Click Next, and then enter the domain name you want to use in the first text box, as shown in Figure 6-13.

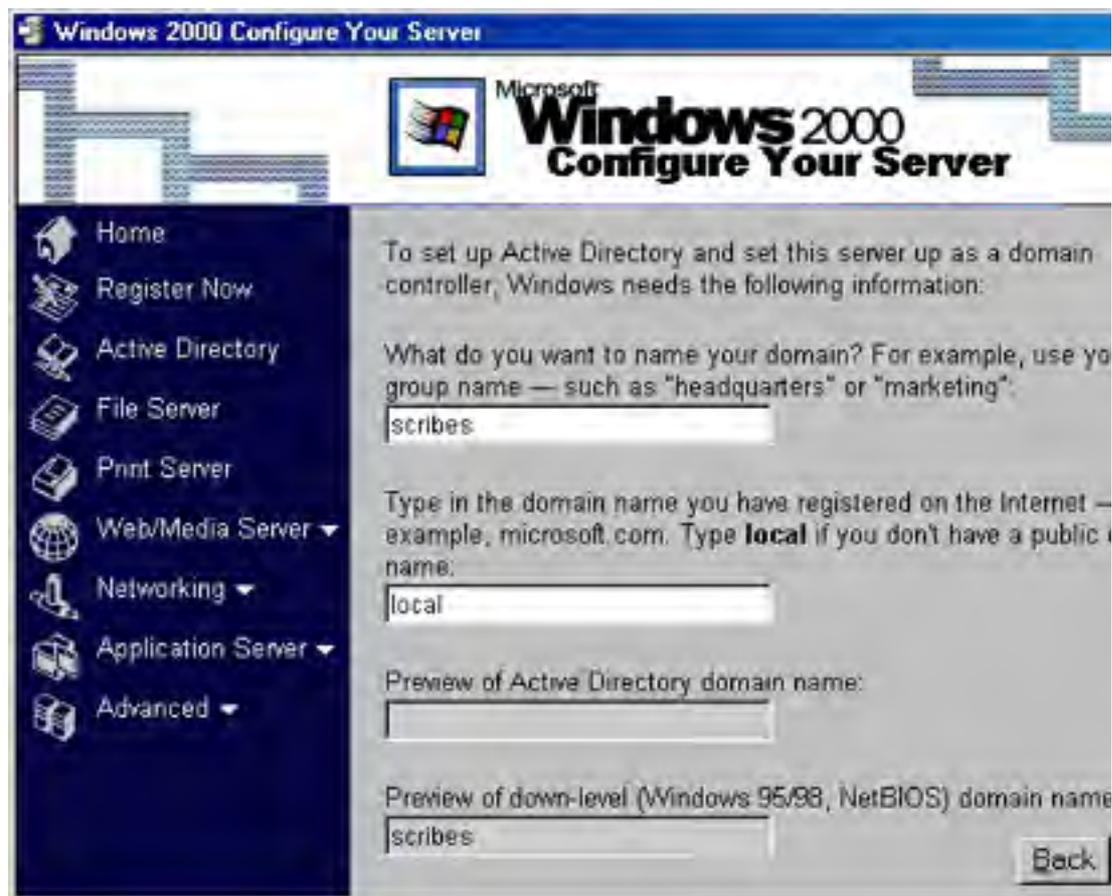

Figure 6-13. Entering your domain name using the Configure Your Server tool.

4. To use an Internet-registered domain name (such as scribes.com) as the root for your fully qualified domain name, enter the Internet domain name in the second text box. Or, to specify that your domain is a local domain that isn't a part of an Internet-registered domain, type *local* in the second text box.
5. Verify that the Active Directory and downlevel domain names are correct in the preview boxes at the bottom of the window, and then click Next.
6. Click Next again. Active Directory, DHCP, and DNS are installed in Unattended mode and Windows restarts. Once logged on, Windows displays the Windows 2000 Configure Your Server tool again. (See [Chapter 11](#) for help with any Active Directory installation questions you are asked, or see the sections on installing DHCP and DNS in [Chapter 14](#) for help with DHCP and DNS questions.)
7. Configure your server to use the static IP address specified in the Windows 2000 Configure Your Server tool. To do this, right-click the Local Area Connection icon in the Network and Dial-Up Connections folder, and choose Properties from the shortcut menu. Select Internet Protocol (TCP/IP), and click Properties. Then enter the proper IP address and subnet mask, and verify that the DNS server addresses include your server's IP address.
8. Open DHCP Manager and expand the DHCP server.
9. Select the DHCP server and choose All Tasks-Authorize from the Action menu.
10. Reboot your computer, and then use the Windows 2000 Configure Your Server tool to add any other services you need.

### **Real World**

#### **Special Facts About Windows 2000 Domain Controllers**

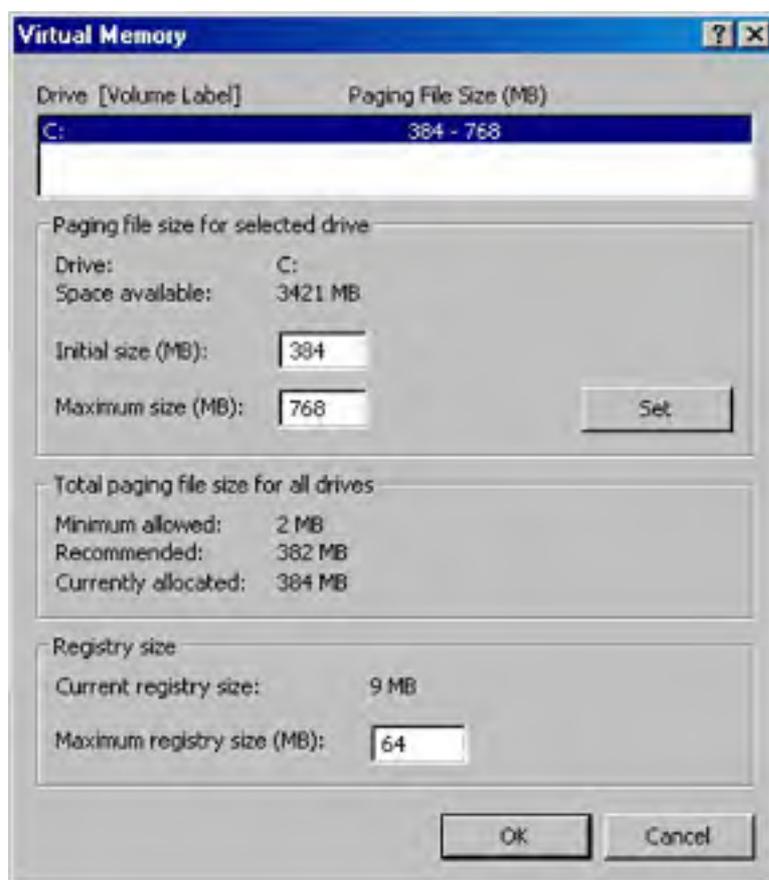

Although it's true that all Windows 2000 domain controllers are equal, some are more equal than others. The first Windows 2000 domain controller is automatically assigned the role of Global Catalog server. At least one Global Catalog server is needed on every domain. The Global Catalog is a database that contains a full replica of all directory objects in its host domain plus a partial replica of all directory objects in every domain in the forest. The Global Catalog's role is to enable the finding of directory information and to provide universal group membership information during logon. After additional controllers are installed, you can reassign the role of Global Catalog server or designate more than one machine as a Global Catalog server. This process is described in [Chapter 11](#).

The first domain controller is also assigned the operations master roles. A single controller must perform each of these roles because they are functions that can't be executed in different places at the same time. (For example, a single controller must handle the creation of security identifiers to ensure that each identifier is unique.) Under most circumstances, you won't have to change the location for any of the operations master roles, but you should be familiar with each of the roles and what happens in the case of failure. See [Chapter 12](#) for information on operations master roles.

## Performance and Memory Tuning

Although the Windows 2000 Server family of operating systems is self-tuning, there are a few settings that you might want to modify to maximize the performance of a server. To adjust the way Windows 2000 Server optimizes its memory, page file, and visual settings, use the following procedure:

1. Double-click the System icon in the Control Panel.
2. Click the Advanced tab and then click Performance Options.
3. In the Optimize Performance For section, choose the Background Services option.
4. Click Change in the Virtual Memory section to open the Virtual Memory dialog box, shown in Figure 6-14.

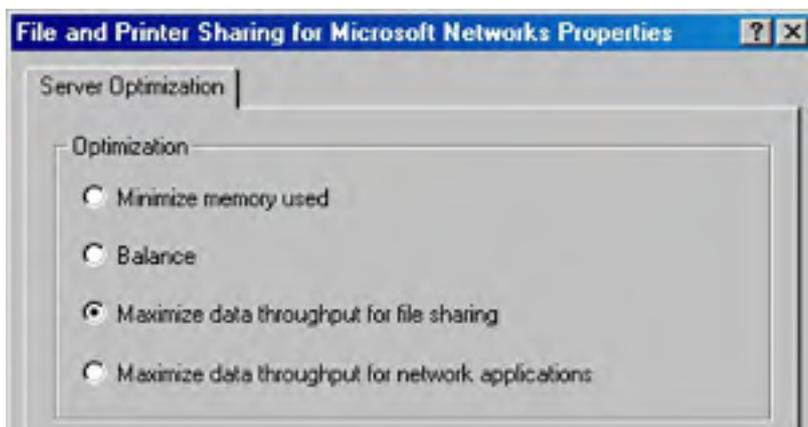

**Figure 6-14.** Changing virtual memory settings.

5. Select the drive for which you want to adjust virtual memory settings.
6. Enter the Initial Size and Maximum Size for the page file and then click Set. Use the following guidelines for optimizing page file sizes:
  - Create a page file on the system (most likely C:\) partition with the initial size and maximum size set to the amount of installed physical RAM. This allows the system to create a memory dump in the event of a system crash.
  - In addition to the page file on the system partition, allocate space for the page file on the fastest drive or drives in the system. Placing it on multiple physical drives improves performance, unless the drives are slow or heavily used (avoid these). Placing page files on multiple partitions on the same drive doesn't improve performance.
  - Place the page file on the fastest drive available. You might want to avoid software or hardware-based RAID volumes, as the data redundancy might reduce performance. Instead pick a simple volume, stripe set, or mirrored volume.

- Create a page file in its own logical partition or in a partition before any data is written to it. This minimizes page file fragmentation. Alternatively, defragment the partition before creating the page file to ensure that the page file is allocated a contiguous area on the hard drive.
- If there is plenty of disk space available, set the initial size and maximum size to the same value. This reduces page file fragmentation because additional hard disk space doesn't have to be allocated for the page file at a later time.
- Use the Page File Bytes counter in Performance Monitor to determine how much virtual memory is consumed under the heaviest usage conditions, and then use this amount to set the initial size, and possibly the maximum size (after increasing the number to anticipate increased future demands).

Microsoft recommends that virtual memory be equal to 1.5 times the amount of physical RAM installed in the server. Web servers don't usually require much virtual memory, so half the physical RAM size would be sufficient, but we like to err on the too big side, say three-fourths as a minimum. Database and other application servers often need lots of virtual memory, so consider setting the virtual memory setting to twice the amount of physical RAM installed.

7. Click OK when finished, and then restart the computer.
8. Click Start, select Settings, and then choose Network And Dial-Up Connections.
9. Right-click the internal network connection and choose Properties from the shortcut menu.
10. Select File And Printer Sharing For Microsoft Networks and then click Properties.
11. Select the memory optimization method that the server should use, as described here and shown in Figure 6-15:
  - **Minimize Memory Used** The best setting for servers that service only a limited number of clients (say 10 or so) or have a limited amount of RAM (less than 160 MB). This setting uses the least amount of RAM for caching.
  - **Balance** Uses somewhat more RAM for caching, improving file sharing speed while still leaving lots of RAM available for applications. This setting is a good choice for domain controllers.
  - **Maximize Data Throughput For File Sharing** This is the default setting and is appropriate for servers that mainly act as file servers. It allocates the largest amount of RAM for the system cache, maximizing file sharing performance but reducing the amount of available RAM for other programs.
  - **Maximize Data Throughput For Network Applications** Allocates a small amount of RAM for the system cache, making as much RAM available for server-based applications as possible while still ensuring good connectivity for clients. This setting is appropriate for servers that run network applications such as Microsoft SQL Server or Microsoft Exchange Server.
12. Click OK when finished.

**Figure 6-15.** *Optimizing memory usage for File and Printer Sharing.*

## Updating Windows

It's important to update Windows 2000 with the latest service pack and any security updates and hot fixes that are appropriate for the server and your network (this is a key point—applying every hot fix that comes out of Redmond could actually decrease your stability). We recommend that you stay on top of the service packs, and deploy only hot fixes and security updates that fix problems you're currently experiencing.

To update Windows, follow these guidelines:

- Install the latest service pack. (You don't have to go out and grab it right away. In general, though, it's a good idea not to fall more than one service pack behind.) You can download the latest service packs from Windows Update, or Microsoft Corporate Windows Update (<http://corporate.windowsupdate.microsoft.com>), among other locations.
- Install any security hot fixes that are important for your server and network. Web servers will need to install many (if not most) of the security updates to stay secure; internal file servers will infrequently need hot fixes. We recommend that you evaluate and test any hot fix before deploying it.
- Install a newer version of Microsoft Internet Explorer if Web browsing will be done locally on the server. The version of Internet Explorer that ships with Windows 2000 has a number of security holes and should be updated.

## Securing Windows

Entire books could be (and have been) written about securing Windows 2000 Server, and rightly so; it's an important topic (and one that we devote considerable space to, including Chapters 18 and 19). We won't launch a big security discussion here, but some security precautions are necessary before considering your server "online." Here's what Microsoft recommends (for a detailed explanation of these suggestions, see <http://www.microsoft.com/technet/security/tools/w2ksvrcl.asp>, or refer to the appropriate sections of this book):

- Eliminate FAT (make sure all hard disk partitions are using NTFS).
- Rename the administrator account and create a strong password for it (and use a different password for each server).
- Set appropriate password policies and account lockout policies for your network.
- Disable unnecessary services, especially Internet Information Services. If not doing file or printer sharing, disable the Server service.
- Don't install unnecessary applications such as e-mail, Microsoft Office, or utilities.
- Disable unnecessary accounts.
- Check folder permissions.
- Disable the Guest account.
- Protect the registry from anonymous access.
- Apply appropriate registry access control lists (ACLs).
- Restrict access to the Local System Authority (LSA).
- Remove unnecessary file shares.
- Install antivirus software and the latest virus definition files.
- Install the latest service pack.
- Install security hot fixes as appropriate for your network.

## **Summary**

If you put in the planning time recommended in the first part of this book, it's probably paying off around now. Although the configuration of various services and protocols is relatively complex, primarily because of the interdependencies among them, you should have a good idea of which services and protocols will best suit the needs of your network in a Windows 2000 environment. In the next chapter, we address the general topic of upgrading existing systems to Windows 2000 and tying them into the network.

# Chapter 7

## **Upgrading to Windows 2000**

Chapters 5 and 6 described how to install and configure Microsoft Windows 2000 on a new or clean system. This chapter moves on to a topic that will probably be more immediately useful: upgrading to Windows 2000.

Because upgrading to a new network environment such as Windows 2000 involves so much more than simply running Setup, this chapter covers many aspects of the process. It discusses the architectural differences between Windows 2000 and prior versions of Windows and how these differences affect the upgrade process, as well as how to plan and prepare for upgrading Microsoft Windows NT domains. It also covers the actual upgrade process for Windows NT servers and Windows NT-based and Microsoft Windows 95/98-based clients. At the end of the chapter, you'll find information on making the transition from a mixed-mode domain with Windows NT and Windows 2000 domain controllers to a native Windows 2000 domain with only Windows 2000 domain controllers.

## Architectural Improvements in Windows 2000

Architectural improvements in Windows 2000 include changes to the types of server roles available and to the type of domain trusts that are used; new support for devices, Plug and Play (PnP), and power management; and, of course, the addition of the Active Directory service. However, all these changes mean that some existing applications and drivers might not work under the new Windows 2000 architecture.

### Domain Controllers and Server Roles in Windows 2000

In Windows 2000, the types of server roles are slightly different from those available under Windows NT. Windows NT 4 servers can have one of four roles: primary domain controller (PDC), backup domain controller (BDC), member server, and stand-alone server.

Windows NT domains are single-master based, with the PDC serving as the master repository for a given domain. All changes to the domain must be carried out by the PDC. BDCs serve as working backups to the PDC and also reduce the load on the PDC by serving client requests themselves. BDCs maintain a current copy of the domain by synchronizing periodically with the PDC; they can be upgraded to the PDC if that server fails or is taken out of service.

Member servers are simply Windows NT servers that belong to a Windows NT domain and usually perform file sharing or print sharing or run some other type of server software, such as Web, Domain Name System (DNS), or Dynamic Host Configuration Protocol (DHCP) server software. Member servers can't be upgraded to a PDC or BDC without a clean reinstallation of Windows NT.

Stand-alone servers are Windows NT servers that do not belong to a Windows NT domain and are instead part of a workgroup. It is important to understand that although a stand-alone server doesn't belong to a Windows NT domain, it isn't limited in its duties as a server. It can still act as a DNS, DHCP, or other type of server, but by definition it can't be a PDC or BDC. Like member servers, you have to reinstall Windows NT from scratch to upgrade a stand-alone server to a PDC or BDC.

The member server and stand-alone server roles are the same in Windows 2000 as in Windows NT, but the PDC and BDC roles are replaced with a single domain controller role. Yes, domains in Windows 2000 are finally multiple-master based, with all Windows 2000 domain controllers acting as peers to one another. Any domain controller can make changes to the domain at will. All domain information is stored in Active Directory, which handles replication between all domain controllers. The trade-off is that Windows 2000 domain controllers cannot exist on a Windows NT domain until the PDC of the domain has been upgraded to Windows 2000. This issue is covered in greater detail later in this chapter, in the section entitled [Planning a Domain Upgrade](#).

Windows 2000 member servers and stand-alone servers can be promoted to domain controller status, and domain controllers can be demoted to member servers or stand-alone servers without reinstalling the operating system—the only way to demote a BDC under Windows NT. However, as always, it's preferable not to make more role changes than necessary.

### Active Directory

Active Directory is probably the most important new feature in the Windows 2000 Server family. It is a scalable, easily administered, fault-tolerant directory service that is required by Windows 2000 domain controllers and is also recommended for use on Windows 2000 DNS servers. Active Directory is covered in detail in Chapters 11 and 12, so we address it only briefly in this chapter. It is useful to review a few points before entering into a discussion about upgrading Windows NT domains to Windows 2000.

#### Active Directory Domains

Although Active Directory doesn't make fundamental changes to the way domains work for end users in Windows 2000, it does introduce some important domain structures that affect the way one should approach domain design. Active Directory, like the directory service in Windows NT, uses domains as the core unit of logical structure. Domains help organize the network structure to match the organization of the company, either politically or geographically. Each domain requires at least one domain controller (and preferably more) to store the domain information, with each domain controller being a master of the domain. See [Chapter 3](#) for more on domain planning.

Active Directory domains use DNS names for domain names instead of the NetBIOS naming structure of Windows NT domains (although NetBIOS names are generated for backward

compatibility). Active Directory domains are hierarchically organized, as required by DNS. In Active Directory, hierarchically organized groups of domains with a contiguous namespace are called trees, and groupings of trees with noncontiguous namespaces are called forests. For example, scribes.com and all subdomains (support.scribes.com, finance.scribes.com, etc.) would belong to a single tree; a different division of the company, wwowidgets.com, might have its own tree in the forest. Because the companies share their networks and are administered together, they belong to the same forest; the suppliers and partners of the companies would have their own forests. Trust relationships can be established between the forests as necessary to allow them to more easily do business with each other.

## Sites, Structural Domains, and Organizational Units

Active Directory also introduces the concepts of sites, structural domains, and organizational units (OUs). A site is defined as a group of one or more Internet Protocol (IP) subnets that share local area network (LAN) connectivity. Within a site there can be one or more domains, or a single domain can span multiple sites. See "Planning the Site Topology" later in this chapter for further information.

Structural domains are domains that contain no accounts; they simply serve as a root to lower level child domains. As such, structural domains make it easy to restructure child domains, and they also make replication between domains easier and faster, as all domains simply replicate with the structural domain, which serves as a sort of replication hub. For a further discussion, see the Real World note "Using Structural Domains," later in this chapter.

Organizational units (OUs) are very similar to domains in that they are containers for network objects such as user accounts and resources. Unlike domains, however, they do not mark a security boundary, and creating OUs doesn't require adding domain controllers (because OUs exist within a domain and therefore make use of the existing domain controller infrastructure). OUs in Active Directory provide an excellent way to provide organization within a domain without the need for additional security policies and domain controllers. They can also easily be converted to domains, and domains can easily be converted to OUs, making them very flexible. You'll find more on the uses and creation of OUs in [Chapter 11](#).

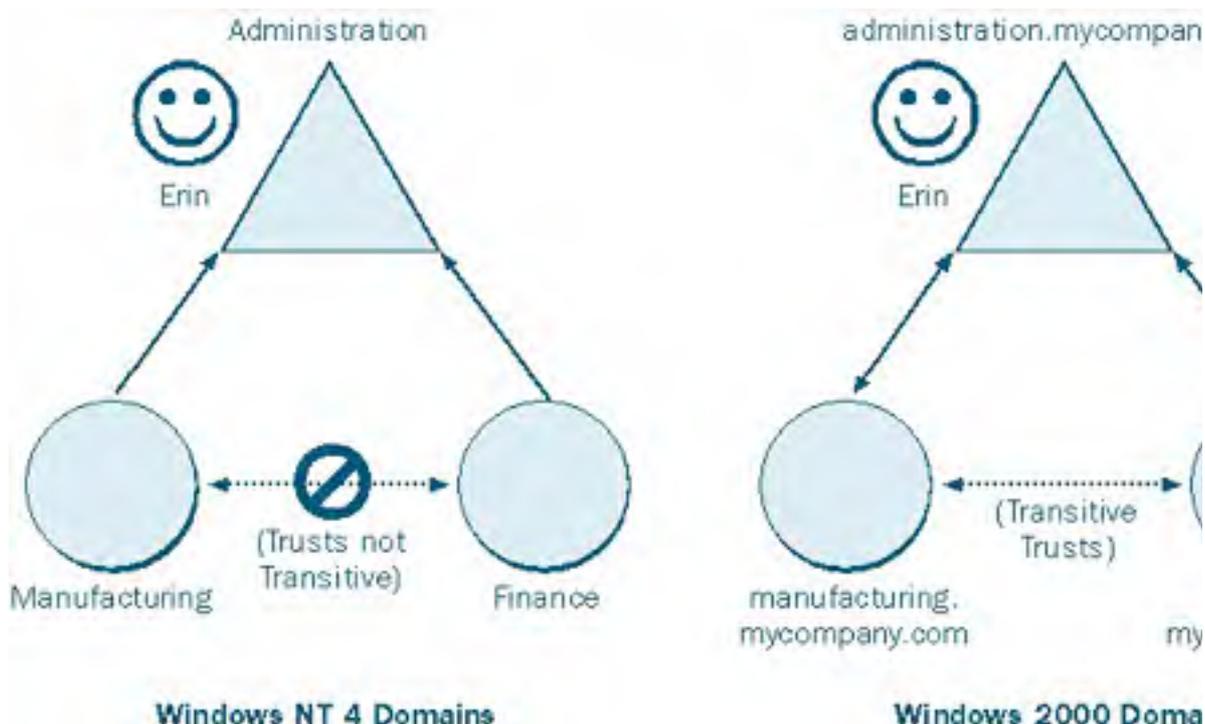

## Trust Relationships in Active Directory

Trust relationships complicate life in an enterprise with multiple Windows NT domains. Windows 2000 takes a big step toward simplification, although, as is often the case with improvements, things might get worse before they get better.

Simply stated, a *trust relationship* is a mechanism by which users and resources in one domain can be authenticated by a domain controller in another domain. For example, say that a user, Erin, in the Windows NT 4 domain Administration, wants to access a resource in the Windows NT 4 domain Manufacturing. When Erin attempts to access the resource, the resource must verify that she has an account that's allowed to access it. If a trust relationship is established so that the Manufacturing domain trusts the Administration domain, the resource in the Manufacturing domain will contact its local BDC or PDC, which will in turn query the PDC or a BDC in the Administration domain and verify that Erin has a valid account and that the account belongs to a group permitted to access the resource.

Among and between Windows NT 4 and earlier domains, all trusts are *nontransitive*, meaning that each trust is a one-way relationship between two domains that must be established explicitly. For two domains to trust each other, two separate trust relationships must be established—one for each direction.

A nontransitive trust is also strictly limited. For example, suppose that the domain Finance also trusts the domain Administration (as shown in Figure 7-1). When nontransitive trusts are involved, this statement tells you only that the Finance and Manufacturing domains both allow users from the Administration group access to their domains. It does not tell you anything about the relationship between the Finance and Manufacturing domains, nor does it indicate whether Administration, in turn, allows either Finance or Manufacturing to authenticate users. Each trust relationship must be established separately and explicitly.

**Figure 7-1.** Three domains under Windows NT 4 and under Windows 2000.

Active Directory introduces *transitive* trusts. Transitive trusts are always two-way, and they support pass-through authentication. Creating a trust between the Administration and Manufacturing domains (now probably called `administration.yourcompany.com` and `manufacturing.yourcompany.com`) would thus automatically mean that users in each domain could be authenticated and be eligible to access resources in the other domain (though they'd still need to have proper permissions, of course).

Pass-through authentication comes into play with child domains. With Active Directory domains, users in the child domain can make use of the parent domain's trusts using the automatic transitive trust that is created between the child domain and the parent domain. For example, let's say you create a `widgets.manufacturing.yourcompany.com` child domain. Users in this domain are automatically eligible to access resources in the `manufacturing.yourcompany.com` domain (the parent domain) as well as the `yourcompany.com` domain (the parent domain of the parent domain, or the grandparent domain if you will).

Transitive trusts become available once a domain is upgraded to Active Directory. Despite some confusion over the matter, they do operate in mixed-mode domains, but they do not apply to remaining Windows NT domains in your company or to clients connected to Windows NT BDCs (these domains and clients rely on existing one-way nontransitive trusts). Explicit one-way trusts are also available between Active Directory-based domains, but they must be manually established.

### Real World

#### Whom Do You Trust?

The question of transitive trusts arises in large multidomained enterprises. But even there, it's not an issue until all of the Windows NT domain controllers have been permanently removed from a domain. Although there are advantages to having all domains be Windows 2000 domains, it's not necessary to rush to reach that point. In the meantime, the existing trusts remain in place during the upgrade process, and the only trusts that are added are the nontransitive ones that you explicitly and deliberately set. This means that if you are creating a new Windows 2000 domain, you have to manually create trusts with existing Windows NT domains.

Table 7-1 shows the possible trust relationships between different types of domains.

**Table 7-1.** Trust relationships between domains of different types

	<b>Windows NT Domain</b>	<b>Windows 2000 Domain (Same Forest)</b>	<b>Windows 2000 Domain (Different Forest)</b>
<b>Windows NT Domain</b>	One-way trust <sup>1</sup>	One-way trust <sup>1</sup>	One-way trust <sup>1</sup>
<b>Windows 2000 Domain</b>	One-way trust <sup>1</sup>	Two-way transitive trust (one-way trusts available)	One-way trust <sup>1</sup>

## Hardware Support

Without dispute, Windows NT has always been very particular about hardware. Users of Windows 95 and Windows 98 have long enjoyed broad device driver support, PnP, Power Management, IEEE 1394 (Firewire), and Universal Serial Bus (USB)—the latter in Windows 95 OSR 2.1 and Windows 98. Windows NT 4 and earlier versions lack support for pretty much all the previously listed features. Windows 2000 changes all of that.

Windows 2000 introduces top-of-the-line support for PnP, USB, IEEE 1394 (Firewire), and Advanced Configuration Power Interface (ACPI) device configuration and power management. Device support is also vastly improved and getting better now that Windows XP is Microsoft's primary desktop operating system (as most Windows XP drivers are backward-compatible with Windows 2000). In most cases, if the device was supported under Windows NT 4, it will be supported under Windows 2000 with a native Windows 2000 driver. However, the same is not always true for Windows 95/98, so check the Hardware Compatibility List (HCL) or contact the device manufacturer to determine whether the device is supported under Windows 2000.

An up-to-date, ACPI-compatible BIOS is required for full use of PnP and Power Management. Legacy Advanced Power Management (APM) and PnP BIOSs are supported, but their features are limited.

Device drivers in Windows 2000 have changed to enhance system stability and to increase the number of devices supported. The Win32 Driver Model (WDM) is now supported, enabling many drivers to work interchangeably with Windows 2000 and Windows 98 (as well as Windows XP). Device Driver Signing is also supported, and drivers that haven't been tested and digitally signed by Microsoft trigger an alert when installed. (Administrators can also create policies preventing unsigned drivers from being installed.) Changes have also been made to the driver model to prevent system instability and to facilitate PnP and Power Management, which unfortunately prevents some Windows NT drivers from working in Windows 2000. In addition, power management and PnP aren't available with Windows NT 4 drivers.

As in Windows NT 4, device drivers written for Windows 95, Windows 3.x, or MS-DOS will not work in Windows 2000. Windows XP drivers should, in most cases, work fine with Windows 2000.

## Software Support

Software support is an area in which Windows 2000 has some compatibility issues (and lags somewhat behind Windows XP). Like Windows NT 4, Windows 2000 might experience compatibility problems with MS-DOS and Windows 3.x programs (especially any that directly access the hardware). Windows 95/98 applications that don't explicitly support Windows NT or Windows 2000 might also run into problems. Nearly all Windows NT 4 applications run under Windows 2000.

Microsoft, recognizing the problem Windows 2000 has with earlier applications, has done a couple of things to address this issue. The first thing they did was release regular Application Compatibility Updates, which are available for download from Windows Update. These updates are a series of tweaks designed to make programs run that previously exhibited problems under Windows 2000. The second thing they did was provide special compatibility modes (as seen in Windows XP) that can be turned on by administrators, a feature that was added in Windows 2000 Service Pack 2 (see [Chapter 25](#) for more information). This allows users or administrators to run a program in a compatibility mode (once compatibility modes have been enabled) designed to simulate Windows 95, Windows 98, or Windows NT with various service packs.

Upgrading an existing Windows 95/98-based system presents additional complexities because vendors often have different versions of their software for Windows 95/98 and Windows NT/2000, or because the same application is installed differently depending on the operating system involved. Consequently, many applications require vendor-provided migration files (upgrade packs) during the operating system upgrade.

## Planning a Domain Upgrade

Upgrading a Windows NT domain to a Windows 2000 domain isn't quite the three-click process that you perform when upgrading a single Windows NT 4 workstation. In fact, considerable planning is necessary before you even start Windows 2000 Setup on the first computer. Some computers, such as the PDC and BDCs, must be upgraded in a specific order, with the PDC being upgraded first. Other computers, such as Windows NT member servers and stand-alone servers, as well as client computers, can be upgraded at any time before or after the actual domain is upgraded.

The following sections are essential for anyone planning a domain upgrade. They cover documenting an existing network, making a recovery plan, planning the Active Directory tree, and developing an upgrade strategy. Subsequent sections cover preparing for the upgrade, the actual upgrade process, and finally, switching an upgraded domain into native Windows 2000 mode.

An *in-place* domain upgrade is a domain upgrade that is performed while leaving the domain intact. Domains can also be upgraded by removing the PDC from the domain, leaving the BDCs to provide services. You upgrade the PDC to Windows 2000, test it, and then bring it back into the production domain.

### Upgrading vs. Migrating to a New Domain

If your current domain structure is unsatisfying, it might be tempting to start from scratch, migrating accounts and resources into a fresh Active Directory domain. Resist this urge.

Migrating to a new domain is fraught with peril. A new domain name is required (a political nightmare in its own right), so all links need to be updated, and users need to adjust to logging onto a different domain. Also it's important to realize that *everyone* needs to sign off on a decision of this magnitude and that can be tough. The decision to migrate to a new domain structure is political, not technical.

With that said, it makes sense to look at migrating to a new domain or domain tree if doing so makes it possible to merge two or three separate domains or trees into a single domain or tree. Just remember to carefully weigh the pros and cons and get everyone's approval before opening up this can of worms.

## Documenting the Existing Network

The first step in planning an in-place domain upgrade is to document the current network structure. To do so, take an inventory of the following network attributes:

- The existing domain model and trusts
- The number and location of the domain controllers
- Account and resource domains
- DNS namespaces currently in use
- Application servers
- Windows NT Routing and Remote Access Service (RRAS) servers
- Whether LAN Manager Replication Service is in use
- Windows NT 3.51 servers

The sections that follow describe how to document each of these features.

### The Existing Domain Model

The type of domain structure, or model, that the existing Windows NT domains use determines how you implement the Windows 2000 Active Directory trees and forest. Table 7-2 summarizes the types of domain models that might be in use.

**Table 7-2.** Domain models available in Windows NT

Domain Model	Description
Single-domain	A single Windows NT domain
Single-master	One account domain and multiple resource domains
Multiple-master	Multiple account domains with two-way trusts between them and multiple resource domains that trust all master domains
Complete trust	Every domain is a resource domain and an account domain, with each domain trusting every other domain

### Existing Trust Relationships

Because trust relationships are preserved during the upgrade process, it's wise to check and document what trust relationships actually exist.

### Location and Number of Domain Controllers

Determine where the PDCs and all BDCs are located. The PDC must be upgraded first. The BDCs can be upgraded after that and obviously cannot serve their intended function during the actual upgrade.

Our preferred way of upgrading a domain is to purchase a new server to use as the PDC to upgrade. This ensures that the computer is modern, compatible, and fast enough to adequately run Microsoft Windows 2000 Server. It also minimizes the amount of junk residing on the hard drive and in the registry, providing the "closest to clean installation" experience possible.

### Account Domains and Resource Domains

Record the current number of account domains and resource domains. Also record how these domains are configured, and give some thought to whether you want to perform a domain restructure before or after you upgrade the network to Windows 2000.

### DNS Namespaces

If the company has already deployed any DNS, you should carefully document the namespaces currently in use. Domains cannot be renamed after they've been created, and they must be unique on the network, so it's important to have domain names that aren't already in use in the organization.

### Application Servers

A crucial and sometimes forgotten step in documenting a network is to make an inventory of the application servers. This includes all DNS, DHCP, and Windows Internet Name Service (WINS) servers, as well as application servers such as Microsoft Exchange servers, SQL servers, proxy servers, and so on. DNS is a required service on a Windows 2000 native domain, so some thought should go into determining whether you want to use existing DNS servers for this purpose, deploy new DNS servers, or use the domain controllers as DNS servers—which is what Microsoft suggests.

Also examine any NetWare servers in the environment and determine whether you want to synchronize Active Directory with Novell Directory Services (NDS). You should also check the release notes included on the Windows 2000 Server CD-ROM for any compatibility issues with the version of NetWare. [Chapter 21](#) discusses interoperating with NetWare.

Samba servers might require access to a real Windows NT 4 domain controller (instead of a Windows 2000 Server running the PDC emulator). Record the location and capabilities of any Samba servers on the network, and make a special note of whether they require access to Windows NT domain controllers (if so, you'll need to postpone switching the network to a native mode until this issue is cleared up).

Application servers such as earlier versions of Exchange, SQL, or media servers should also be evaluated for compatibility with the new Active Directory domains. Most servers will have no problems, but this is a good opportunity to double-check, as well as to reevaluate these servers' roles and their effectiveness on the network.

### **Windows NT RRAS Servers**

Windows NT 4 Routing and Remote Access (RRAS) servers need access to a *real* BDC for user information, and thus cease to work properly after the last BDC is upgraded. For this reason, upgrade any Windows NT 4 RRAS servers before you promote the last BDC. Alternatively, you can loosen the security settings for Active Directory such that Windows NT 4 RRAS servers can still work properly (this is one of the first questions in the Active Directory Setup Wizard), although this isn't optimal. Windows 2000 Server provides much more powerful and reliable RRAS services, so we recommend that you bite the bullet and upgrade or replace any old RRAS servers.

### **LAN Manager Replication Services**

The LAN Manager Replication Service feature of Windows NT isn't supported on Windows 2000 Server-based networks and needs to be disabled or replaced before a network upgrade. This service is used to replicate files (usually logon scripts) on servers using Import and Export directories.

It is replaced in Windows 2000 Server by the file replication service (FRS), which makes use of the system volume (SYSVOL) on domain controllers to replicate files to other domain controllers in a multiple-master fashion. It is automatically installed on domain controllers.

It is possible to maintain LAN Manager Replication Service on an Active Directory network if you really must, although we don't recommend it. For information on setting this up, see the *Microsoft Windows 2000 Server Resource Kit*.

### **Windows NT 3.51 Servers**

If there are still Windows NT 3.51 servers and/or clients on the network, it's time to upgrade or get rid of them. Windows NT 3.51 computers exhibit problems in an Active Directory domain that make them generally unsuitable for use. The problems include Windows NT 3.51 computers either denying access to user or group logons, or incorrectly granting access to users or groups that have been denied access (not a good thing). These difficulties occur because of the way in which Windows NT 3.51 generates access tokens when a user logs on to the server.

If you absolutely can't part with your Windows NT 3.51 (or earlier) computers, create or leave an existing domain running under Windows NT 4 and create the appropriate trust relationship between this domain and your Active Directory structure. Just keep them off Active Directory domains.

### **Making a Recovery Plan**

Upgrading a domain involves a fair amount of risk. If the PDC fails the upgrade and there aren't any BDCs available, the entire domain can be brought down. To protect your network from this unhappy possibility (and others), you need a recovery plan.

The following sections provide specific recommendations to follow to safeguard a network from disasters—just in case.

#### **Make Sure All Domains Have at Least One BDC**

Be sure that all domains you plan to upgrade have at least one BDC in addition to the PDC. This prevents the domain from being orphaned (or lost entirely) if the PDC fails the upgrade. Having a working and recently synchronized BDC also allows the network to function (almost) normally while you upgrade the PDC (some programs or services such as WINS don't like it when the PDC is gone).

#### **Back Up Each Computer Before Upgrading**

It's just common sense to back up the systems before upgrading them. This is perhaps overly cautious on some Windows NT desktop systems, but it really is important on servers, especially domain controllers. Also, make sure that you test the backups; there's nothing more useless than a corrupt backup tape.

## Synchronize All BDCs with the PDC

We've already said this, but it's worth repeating: synchronize the PDC with all of its replication partners before upgrading it. If the PDC fails the domain upgrade, you can promote a BDC to the PDC and the domain won't lose any changes.

## Take a BDC Offline for Backup

Having freshly synchronized BDCs and new tape backups of the PDC will protect you from most disasters. However, it's good insurance to take a freshly synchronized BDC offline before upgrading the PDC. This provides you with a quickly available, working backup of the domain as it existed before you started the upgrade process. If the upgraded PDC replicates bad domain information to the BDCs or the domain becomes damaged in some other way, having an offline backup allows you to go back and start over.

To prepare a BDC to act as an offline domain backup, synchronize the BDC with the PDC domain, back up the BDC, and then disconnect the network cable to the BDC. If a major disaster occurs after upgrading the PDC and it's necessary to restore the domain to its pre-Active Directory state, use the following steps:

1. Demote any Windows 2000 or later domain controllers on the network back to member server status.
2. Reconnect the offline BDC to the network.
3. Promote the formerly offline BDC to a PDC.
4. Synchronize the new PDC with the other BDCs on the network. This returns the domain to the state it was in immediately before you took the BDC offline.

All changes to your domain performed after taking the backup BDC offline will be lost if you bring the BDC back online and promote it to a PDC. Because of this, we recommend keeping a record of any changes you make (such as creating or deleting accounts, changing group memberships or trust relationships), so that in the event of a disaster you can manually re-create the lost changes.

## Relax

Don't let all of these warnings put you off. If you take precautions and the upgrade goes faultlessly, you won't have to resort to restoring backups or using other recovery mechanisms. That's good news. Just remember that no one ever lost a job because of being too prepared.

## Plan the Active Directory Tree

There are several steps you should take in planning the Active Directory tree, including defining the DNS namespace and creating the initial tree structure. This section briefly covers these steps. More detailed information on planning the namespace and the domain structure can be found in [Chapter 3](#).

**Define the Namespace** When deciding how to implement a DNS namespace, you usually need to decide whether to use an existing DNS namespace and create the root domain with an existing domain name or create a new root domain and associated DNS namespace. The decision is crucial because the root domain can't be easily deleted or renamed; you're pretty much stuck with it. (You can change or delete the root domain if you really must, but it involves taking down the entire domain—not a whole lot of fun.) Domain names are also highly political in nature, so if you're fond of your job, don't create the domain structure and namespace without first getting the approval of the powers that be.

With that said, the following list summarizes the tasks necessary to define and implement the namespace. (The specifics of some of these tasks are given in the sections that follow.)

- Decide either that you can use an existing domain name for the root domain or that a new one is necessary.
- If you are going to use a new domain name, determine what constraints you have in the name selection process and go through the proper channels to pick the domain name.

- Set up the root domain to form the top level of the namespace, with a couple of domain controllers for redundancy.
- Set up one or more DNS servers for the root domain tree. The DNS server needs to support the service resource record (the DNS resource record for specifying the location of services) and should ideally support dynamic updates as well. Microsoft recommends installing DNS on each domain controller and storing the zone data in Active Directory—not a bad idea.
- Add the other domains as child domains under the root domain. This is an excellent time to perform a domain restructure or to at least consolidate some of the resource domains into OUs.

**Create the Initial Tree Structure** After you've decided on the DNS namespace, you're ready to plan the Active Directory tree in detail. For this chapter, we are going to assume that you have a single-tree forest, with all domains sharing a contiguous namespace. In practice, many companies will need to use a forest with multiple trees, each having its own namespace. However, the process is no different; each tree is constructed and then added to the forest in the same way.

The first domain that you upgrade to Windows 2000 (or create if you're using a multiple-master domain model that doesn't lend itself to consolidation under one of the current domains) needs to be the root domain. The root domain stores the configuration and schema for the entire Active Directory forest and cannot be renamed or deleted.

### Adapt to Specific Domain Models

Four domain models are available in Windows NT: the single-domain model, the single-master-domain model, the multiple-master-domain model, and the complete trust model (see Table 7-2 for a summary).

**Single-Domain Model** The Windows NT single-domain model consists of a single domain, with all accounts and resources stored together.

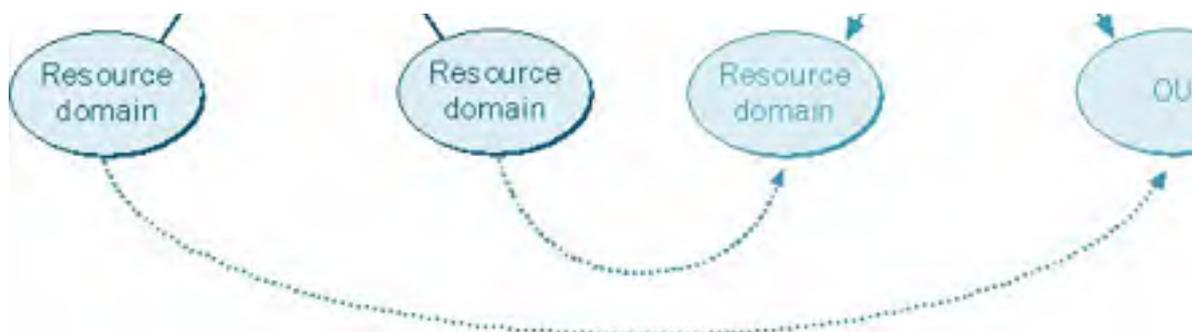

The single-domain model is easy to upgrade: the single domain under Windows NT becomes the root domain in Active Directory under Windows 2000. You can then use OUs to organize the accounts and resources and delegate some of the administrative burden.

**Single-Master-Domain Model** The Windows NT single-master-domain model consists of one master domain that contains all user accounts, and one or more resource domains that trust the master domain and only contain computer accounts and other resources.

If you have a single-master-domain model, make the former master domain the root of the tree and add the resource domains as child domains of the root. If the company has a centralized network structure, you might want to consider restructuring the domains into a single domain after you've upgraded the domains to Active Directory. You can use OUs either to mimic the resource domains or to organize them more logically, with the accounts and resources grouped and organized according to the company's structure.

Merging the resource domains back into a single domain offers a number of advantages. Because there are fewer domains to manage, the administrative burden is less. You can use OUs to create a detailed network structure without dealing with trusts. In addition, you can delegate administrative authority to the OUs, giving you the flexibility to handle the administrative tasks the way you want. Active Directory queries are also performed faster and more efficiently in a single domain. Finally, because OUs don't require domain controllers, there is the potential to free up some underused computing resources for other tasks. Figure 72 shows a single-master Windows NT domain converted to a Windows 2000 Active Directory tree.

**Figure 7-2.** A single-master Windows NT domain converted to a Windows 2000 Active Directory tree, with a resource domain converted to an OU after switching to native mode.

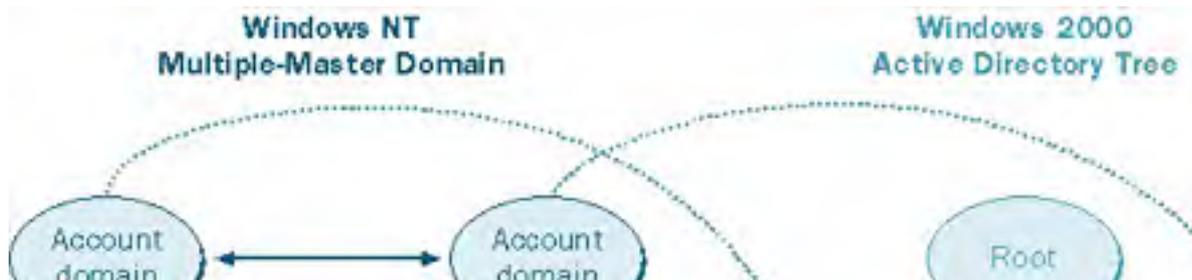

A company with a more decentralized organization, or one with different business units, might want to stick with multiple domains but convert its resource domains into full-fledged domains, with both resources and user accounts. (With Active Directory, there is no reason to keep distinct resource domains.) This arrangement allows users to be in the same domain as the resources that they use, reducing traffic and making it easier for users to find and access the resources they need. You should wait, however, until all relevant domains have been upgraded before moving the accounts because transitive trusts make moving accounts between domains much easier, and this type of trust is available only between Active Directory domains. Alternately, you can establish a two-way trust between the resource domains and the parent domain, but it usually makes more sense to wait until all domains are running in native mode.

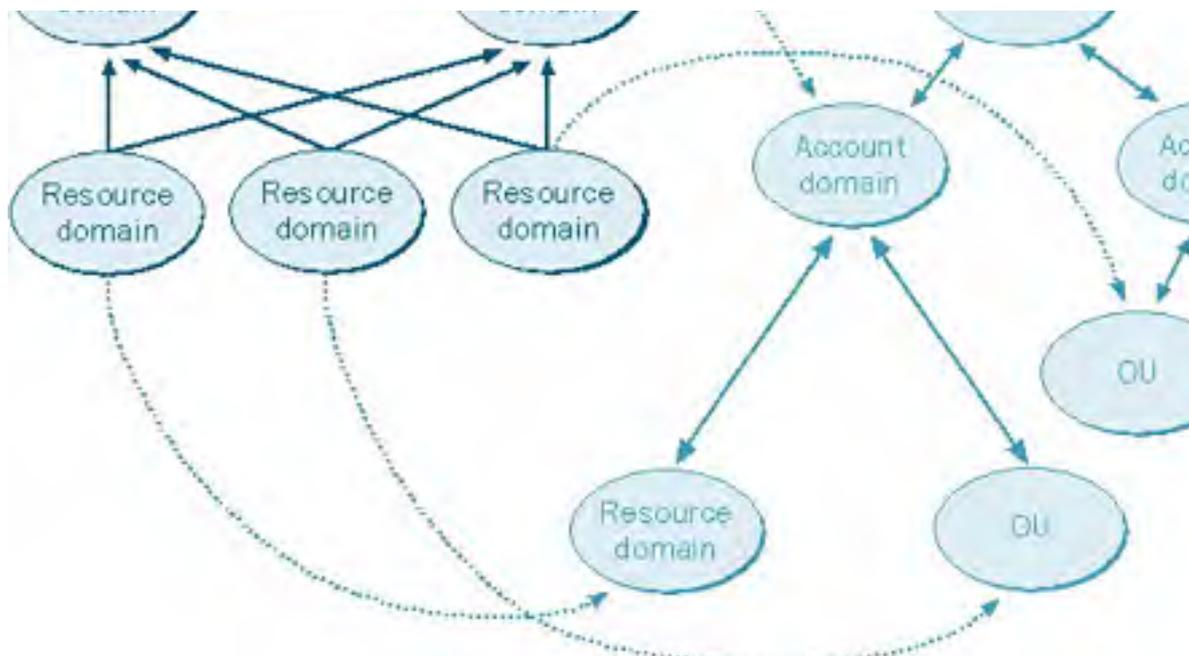

Third-party solutions can provide much of this organizational flexibility in Windows NT 4, with the intent of permitting companies to restructure their domains in a way that works well with Active Directory before they upgrade. For example, Fastlane Technologies sells a product called Fastlane Migrator (formerly DM Manager), which allows companies to upgrade Windows NT 4 domains into a multimaster structure that is very similar to that provided by Active Directory. Using this product allows a company to restructure its domains into a hierarchical domain structure that can be very easily upgraded to an Active Directory-based network once the company is ready, while benefiting from many of Active Directory's features in the meantime.

**Multiple-Master-Domain Model** The multiple-master-domain model in Windows NT consists of a network with two or more master domains that contain all the user accounts, and multiple resource domains that trust each master domain and contain all of the computer accounts and other resources. Very large networks use this model to circumvent the Windows NT limit of 40,000 objects per domain.

Because of the flexibility and advantages the single-domain model has to offer, many companies with a multiple-master-domain model choose to consolidate their domains into a single Windows 2000 domain, using OUs to hierarchically structure their network. If you choose to consolidate the domains, you should first perform the domain upgrade just as if you were going to preserve the existing domain structure, and then perform the domain consolidation. After the domains are upgraded, all accounts can be moved into the single domain without the need to reassign permissions on the objects.

If you want to create a single-domain tree (with a contiguous namespace) during the domain upgrade, you can use one of the existing domains for the root of the tree, or create a new root domain and add the other master domains as its children, as shown in Figure 7-3. You might want to consider using a structural domain for this root domain. (See the Real World sidebar "Using Structural Domains," later in this chapter.) Upgrade or create the root domain first. After this domain is up and running with a couple of domain controllers, upgrade the rest of the domains and add them to the tree.

**Figure 7-3.** A multiple-master Windows NT domain converted to a Windows 2000 Active Directory tree, with two resource domains converted to OUs after switching to native mode.

If you want to keep each master domain in an authoritative role, you can create a multiple-tree forest, with each master domain seeded as the root for a new tree in the forest. In this case, it doesn't matter which master domain you upgrade first, but you must upgrade the master domain for each tree before you upgrade the resource domains you plan to add to the tree.

## Real World

### Multiple-Master Domains and the Case for Domain Consolidation

The Windows NT multiple-master-domain model is widely used in larger organizations for a couple of reasons. First, it allows the network to grow beyond the limitations of the single Security Accounts Manager (SAM) that single domains and single-master domains use. The SAM in Windows NT is stored in the system registry, and once it grows past 40 MB, performance degradation is noticeable. This means that the practical limit for a domain is 40,000 objects, with a maximum of 20,000 user accounts. To have more user accounts or objects than this, Microsoft recommends moving to a multiple-master-domain model.

The second reason that companies use multiple-master domains under Windows NT is to allow for physically different network sites that don't possess wide area network (WAN) connections that are fast and reliable enough to allow domain controller replication to take place without consuming an inappropriate amount of the WAN bandwidth. Using a master domain in each site gets around this lack of adequate connectivity, because no replication takes place between master account domains and all of the WAN bandwidth is available for other uses.

The third reason to use a multiple-master Windows NT domain structure is to reflect the company's organization in cases where different parts of the company need to control their own resources and users. Each master account domain can have its own administrator or the administration can be centralized, depending on the desires of the company.

Active Directory deals with these issues effectively, permitting many companies to move to a single-domain model (or at least to reduce the number of domains) and gain the advantages that model has to offer. Active Directory stores all domain information in its database (which is external to the registry and free to grow in size), with each domain storing its part of the entire directory instead of one server storing the entire network schema, allowing you to scale the domain to approximately a million objects. No other domain is necessary; all organization can be done with OUs. You can also create multiple physical sites, with a single domain spanning all sites and intersite replication set up to make the best use of slow WAN links.

---

**Complete Trust Model** The Windows NT complete trust model involves multiple domains that all trust each other.

The Windows NT complete trust model is used most often by very decentralized companies or by companies that implemented domains in a piecemeal fashion and gradually connected them. The model provides a lot of autonomy and flexibility for each master domain, but it also entails a large administrative burden.

As with the multiple-master-domain model, many companies, when upgrading a domain that uses the complete trust model to Windows 2000, try to consolidate their domains into a single tree or even a single domain. However, if you want to maintain the autonomy of the current domain structure of the complete trust model, you can set up each current master domain as a new tree or (if necessary) as a new forest. When you create the Active Directory structure like this, you automatically reduce the amount of administration necessary, as all trusts between domains in an Active Directory tree or forest are automatically transitive.

When you upgrade the domain, create the root domain first, either by creating a new domain (structural or normal) or by upgrading an existing domain and seeding it as the root of the Active Directory tree. Once you have the root up and running with a couple of domain controllers, you can move on to upgrading the other domains and adding them as children of the root domain or as roots in new trees or forests. If necessary, after upgrading all domains and switching to native-mode operation, you can replace any transitive trusts with Windows NT-style one-way trusts to limit access within a forest or to provide external domains access to specific domains in the tree or forest.

A one-way trust can also be set up to permit a legacy Windows 3.51 or Windows NT 4 domain or a child domain of another forest (such as one belonging to a business partner) to access a specific domain in the tree or forest. When you set up an explicit one-way trust in Windows 2000, it works identically to trusts in Windows NT—that is, the trust is not transitive. If you grant a domain access to a single domain in the tree or forest, the trusted domain cannot access any other domain in the tree, even though the tree is linked with transitive trusts.

## Planning the Site Topology

*Sites*, an important new feature in Windows 2000, define the boundaries of LAN connectivity, making WAN links more efficient. When you set up sites that mark the sections of the network that have high-speed connectivity, Active Directory tunes the way it uses the WAN links by reducing the frequency of replication between sites and by directing clients' service requests (such as logons or directory searches) to domain controllers that are available locally.

Sites are independent of domains. Whereas domains typically mirror a company's logical organizational structure, sites mirror the physical network structure of a company. A single site might consist of one or more domains, trees, or even forests, and a single domain can span multiple sites. A site can consist of a single IP subnet (often the case because subnets frequently mark physical network boundaries) or multiple IP subnets, but all subnets must share reliable, high-speed connectivity to be a part of a single site.

In these days of Asynchronous Transfer Mode (ATM) WAN links, it is becoming increasingly common for a company's WAN link to be as fast (or sometimes faster) than an internal LAN. However, the WAN link charge might be based on usage, or a company might use the link heavily for real-time, bandwidth-intensive tasks such as video, reducing the available bandwidth. In such cases, you might still want to set up a site structure for the Active Directory forest to avoid burdening the WAN link with excessive replication and service requests.

When planning to upgrade a Windows NT domain to Windows 2000, it is important to plan the site topology so that you can set up the site structure promptly after upgrading. Ask yourself the following questions and make a record of your answers:

- What sites will you need to create in the Active Directory forest?
- What links are available between these sites, and how fast and expensive are they? Are they already heavily utilized, or is an abundance of bandwidth available?
- Are there any planned links between the sites?

- Are there any domains that will span physical sites, and if so, are the links between the sites fast enough to support this?

Two types of connections are available for intersite replication: point-to-point synchronous low-speed RPC and Simple Mail Transfer Protocol (SMTP). Any domains that span multiple sites must have at least a point-to-point synchronous low-speed RPC connection between the sites within the domain. This connection is required because you can't use SMTP for intersite replication between domain controllers in the same domain; you can use SMTP links only for schema, configuration, and Global Catalog (GC) information replication. Therefore, if you have multisite domains, double-check the link between the sites to make sure that you have adequate connectivity for this setup.

It's a good idea for there to be a Global Catalog server on each site to allow a local domain controller to service requests for any resource in the forest without having to use the WAN link. However, the Global Catalog server shouldn't be the same server as the infrastructure master unless there are no other domain controllers in the domain, as this configuration breaks the infrastructure master's ability to update other domain controllers in the domain (see [Chapter 12](#) for information about the infrastructure master role).

We also recommend placing at least one DNS server in each site, and having a minimum of two domain controllers per site for redundancy (this isn't as important for remote sites with a small number of clients).

Sites are easy to reconfigure, and should be tuned as your network links change.

## Real World

### Using Structural Domains

Companies that use the multiple-master-domain or complete trust model under Windows NT usually choose an existing domain to use as the root for their Active Directory tree. However, some organizations choose to use a structural domain as the root of their tree, with the former master domains as child domains.

A structural domain is simply a domain without user accounts or resources—it exists purely to form the structure of the domain (hence the name) as well as to aid in easy and efficient interdomain replication. Structural domains can be used to provide a domain structure that is well suited to further restructuring in the future. By placing one or more levels of structural domains in the Active Directory tree, you provide an unchanging anchor in the domain tree, under which you can move child domains without altering the higher level domain structure. At the same time, the structural root domain acts as a shield to the world so that changes in complexity are hidden behind it.

Structural domains are also useful for replication between sites, especially when accessing or replicating the Global Catalog (GC), which is the master catalog for all objects in the host domain's portion of Active Directory and a partial catalog of objects stored in other domains. If you have more than one site, you might choose to create a structural domain at the root that spans all sites and maintains a copy of the GC at each site. (You could also store a copy of the GC in the top-level local domain at each site and just use the structural domain as a link between the sites.) Having an on-site GC permits the local domains at all sites to concentrate on intrasite data processing and replication, with all intersite replication performed by the structural domain.

Using structural domains for replication also makes setting up and maintaining replication links easier. Child domains simply replicate upward to the parent domain, obviating the need to know the name of each domain you need to replicate with.

## More Info

For more information about structural domains, see *Microsoft Windows 2000 Distributed Systems Guide*.

## Developing an Upgrade Strategy

After documenting the existing network infrastructure, making a recovery plan, and designing the Active Directory trees and sites, you're ready to put it all together and create an actual upgrade plan. This section presents some general guidelines that apply to all domain upgrades, as well as some tips for specific domain models.

### **Make Sure the PDC Is Sufficiently Powerful**

Start the domain upgrade by carefully examining the current PDC. Although Windows 2000 uses peer-based, multiple-master domain controllers, the first domain controller retains extra services that in some cases cannot easily be moved to other domain controllers. These services include the Global Catalog server, the Operations Master, and the PDC emulator. (The PDC emulator provides services for Windows NT and Windows 95/98 clients and also performs some tasks in a pure Windows 2000 environment.) In other words, all domain controllers are equal, but the first Windows 2000 domain controller is a little more equal than the others, so you want that machine to be especially fast and powerful.

Our preferred method of dealing with this is by going out and buying a brand new, powerful computer, putting Windows NT 4 Server on it as a BDC with Service Pack 6a and the latest hot fixes. Promote the server to your PDC, let it sit for a little while, and then take it offline and perform the upgrade to Windows 2000 Server. This ensures that your first domain controller is on the most powerful and up-to-date hardware you have available, and also provides the closest to clean-install experience possible from an upgrade.

### **Create the New Root Domain Before Upgrading the PDC**

If you're moving from a multiple-master-domain or complete trust model and want to create a new domain to serve as the root of the domain tree, you need to do this before you upgrade the PDC. By the way, creating this new root domain, whether it's a structural domain or not, involves a brand new system (or at least a clean install) with Windows 2000. After you have created the new domain and have it running with a couple of domain controllers (as well as any new systems or clean installs), you can upgrade the PDC and join it to this new tree as a child domain.

### **Upgrade or Retire Any Incompatible Clients and Servers**

If you have any Windows NT 4 RRAS servers or computers running Windows NT 3.51 or earlier, upgrade or retire these systems as discussed earlier in this chapter.

Servers using the LAN Manager Replication Service should disable this service, because it's incompatible with Active Directory networks. The file replication service (FRS) feature of Windows 2000 Server domain controllers replaces it.

### **Upgrade the PDC First**

The first server to be upgraded must be the Windows NT PDC in the account domain you want to use as the root of the new Active Directory tree. This is true whether the tree you're creating is the first in the forest or the twentieth in the third forest—you always need to upgrade the PDC first if you want to upgrade the Windows NT domain instead of creating a new domain.

### **Upgrade the BDCs**

Upgrade the BDCs as soon as the first Windows 2000 Server domain controller is up and running properly. Upgrade BDCs one at a time, but pause before upgrading the last BDC. Verify that you've dealt with all incompatible clients and servers, and to be extra safe, take the last BDC offline for a while before upgrading it. If nothing erupts in flames, go ahead and upgrade it.

Make sure that the first domain controller is visible on the network when upgrading a BDC. When you upgrade a BDC, it only replicates with the PDC emulator. If the former PDC isn't available, the BDC tries to configure itself as the first domain controller in the domain, creating serious problems when the first domain controller comes back online.

### **Upgrade Member Servers and Clients Independently**

Upgrade member servers and workstations whenever you want—either before or after you upgrade the domain. Windows 2000 and Windows XP clients and member servers work perfectly well with Windows NT domains; however, the benefits of Active Directory aren't available to them until the domain is upgraded.

## **Schedule the Domain Upgrade Appropriately**

Schedule the domain upgrade at a time that will have the lowest impact on the user population. Although it's probably a forlorn hope, it's best to avoid upgrades during major projects and at the busiest times of year. Even perfect upgrades produce some impact on the users, especially if you perform any domain restructuring or consolidation.

## Preparing Domains and Computers for Upgrading

The first step in upgrading to Windows 2000 is to prepare the domains and the computers. This important step streamlines the upgrade process and makes it go as smoothly as possible.

### Preparing the Domains

We recommend that you perform the following actions before upgrading a Windows NT-based domain to Active Directory:

- Verify that all PDCs and BDCs that you plan to upgrade are running Windows NT 4 Server or Enterprise Edition with Service Pack 5 or later (Service Pack 6a is preferable).
- Clean up the directories and user accounts to eliminate old baggage. When you upgrade the domain, all user accounts are moved into Active Directory—and although Active Directory is extremely scalable, disused accounts do take up a decent chunk of hard disk space. There's no point in storing and replicating disused accounts indefinitely, so delete them before you upgrade.
- Clean out unused directories and uninstall outdated software.
- Disable trusts that you don't want preserved.
- Synchronize the PDC with all of the BDCs, and then implement the recovery plan described earlier in the section [Making a Recovery Plan](#), including taking one of the BDCs offline and disconnecting it from the network.

### Preparing the Computers

To prepare the computers for the upgrade, follow these steps for each computer involved:

1. Check the Windows 2000 system requirements to make sure that the computer meets them. Just because the computer fulfills the minimum system requirements doesn't necessarily mean that it's up to the tasks you have planned for it. (For a reminder of Microsoft's minimum system requirements for running Windows 2000 Server, as well as our recommendations for a more realistic set of requirements for a useful system, see Table 5-1.)

#### **Real World**

##### **Departing from the HCL**

Although it's true that many devices not in the HCL can be made to work most of the time, servers are needed all of the time. If you depart from the HCL when configuring a domain controller or other important server, you are taking an unjustifiable risk. Sooner or later, some traceable-to-the-hardware fault will show up, and you'll have no recourse. Microsoft will rightly point out that you should be using hardware from the HCL. The manufacturer of the hardware will shrug and say that they're "working on" the drivers. This is not a good position to be in.

If you have machines that are not 100 percent compatible and certified, try them out as clients. Windows XP and Windows 2000 will work perfectly well with hardware that's not on the HCL.

2. Check the HCL on the Microsoft Web site (<http://www.microsoft.com/hcl>). If updated drivers are available for the hardware, download and copy them to a floppy disk or available local disk so that you can use them during installation, if necessary. If a component in the system is not listed in the Microsoft HCL, you can visit the manufacturer's Web site or contact the manufacturer of the device to see if updated drivers are available. In general, you should probably replace components that are not listed as 100 percent compatible.

3. Read the Read1st.txt and Relnotes.doc files on the Windows 2000 CD-ROM to check for application or hardware issues.
4. If you're upgrading from Windows NT 4, make sure that Service Pack 5, or preferably, Service Pack 6a is installed.
5. Check the Event Viewer. Fix any problems *before* you upgrade.
6. Uninstall any virus protection programs you have installed, unless you know that they work under Windows 2000 without modification.
7. Perform and verify a full system backup.
8. Create or update the emergency repair disk.
9. Record the hardware configuration of the system for reference in case of a hardware conflict or problem. Items to record include installed devices, interrupt requests (IRQs), jumper settings, and the hard disk configurations.
10. Disable disk mirroring if you are using it. (You can enable it after you finish upgrading.)
11. Uncompress the hard disk. (This applies to Windows 95/98 clients only.)
12. Disconnect the serial cable to any serial port uninterruptible power supply (UPS) devices. (USB UPS devices can be left plugged in.)
13. Locate all drivers and get the Windows 2000 CD-ROM or connect to the network share with the Windows 2000 installation files.

Take a deep breath and begin. The remainder of this chapter covers upgrading systems to Windows 2000.

## Upgrading to Windows 2000 Professional from Windows 95/98

Although this book concentrates on Windows 2000 server issues, in all likelihood you'll spend more time performing client upgrades than server upgrades (although by now you're probably upgrading clients to Windows XP instead of Windows 2000 Professional, but the procedure is similar).

Windows 95/98 upgrades are the most difficult upgrade path to Windows 2000, and because of these difficulties, we recommend that you consider performing clean installations instead of upgrades whenever possible. Before deciding whether to upgrade or to perform new installations, read the sections that follow and test the upgrade on some clients that are representative of the client population. ([Chapter 5](#) covers performing multiple, identical installations of Windows 2000.)

### Real World

#### Why Windows 2000 Professional?

Windows 2000 Professional, and its successor Windows XP, are by far the best business clients that Microsoft has ever created. Although you can use Windows 98 and Windows Me clients on a corporate network, their lack of stability, security, and manageability make them poor choices, and we strongly urge you to replace these systems with Windows 2000 or Windows XP-based systems as appropriate.

Windows 2000 Professional has remarkable system stability, surpassing even that of Windows NT Workstation. System security is customizable; you can make the client's security very loose or extremely tight. (Windows NT 3.51 is qualified for C2-level security, and Windows NT 4 and Windows 2000 are also expected to receive this qualification when they emerge from the somewhat lengthy testing process.) Windows 2000 is also built for speed, with an efficient 32-bit, fully multithreaded, preemptive multitasking and symmetric multiprocessing (SMP) enabled kernel, allowing users to run more applications and to run those applications faster. Users with multiple processors and software written to take advantage of SMP can make use of a second processor—something not available in Windows 95/98. Windows 2000 is actually significantly faster in most applications than Windows 98 on equivalent hardware (assuming that the hardware meets the minimum system requirements for Windows 2000).

Windows 2000 Professional is designed to complement the Windows 2000 Server family, and as such provides the best client services for Windows 2000-based networks, greatly surpassing Windows NT 4 Workstation's excellent network facilities. On a Windows 2000 domain, Windows 2000 Professional clients can be managed remotely, make use of roving desktops, and take advantage of remotely installed applications. (Even the operating system can be installed remotely.)

The choice between Windows 2000 Professional and Windows XP is a bit of a tough decision—in general they're very similar. We recommend that you evaluate Windows XP Professional and determine whether its new features and enhanced core operating system warrant upgrading any systems, and carefully weigh the benefits versus the cost of upgrading. However, it's a slam-dunk for new systems—get Windows XP Professional.

### Difficulties Involved with Windows 95/98 Upgrades

A direct upgrade from Windows 95 or Windows 98 to Windows 2000 is possible, and, to paraphrase Dr. Samuel Johnson, it is not done well, but one is surprised to find it done at all (Windows Me cannot be upgraded to Windows 2000, although it can be upgraded to Windows XP). The difficulty lies in a fundamental difference in architectures: Windows 2000 is based on Windows NT, and Windows 95 and Windows 98 are heirs to MS-DOS/Windows 3.x (although obviously all of the later operating systems include huge amounts of new code). To further complicate matters, Windows 95 and 98 don't use the same drivers as Windows 2000 (unless you use WDM drivers in Windows 98), and applications are often coded differently for Windows 95/98 than they are for Windows 2000. These are major obstacles to overcome, although if Windows 2000 drivers are available for the system components, the driver issue can be easily dealt with.

The fact is that some Windows 95/98 applications won't run under Windows 2000 without modification. Thus, when performing an upgrade from Windows 95 or Windows 98, it is important to either uninstall applications that don't run without modification on both Windows 98 and Windows 2000 or to obtain an upgrade pack (also called a migration DLL) from the application vendor.

With that said, you *can* upgrade a Windows 95-based or Windows 98-based system to Windows 2000 Professional, and it can be made to work. However, a prudent person will perform a few upgrades on representative systems before deciding on the upgrade strategy.

Many application packages install different versions of the same program, depending on whether the installation was run under Windows 95/98 or Windows 2000. When this is the case, the Windows 95/98 version usually won't run under Windows 2000. If you are facing this situation, you need to obtain an upgrade pack or a migration DLL from the application vendor, or you can uninstall the application before the upgrade and then install the Windows 2000-compatible version afterward.

## Using a Dual Boot

If you must deal with legacy applications that work only under Windows 95/98, you can set up a Windows 95/98 and Windows 2000 dual boot (or you can test their functionality using a compatibility mode provided by Service Pack 2 and later, or using Windows XP, which has somewhat enhanced compatibility). Dual booting allows users to select the operating system at boot time, with each operating system installed on a separate partition or disk drive and maintaining its own applications. Although using a dual boot allows a lot of flexibility, it isn't something you want to do on a large scale because of the additional administrative work and extra resources required.

If you want to perform a dual boot with Windows 95/98, you should be aware of the following limitations:

- Windows 95/98 cannot access NTFS partitions or dynamic disks, although Windows 2000 can access all FAT and FAT32 partitions. Therefore, if you need to be able to access all data on the drive from both operating systems, you need to use FAT or FAT32 to format the partitions. However, using FAT or FAT32 eliminates many of the security advantages Windows 2000 has to offer, so use this solution with caution.
- Each application must be installed separately on each operating system.
- You need a different computer name for each operating system. The computer appears on the network as *name1* when it's booted into Windows 95 or Windows 98; it appears as *name2* when it's booted into Windows 2000.

If you are currently using a dual boot between Windows 95/98 and Windows NT, you can upgrade the Windows NT installation to Windows 2000 and then use a dual boot between Windows 95/98 and Windows 2000. However, in this situation, you can't upgrade the Windows 95/98 installation to Windows 2000.

To set up a dual boot, while in Windows 95/98, either launch Setup or, if you have Auto Insert Notification enabled, simply insert the Windows 2000 CD-ROM and click No when prompted to upgrade to Windows 2000. In the first window you see after launching Setup or clicking No, select Install A New Copy Of Windows 2000 to perform a clean install. See [Chapter 5](#) for a complete description of the installation process.

Besides a dual boot, you can use virtual computer products such as VMware Workstation or Connectix Virtual PC for Windows, which allow you to run operating systems such as Windows 95, Linux, or DOS within a virtual computing environment which is run as a Windows application. Although these products cost between \$200 and \$300, they provide a lot of flexibility, and are worth evaluating.

## Performing the Upgrade

You can launch Setup either from the Windows 2000 CD-ROM or from a network drive. In either case, first launch Windows 95 or Windows 98, close all programs, and uninstall any virus protection programs you have installed.

To launch Setup from the CD-ROM, insert the Windows 2000 CD-ROM. The Microsoft Windows 2000 CD dialog box appears if you have CD-ROM AutoPlay (Auto Insert Notification) enabled. (If this is not enabled, open the i386 folder on the CD-ROM and double-click Winnt32.exe.) This dialog box asks if you want to upgrade the version of Windows, as shown in Figure 7-4. Click Yes to start Setup.

**Figure 7-4.** The Microsoft Windows 2000 CD dialog box.

To upgrade to Windows 2000 Professional from across a network, launch the Winnt32.exe program on the network drive containing the Windows 2000 Advanced Server Setup files, and then proceed with Setup. After you've launched Setup, follow these steps to upgrade the computer to Windows 2000 Professional:

1. Select the Upgrade To Windows 2000 option, and then click Next (Figure 7-5). This upgrades the computer to Windows 2000 Professional while keeping the settings and programs intact.

**Figure 7-5.** The first screen of the Windows 2000 Setup Wizard.

2. Read through the licensing agreement, select the I Accept This Agreement option, and then click Next.
3. Click the hyperlink provided to connect to Microsoft's Web site to look for upgrade files you might need, and then click Next. Setup then scans the system for incompatible software and hardware.

4. If you have upgrade packs (also known as migration DLLs) for any of the programs, select the Yes, I Have Upgrade Packs option, and then click Add to select the folder containing the files. If you don't have upgrade packs, select the second option and click Next.
5. Indicate whether you want to upgrade the drive to NTFS in the next screen, and then click Next. (NTFS is necessary to use the security features of Windows 2000.)
6. If you know that you have hardware for which Windows 2000 doesn't have drivers, click Provide Files to indicate that you will give Setup updated drivers, and then click Next.
7. Setup displays an upgrade report that documents the status of the hardware and software. Read this report carefully to determine whether or not you still want to perform the upgrade. Uninstall programs that Setup reports might cause problems, and then click Next to let Setup upgrade the computer. The Setup program proceeds.

If you don't provide updated drivers, the devices with outdated drivers won't work until you install newer drivers. You can do this after installing Windows 2000 without causing problems.

## Upgrading to Windows 2000 Server from Windows NT

For existing Windows NT servers or clients, upgrading to Windows 2000 Server or Advanced Server is by far the easiest path. Doing so allows you to preserve all of the settings and, when upgrading the PDC, it allows you to preserve the domain and all of its user accounts and resources. Performing a clean installation (covered extensively in [Chapter 5](#)) is also an option, but it is unnecessary unless you are running a server operating system other than Windows NT 3.51 or Windows NT 4. (Servers running earlier versions of Windows NT are usually better off upgrading to 3.51 or 4 first and then upgrading to Windows 2000, rather than performing a clean install.)

Similarly, setting up a dual boot is not recommended unless you have some need to use the existing Windows NT server or client configuration part of the time. Dual booting between Windows NT 4 and Windows 2000 has a number of limitations; for more information, see "Dual-Boot Considerations" in [Chapter 5](#).

To upgrade to Windows 2000 Advanced Server with the Windows 2000 Advanced Server upgrade CD-ROM, you need to be running Windows NT 4 Enterprise Edition. If you have the full version of Windows 2000 Advanced Server, intended for new computers, you can upgrade from any of the following products:

- Windows NT 4 Enterprise Edition
- Windows NT 4 Terminal Server
- Windows NT 4 Server
- Windows NT 3.51 Server

After you've planned the domain upgrade and prepared the computer (as discussed earlier in this chapter), you're ready to begin the upgrade. If you're upgrading a PDC, synchronize with the domain's BDCs one last time before you start the upgrade.

Close all open programs and disable all virus protection programs, and then insert the Windows 2000 CD-ROM. The Microsoft Windows 2000 CD dialog box appears if you have CD-ROM AutoPlay (Auto Insert Notification) enabled. (If this is not enabled, open the i386 folder on the CD-ROM and double-click Winnt32.exe.) The dialog box asks if you want to upgrade the version of Windows. Click Yes to start Setup, and then follow these steps to upgrade to Windows 2000:

1. Select the Upgrade To Windows 2000 option, and then click Next. This upgrades the computer to Windows 2000 while keeping the settings and programs intact.
2. Read through the licensing agreement, select the I Accept This Agreement option, and then click Next.
3. If Setup finds hardware that isn't compatible with Windows 2000, it lists it in the next screen. Select the incompatible hardware and click Have Disk to provide updated Windows 2000 drivers for the device, and then click Next. At this point, Setup reboots, installs Windows 2000, and then reboots into the now upgraded operating system.
4. If you are upgrading a PDC or BDC, the Active Directory Installation Wizard starts. See [Chapter 11](#) for information on how to use this wizard to install Active Directory and a DNS server if you want to deploy both services on the domain controller (a good idea).

## Switching Domain Operational Modes

After you upgrade the PDC of a Windows NT 4 domain to Windows 2000, the Active Directory domain and the forest in which it was seeded operate in *mixed mode*. While a domain is in mixed mode, Windows NT 4 BDCs and Windows 2000 domain controllers can coexist on the network.

Most companies will find themselves remaining in mixed mode for some time to ensure compatibility with existing Windows NT 4 BDCs or other servers such as Samba that need access to a "real" NT 4 BDC. However, there are advantages to using the Windows 2000 Server native mode, as described in Table 7-4.

Microsoft recommends a speedy switch to Windows 2000 native mode; however we recommend a more cautious approach. Running in mixed mode also allows nervous network administrators a chance to start using Active Directory in a limited manner without losing their Windows NT 4 safety net. Wait until it's completely clear there is no need for NT 4 BDCs before making the domain mode upgrade, because once you've upgraded the domain mode, there is no going back.

Windows NT 4 member servers work in a Windows 2000 native-mode domain, as do Windows NT 4-based and Windows 95/98-based clients (however Windows 95/98 clients should install the directory services client from the Windows 2000 CD, and Windows NT 4 clients from <http://www.microsoft.com/ntserver/nts/downloads/other/adsi25/x86.asp>). Native mode refers only to the domain controllers, not to all machines in the domain.

**Table 7-4.** *The differences among Windows NT 4 domains, Windows 2000 mixed-mode domains, and Windows 2000 native-mode domains*

Feature	Windows NT 4	Windows 2000 Mixed Mode	Windows 2000 Native Mode
Supported domain controllers	Windows NT 4, 3.51 BDCs	Windows 2000, Windows NT 4 BDCs	Windows 2000
Objects per domain	Fewer than 40,000 (20,000 user accounts) recommended	Fewer than 40,000 (20,000 user accounts) recommended	Up to 1 million
Multimaster replication	No	Yes	Yes
Group types	Global, Local	Global, Local	Universal, Domain Global, Domain Local, Local
Nested groups	No	No	Yes
Cross-domain administration	Limited	Limited	Full
Password filters	Installed manually on each PDC and BDC	Installed manually on each domain controller	Installed automatically on all domain controllers
Queries using Desktop Change/Configuration Management	No	Only on Windows 2000 domain controllers	Yes
Authentication protocols	NTLM	NTLM, Kerberos	Kerberos
Group membership replication	Entire group membership list	Entire group membership list	Entire group membership list

**Real World**

### Existing Clients Still Work in Native Mode

It's important to understand that not all systems in the domain have to be running Windows 2000 or Windows XP to operate a native-mode domain. Native mode affects only the operation of the domain controllers. The issue of having legacy (Windows NT, Windows 95/98/Me, or DOS/Windows 3.x) systems in the domain is important, however, when it comes to planning WINS server deployment. As long as you have legacy clients and servers in the domain, you need WINS servers for NetBIOS name resolution (unless you have a small, nonrouted network that can handle NetBIOS name resolution using broadcast). In addition, you shouldn't turn off NetBIOS over TCP/IP, even if your network consists entirely of Windows 2000 and Windows XP systems, because legacy applications (which are many) still rely on NetBIOS calls for network communication.

When you've verified that no legacy domain controllers are needed (or will ever be needed) on the network, you can raise the domain functionality (upgrade the domain mode). To make the switch, log on to a domain controller using an administrator account and follow these steps:

Before eliminating or upgrading the last Windows NT 4 BDC or Windows 2000 domain controller and switching domain modes, we recommend taking it offline for a while, if possible. This allows you to test whether there are any remaining legacy applications or servers that need access to an older domain controller, before it's too late to go back.

1. Launch Active Directory Domains and Trusts from the Administrative Tools folder on the Programs menu.
2. Right-click the domain you want to convert to native mode and choose Properties from the shortcut menu.
3. Click Change Mode in the Properties dialog box, shown in Figure 7-6. Notice that the Domain Operation Mode box displays Mixed Mode.

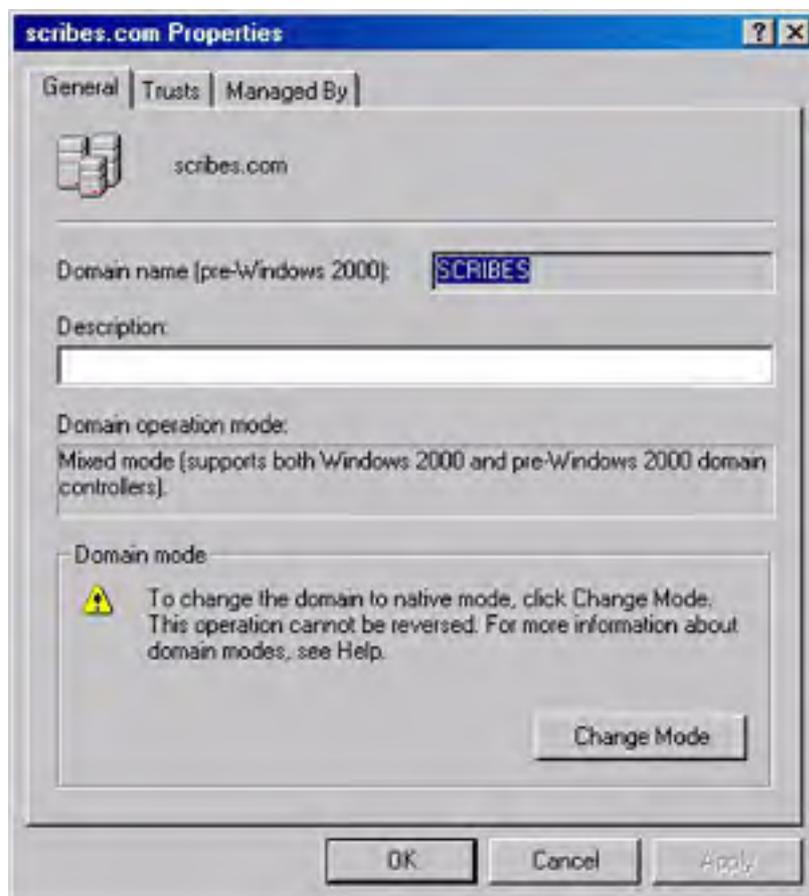

Figure 7-6. The Change Mode button.

4. When Windows 2000 asks you to verify the switch, click OK. Click OK in the next dialog box also.
5. Reboot the domain controller you made changes to as well as every domain controller in the domain after the modified domain controller reports that it is running in native mode.

Switching to native mode is an irreversible procedure. After switching to native mode, you cannot use Windows NT 4 domain controllers in the domain.

You can only upgrade the functionality of a forest once all domains within the forest are functioning in the desired native mode. After a forest is upgraded, you can only add domains operating in the same mode or higher. To add a domain with a lower functionality level, you'd have to create a whole new forest.

## **Summary**

Upgrading existing servers and clients to Windows 2000 involves even more planning than creating a domain from the ground up, and upgrading machines running Windows 95 and Windows 98 introduces additional complexity. Changing a network's structure before beginning your upgrade can make it function better under Active Directory. As the system administrator, you should recommend new installations on clients and upgraded installations on servers whenever possible. The next chapter moves on to the installation and configuration of printers—after the computers themselves, the most important component of many networks.

# Chapter 8

## **Installing and Managing Printers**

Back in the early, heady days of desktop personal computers, people talked a lot about the coming "paperless office." Alas, that day not only hasn't arrived, but in most companies, the paper recycling box is the biggest receptacle in the building!

The cost of basic printers has declined over the years, but increasingly, companies have invested in sophisticated high-speed color printers that enable users to handle jobs that once required an outside print shop. These are expensive both to buy and to use. Therefore, printer sharing remains an important function of enterprise networks. Setting up multiple users to share printers reduces cost and can increase printing output. Routine work can be directed to less expensive printers, long print jobs can be scheduled for off hours, and access to high-end printers can be limited.

All printer administration is done from the Printers And Faxes folder, which appears in Control Panel among other places. To administer a remote print server, connect to the print server in Windows Explorer or My Network Places and open the Printers And Faxes folder (if using a Microsoft Windows XP system) or the Printers folder (if using another version of Windows).

## Understanding the Basics

Before we get into the nitty-gritty of using Microsoft Windows 2000 Server as a print server, it is helpful for you to understand the basics of how Windows 2000 Server deals with printers and print servers.

### Printer Terminology

Printer terminology is a good deal more confusing than it has to be because of the historical use of different names for the same object. In Microsoft Windows NT 4, *print device* is the name for the actual printer, and *printer* designates the software interface. So in other words, *printer* is used to mean the logical entity. In a NetWare or OS/2 networking environment, the term *print queue* is used instead of *printer* (meaning the logical printer), but the net effect is the same.

Although there is currently some inconsistency about what terms to use, Microsoft now uses *printer* to mean the device that does the actual printing and *logical printer* to mean the software interface. In this book, we'll gladly conform to this convention and refer to the print device as the printer. We'll refer to the software interface as the logical printer or, occasionally, the printer driver.

You can have one logical printer associated with a single printer, or you can have several logical printers associated with a single printer. In this second arrangement, the logical printers can be configured at different priority levels so that one logical printer handles normal printing and another handles print jobs that should be printed during off-peak hours. For a printer that can use either PostScript or Printer Control Language (PCL), two logical printers allow users to choose which type of printing to do.

A single logical printer can also be associated with multiple physical printers. If all the print devices use the same printer driver, a single logical printer allows jobs to be sent to the first available physical printer. This arrangement is called a *printer pool*. The advantage of a printer pool is that an administrator can add or remove physical printers without affecting the users' configurations because the physical printers are interchangeable.

### Understanding Network Printers

Network printers are normal printers with additional network hardware such as a network interface card and additional memory, and sometimes a hard disk for spooling large documents. These printers run the appropriate protocol for the network (usually TCP/IP or Internetwork Packet Exchange [IPX] protocol) and have their own unique network address.

Network printers are the type most commonly used with print servers, as discussed later in this section, but these printers can also function by themselves on a network without a print server.

Network printers are popular in most companies because of their ease of configuration, printing speed, and flexibility in location relative to the print server and clients. No specialized hardware is required on the print server, which isn't always the case with print servers printing to multiple serial or parallel port printers. The direct connection to the network (at either 10 Mb/sec or 100 Mb/sec) also provides a much faster interface than the relatively slow parallel port often used by stand-alone print servers.

Network printers can also be set up without a print server, eliminating the cost of an additional computer. However, because no server is queuing the print jobs from clients, each user sees only his or her own documents in the print queue and can't see where a document is in relation to other documents waiting to print. Similarly, because no single print queue exists, the print jobs destined for this printer cannot be centrally managed, and only the user with the currently printing document sees any error messages (such as messages about paper jams). Finally, all preprint processing occurs on the user's computer, increasing the amount of time the computer is partially or completely unavailable for other tasks. For these reasons a print server is desirable with network printers.

One last point about network printers—many of the newer ones support Internet Printing using the Internet Printing Protocol (IPP). The Internet Printing feature allows a user with sufficient permissions and Microsoft Internet Explorer 4 or later to print to an Internet Printing-enabled printer from anywhere in the world (or from the user's intranet), not just from the local network.

## Understanding Print Servers

*Print servers* are computers (or sometimes network appliances) that manage the communications between printers and the client computers that want to print to the printers.

Microsoft Windows 2000 Professional and the various Windows 2000 Server versions work as print servers; however, Windows 2000 Professional can support a maximum of only 10 simultaneous users and is unable to support Macintosh or NetWare clients. Windows 2000 Server doesn't have these limitations.

Generally, there are two approaches to print servers. Microsoft's approach in Windows 2000 and Windows NT is to have a print server that is fairly "intelligent," providing clients with appropriate printer drivers and maintaining the printer queue, as well as handling communication between the printers and the client computers.

In contrast, UNIX (and some companies such as Intel and Milan) uses a relatively "dumb" print server. The most popular form of dumb print server is the Line Printer Daemon (LPD). A dumb print server usually acts strictly as an interface between the network and the printer, with each client maintaining its own printer queue. The LPD service runs either on a UNIX server, on a network appliance that provides LPD and network access functionality, or within a printer connected directly to the network. Clients use the Line Printer Remote (LPR) service—an integral part of UNIX and optional in Windows 2000 and Windows NT—to communicate with the LPD service, which then communicates with the printer.

Windows 2000 Server can also be an LPD server for compatibility with UNIX clients and other clients using the LPR service.

Because of the limitations of the LPD service, Windows 2000 and Windows NT print servers are almost always used instead of LPD servers when the network consists mostly of Windows clients. In a mixed UNIX and Windows environment, the LPD service can be installed on a Windows 2000 print server to provide printing services to UNIX clients. A common alternative is for Windows print servers to connect to printers using the LPD service (either on the printer or by connecting to a device running the LPD service), just as if they were normal network printers. In this scenario Windows clients have the benefits of a standard Windows print server while maintaining compatibility with UNIX clients, who interface directly with the LPD service associated with the printer.

### Real World

#### The Line Printer Daemon Service

Printers are often plugged in to a small network device or a UNIX server running the Line Printer Daemon (LPD) service. Devices or computers running LPD are called print servers, although they don't operate in the same manner as Windows 2000 or Windows NT print servers.

The LPD service acts as a network gateway for printers to communicate with UNIX clients or other clients using the Line Printer Remote (LPR) service, and many network printers come with the LPD service built in. Printers that lack a network interface can be connected to a device or computer running LPD, which then acts as a network interface card for the printer providing the LPD's usual function of allowing UNIX clients to print to the attached device. Printers using a print server running LPD can be accessed only by clients running the LPR service—an integral part of UNIX and an optional part of Windows and some other operating systems.

Usually if a printer using the LPD service needs to be accessed by Windows clients, a Windows 2000 or Windows NT print server connects to the LPD and shares the printer out as if it were directly attached to the Windows print server instead of through LPD. The Windows print server holds the printer queue and then sends each print job to LPD, which passes the job to the printer. Alternately (or in some cases, additionally), the Windows 2000 server can connect directly to the printer using either a standard TCP/IP printer port or the LPR service, and then run the LPD service to provide print functionality to both Windows and UNIX clients.

## Methods of Connecting Printers to Print Servers

Printers can be directly connected to the print server by a network connection to a network printer or with a parallel or serial port connection, although the latter has generally fallen out of favor because of the amount of processing power consumed by managing the ports. USB (Universal Serial Bus) and IEEE 1394 (Firewire or iLink) printers eliminate some of the disadvantages of connecting printers directly to the print server, but by far the most popular way to connect printers to a print server is using a network connection.

Network printers have built-in network cards and usually additional memory (and sometimes even hard disks). These printers run the appropriate protocol in use on the network (usually TCP/IP or IPX) and have their own unique network addresses.

As mentioned in the earlier section [Understanding Network Printers](#), a network connection provides increased bandwidth to a printer. However, more important than the increased bandwidth is the processing power conserved by using a network connection compared with a parallel port connection. The high CPU use of parallel and serial port printers causes undue strain on the print server and is one of the primary reasons network printers have become so popular.

Flexibility in locating network printers is another factor that has made network printers successful. Although a print server can manage printers in widely separated locations, increasing the number of printers connected to a single computer inevitably produces cabling inconveniences. It's often easier to plug printers into nearby hubs than it is to run cables (which have length limitations) to all the printers serviced by the print server.

## Advantages of Windows 2000 Print Servers

Windows 2000 and Windows NT print servers offer a number of advantages over printers directly connected to the network or connected to the network by a device running the LPD service. All documents are spooled to the print server instead of directly to the printer, allowing client computers to hand off documents to the print server quickly and to continue working while the server queues the documents and handles any additional processing. Because all documents are queued on the print server, all clients can view a centralized queue for the printer, see any error messages, and, if the users possess the proper permissions, administer the printer or printer queue.

Print servers can also provide a single audit log of all the documents printed by each user as well as any printer management performed. In addition, print servers provide central control over printer driver settings, and they can be set up to provide printer drivers to Windows 2000 and Windows NT clients who download them as needed. Windows clients can also locate printers by browsing the network or searching the Active Directory service. Bear in mind that any computer acting as a print server is partially occupied with printing tasks, so any other server applications being run on the same machine might suffer performance degradations. In general, file-sharing services take precedence, so printing throughput is reduced before file sharing is slowed.

## Understanding the Printing Process

There are a couple of aspects of the Windows printing process that are useful to understand: the actual sequence of events when you print a document, and the printer data types.

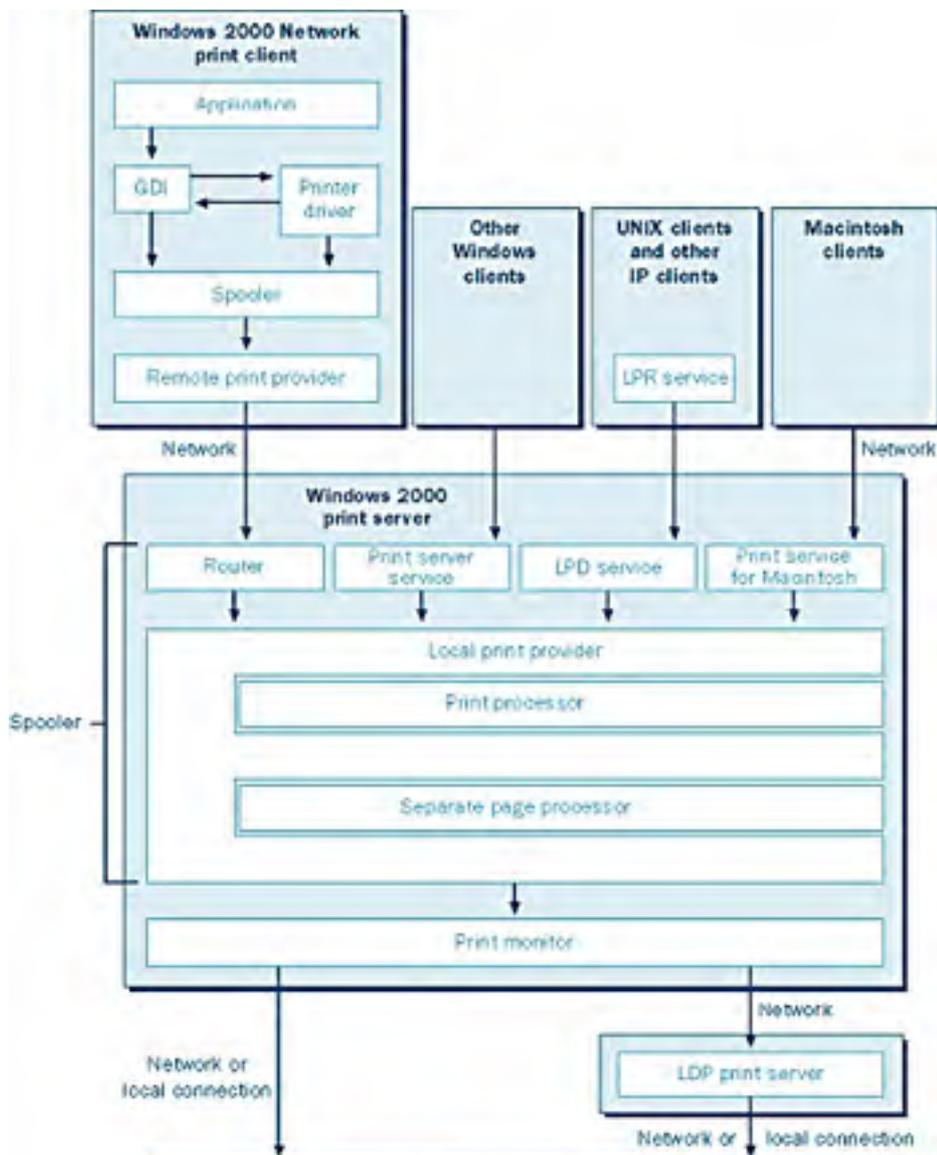

## What Happens When You Print a Document

When a Windows XP or Windows 2000 client prints a document, the following sequence of events occurs, as illustrated by Figure 8-1:

1. The application calls the Windows Graphical Device Interface (GDI), which calls the locally installed printer driver for the remote print device.
2. The GDI and the printer driver cooperate to render the document in the printer language of the printer.
3. Windows sends the rendered document with *enhanced metafile* (EMF) data type to the client side of the spooler (Winspool.drv).
4. Winspool.drv then makes a remote procedure call (RPC) connection with the Windows print server's spooler service (Spoolsvr.exe).
5. The print server's spooler service makes an application programming interface (API) call to the print server's print router (Spools.dll).

6. The print router communicates with the client's remote print provider (Win32spl.dll), which then establishes an RPC connection directly with the print server's spooler service and sends the print job over the network.
7. The document is saved in the print queue as an .SPL (spool) file by the local print provider.
8. When the print job reaches the front of the queue, the local print provider on the print server polls the print processor to determine whether the print job needs to be converted to a different data type before printing.
9. The print job moves to the Separator Page Processor (SPP) for the insertion of a separator page, if required.
10. The job is despoiled to the language monitor, and from there through the appropriate printer port (most likely a standard TCP/IP port) to the printer itself.
11. The printer receives the print job either in its entirety, or gradually as the print monitor feeds the printer at the appropriate rate to keep the printer's buffers full. The printer converts each page to a bitmap format and then prints the document.

Clients other than Windows 2000 and Windows XP process print jobs slightly differently. For example, LPR clients such as a UNIX client maintain their own print queues and interface with the LPD component of Windows 2000 Print Services for UNIX. See Figure 8-1 for further information, or consult the Windows 2000 Server Resource Kit.

**Figure 8-1.** *Windows 2000's interaction with various services to print a document.*

## **Printer Data Types**

After a print job reaches the beginning of the print queue, the local print provider polls the print processor to determine whether the print job is in the correct data type for the printer. If the print job is in the incorrect format, the print processor needs to convert it. The data type that is used to represent a print job is important not only because of the need to match the data type supported by the printer, but also because of performance considerations. Therefore, you need to understand the differences between the two main data types supported by the default Windows print processor. (Third-party print processors occasionally—but not often—supply additional data types.)

The most commonly used printer data type supported by Windows is *enhanced metafile* (EMF). This is the default data type for Windows 2000 or Windows NT clients using the popular PCL page description language. The EMF data type is a metafile format that allows better portability, smaller print jobs, and less time consumed on the client workstation preparing a document for printing. EMF files also generally consume somewhat less network bandwidth, but they do require more processing on the print server than do raw print jobs.

The second most commonly used data type is the *raw* data type, which is the default data type for PostScript printers and all clients not running Windows 2000 or Windows NT. Raw print jobs are processed entirely on the client computer and aren't modified at all by the print server.

The Windows 2000 print processor (Winprint) supports three other data types, although they aren't used as often. The data types are *raw (FF appended)*, *raw (FF auto)*, and *text*. *Raw (FF appended)* appends a form-feed character to the print job, which is required by some applications that otherwise don't print the last page when using the *raw* data type with PCL printers. The *raw (FF auto)* data type automatically checks for the presence of a trailing form-feed character and adds one if necessary. The *text* data type encodes the entire print job as plain ANSI text, and then adds any other print specification using the printer's factory default settings. This data type is useful for printers that don't operate properly with other data types.

## Planning Printer Deployment

Your company probably already has printers deployed, and hopefully you also have naming conventions and guidelines for putting new printers in place. Even so, you should still review this section, especially if you plan to use the new printer location feature of Windows 2000 and Active Directory, discussed later in this chapter. This feature allows users to more easily locate nearby printers that have the features they need. This section covers establishing naming conventions for printers, creating location-naming conventions for use with and without Active Directory, and choosing printers and sizing print servers to meet the network's needs.

### Establishing Printer Naming Conventions

In the past, a solid and effective printer naming convention was vital, as the printer name was the primary attribute a user had to go by when selecting a printer to use. With a network using Active Directory, users can now browse or search for printers based on their attributes and—just as important—their location. For this reason, in large organizations, printer location names (discussed in the next section) have become more important than actual printer names.

However, printer names are still important, especially if you choose not to enable printer location tracking, since they serve as a brief summary of the printer and its capabilities.

Like planning the network namespace, planning the naming convention you use for printers is important for maintaining a logical and user-friendly computing environment. For an enterprise, be sure to get management support for the convention. You want to establish a naming scheme that's actually enforceable in the company.

On Windows-based machines, you work with two names: the printer name and the share name. A *printer name* is the name given to a printer at the time of installation, and it can be any length up to 220 characters. A *share name* is the name given to the printer for use on the network, and it can be up to 80 characters long—although it's usually kept to 8 characters or fewer for compatibility with MS-DOS and Windows 3.x-based clients. Printer names show up on the print server and in the comments field when Windows clients browse for a printer. The share name is the name that all clients see when they browse for a printer, use the Add Printer Wizard, or use the Net Use command.

Some legacy applications experience problems with printers that have a fully qualified printer name (the computer name and printer share name combined) that exceeds 31 characters. This problem can also occur with printers with names shorter than 31 characters if the default printer's name exceeds 31 characters. In addition, MS-DOS and Windows 3.x clients can't access printers with share names longer than 8 characters followed by a 3-character extension. Clients using other operating systems might also have trouble with names longer than 31 characters or containing spaces or other special characters.

Effective printer naming methods convey as much relevant information about the printers as possible while keeping the name user friendly and compatible with all relevant clients. Usually the printer name used is the actual name of the printer followed by a number if multiple identical printers exist in the same location. Some companies might want to include the location of the printer in the printer name also, so an HP LaserJet 8100 laser printer might be named LaserJet8100\_1 or LaserJet8100\_Floor10\_1.

The share name needs to be shorter and is often a generic reference to the printer's capabilities. For example, the HP LaserJet 8100 printer just mentioned might use HPLaser1 as its share name. If you have a color laser printer, you might use ClrLaser as a share name. You can optionally use a three-letter extension on the share name and still maintain compatibility with MS-DOS clients—some companies use the extension to denote the number of the printer or to refer to its capabilities.

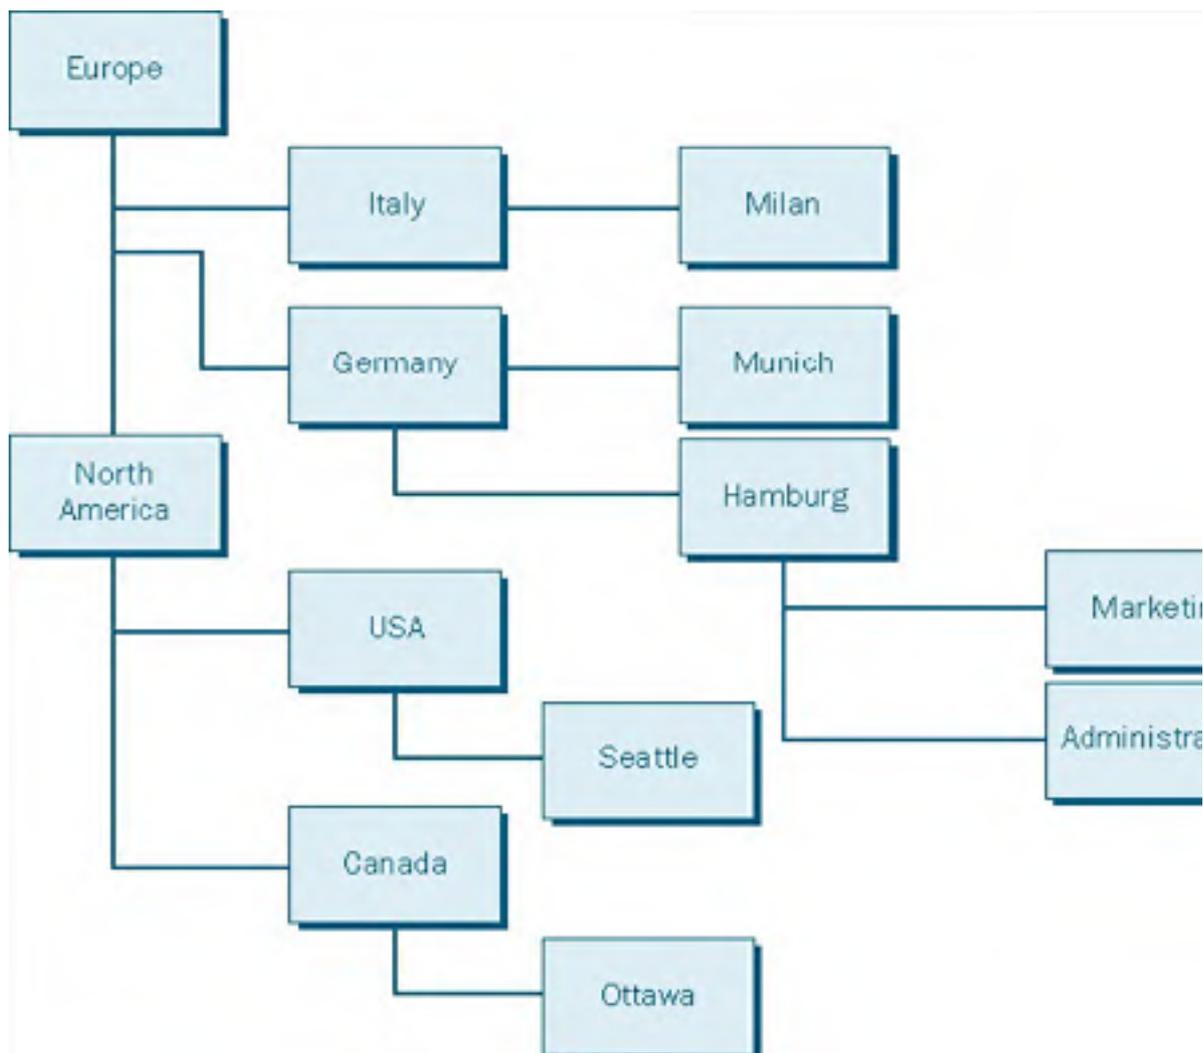

Avoid using spaces or other special characters in share names unless you maintain an all-Windows 2000 network. Otherwise, some clients, such as UNIX and MS-DOS, won't be able to recognize the names.

## Creating Location-Naming Conventions

In small organizations, finding printers is easy: stand up and look around, or ask the person sitting next to you.

This doesn't work as well in larger organizations where printers are widely scattered and of varying capabilities. A much easier way is to browse or search for printers in Active Directory based on the criteria you want, including printer features and printer location.

However, for printer locations to work, location names need to be carefully determined and consistently applied. Location names are similar in form to domain names and are written in the form *name/name/name/name*. They start with the most general location name and become progressively more specific. For example, a multinational corporation might have the location name structure shown in Figure 8-2.

**Figure 8-2.** A sample location name structure.

The Seattle location, for example, could be written NorthAmerica/USA/Seattle. Each part name can be a maximum of 32 characters and can contain any characters except the forward slash (/), which is reserved for use as a delimiter. The entire location name must be no longer than 260 characters, with a maximum of 256 levels.

If you're not using Active Directory to store printer information, you can still include location information with printers, although this approach has some limitations. To enter location information, type the location name in the General tab of the printer's Properties dialog box. When you do this, be careful and consistent with location names. Make sure that all administrators use the same name for a particular location, and keep the names short and easy to remember: users need to know the exact location names when they search for printers if Active Directory's location-browsing capabilities are unavailable. For more on printer location tracking, see "Using Printer Location Tracking" later in this chapter.

## Choosing Printers and Print Servers

Deploying the right printers and print servers is an important task. Although it isn't possible to give specific hardware recommendations, there are some generalizations that can be made even for an existing network. These tips apply any time you want to add a printer, add a print server, or evaluate how well the current deployment is serving your needs.

### Guidelines for Choosing Printers

Before deploying printers for the network, make sure that they adequately meet the users' requirements. To begin this process, first determine what kinds of printing services each group of users needs by considering such factors as print volume, graphics requirements, and features.

Some user populations require printer features such as collating, double-sided printing, envelope feeders, or large-format printing. Try to match the printer's duty cycle (how many pages the printer is designed to print each month) to the expected print volume. When a printer's duty cycle is consistently exceeded, you risk increased maintenance costs and repairs.

If you have a group of users in relatively close proximity, you can place heavy-duty laser printers in a centralized location for all users. This approach is usually more cost-effective than trying to deploy multiple, lower cost laser or inkjet printers. It also increases the number of features available to users and simplifies administration and maintenance chores. Even if users are scattered and have a range of needs, using a few high-volume printers is more practical than placing a cheap inkjet on every other user's desk. Just be careful not to place all the eggs in one basket by purchasing a single high-volume printer that will leave a whole group of users without printing service when the printer requires maintenance.

In the long term, laser printers are almost always less expensive for black-and-white printing than even the most cost-effective inkjet alternative. This is now usually the case for color printing also. Although inkjet printers are often better suited for printing photos, be aware of their slower speeds and higher consumable costs.

After determining the type of printers you need, check the Windows 2000 Hardware Compatibility List (HCL) to ascertain whether the printer is supported. Some newer printers might not be listed, so check whether the manufacturer provides Windows 2000 drivers and is in the process of getting the printer certified. If you already have a service contract for a particular manufacturer's printers, you'll probably want to stick to that brand to reduce maintenance headaches. Finally, determine the type of printer interface to use. You'll probably want to get printers with network interfaces built in. To directly connect the printers to a print server, consider printers with USB or IEEE 1394 (Firewire or iLink) interfaces for faster print speeds and easier configuration.

Try to keep printers and print servers on the same network segment as the users of the printer if you expect a high print volume. This approach minimizes the impact to users on other parts of the network. In any case, try to minimize the number of network hops a print job needs to take to get from users to their default printer.

### Guidelines for Choosing Print Servers

Sizing a print server is much like determining the requirements of any other type of server. Collect information and monitor any existing solutions to see where bottlenecks are, deploy the server, and then monitor and tune the server to make sure that it is achieving the performance requirements.

Unless you need to support a large volume of printing or extremely large or complex documents, print servers generally don't need expensive hardware. Often, computers that have become too slow for their original tasks will do admirably.

A print server must have enough disk space to hold all print jobs while they wait in the printer queue. The amount of space required depends both on the size of the print jobs and on how long the print queue will get. For best performance, use a fast, dedicated drive just for the print spool folder, and don't place any system files—especially the swap file—on this drive. Windows 2000 gives file sharing a higher priority than printer sharing, so if you're using the print server for both services, printing might be slowed to prevent a decline in file access performance.

To monitor the performance of print servers to determine whether they are performing optimally, launch the Performance snap-in from the Administrative Tools folder and add counters from the new *Print Queue* object under the Performance category.

## Real World

### Preparing for Print Server Failure

Many companies have a secondary print server in case the primary print server fails. When the primary print server fails, the administrator has three alternatives. One choice is to send out e-mail instructing users to choose ReserveServer2 for printing. This option is easiest for the administrator but, inevitably, some users just can't manage the switch.

A second option is for the administrator to switch the users from PrintServer1 to ReserveServer2, which normally has another function but can act as the print server if the primary server fails. Although this switching process requires some effort by the administrator, it usually takes less time than repairing the primary print server. More important, users can print unimpeded while the primary print server is being fixed. (The two network events that you interrupt at peril are printing and e-mail. When either one isn't working, the complaints are immediate and loud.)

A third method is the most transparent to the users and works because a print server—in fact, any server—can have more than one name. If the normal PrintServer1 goes offline, you can go to ReserveServer2 and add an alias (PrintServer1); from the point of view of the users and the network, this printer then becomes PrintServer1, and work continues uninterrupted. To give a server a secondary name, you'll need to modify the registry. Go to the registry key

```
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\LanmanServer\
```

and add the value *OptionalNames REG\_SZ String: [Alias]*. (Replace *Alias* with the server name.)

You'll need to reboot the server to see the change. All the usual warnings apply about not modifying the registry unless you have a saved copy. Also, if you're using Windows Internet Name Service (WINS), you'll have to add a static IP address for the duration, or WINS won't be able to find the server. When you're ready to bring the original Print Server1 back online, remove the alias. To monitor the performance of print servers to determine whether they are performing optimally, launch the Performance snap-in from the Administrative Tools folder and add counters from the new *Print Queue* object under the Performance category.

## Installing Printers

To add a printer to the system in Windows 2000, as in Windows NT 4 and Windows 95/98, you use the Add Printer Wizard. If you've configured printers in any version of Windows since Windows 95, you'll find that the process is similar in Windows 2000.

To change the default behavior of the Add Printer Wizard for clients, servers, or both, use the Group Policy snap-in, covered in [Chapter 9](#).

After adding a printer using the Add Printer Wizard, you'll need to set up the appropriate permissions for the printer, set up any installable options with which the printer is equipped, and set the printing defaults. See the [Changing Printer Options](#) section later in this chapter for more information.

To enable Macintosh clients to print to the print server, use the Windows 2000 Add Component Wizard to install Macintosh print services, and make sure that the server is running the AppleTalk protocol. To allow clients that use the LPR service (such as UNIX clients) to print to the server, install UNIX print services, and make sure that the LPD system service is started if it's not started automatically. You'll find more on UNIX printing in [Chapter 22](#) and more on Macintosh printing in [Chapter 23](#).

## Adding Local Printers

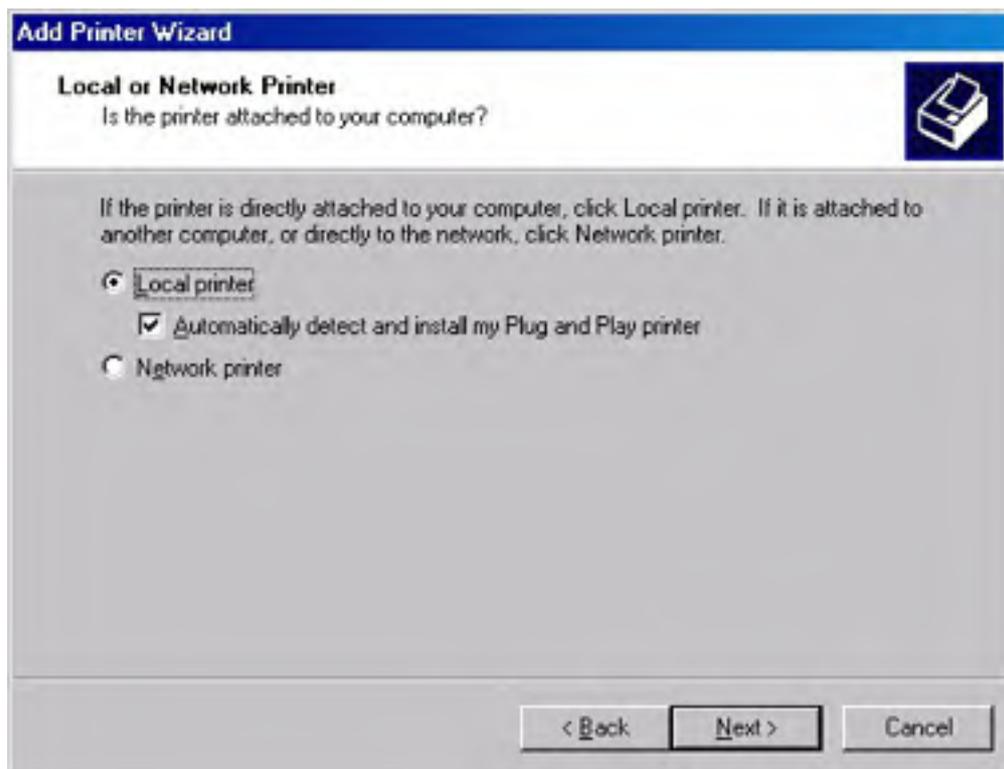

Physically connecting printers to the print server isn't popular these days, but sometimes you'll still want to do it.

If you're using a USB or IEEE 1394 connection to the printer, Windows automatically detects the printer and installs it on the server as soon as you plug the printer into the server (although you are prompted for drivers). In Windows 2000 Server, the Add Printer Wizard automatically shares the printer and publishes it in Active Directory unless you select Do Not Share This Printer on the Printer Sharing screen. In Windows 2000 Professional, the default is to not share the printer unless you select Share As on the Printer Sharing screen—then the printer is shared and published.

Whether the computer is a print server or simply a workstation, understanding the process of installing a printer under Windows 2000 is helpful. (All versions of Windows 2000 handle adding local printers in the same way.) To use the Add Printer Wizard to set up a local printer that is physically connected to the system, follow these steps:

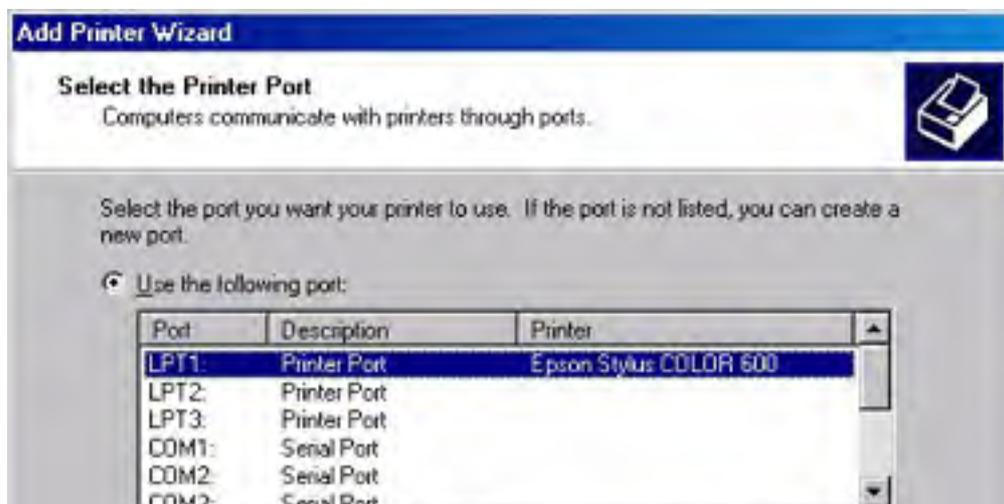

1. Connect the printer to the appropriate port on the server.
2. Click Start, choose Settings, and then click Printers to open the Printers folder.
3. Double-click the Add Printer icon to start the Add Printer Wizard.
4. Click Next in the first screen to begin using the Add Printer Wizard.
5. Select the Local Printer option, select the Automatically Detect My Printer check box (Figure 8-3), and then click Next.

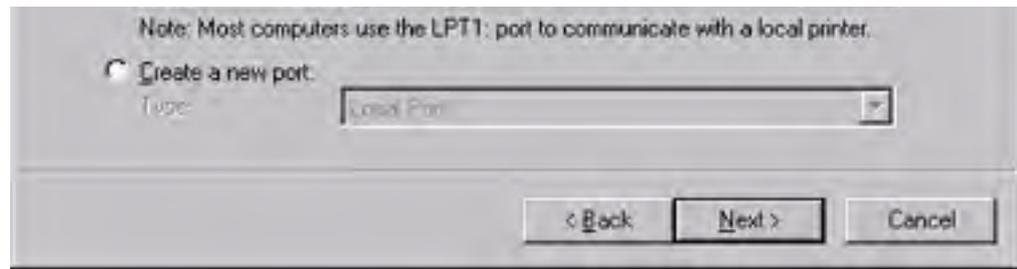

If you're installing a Plug and Play (PnP) printer, always select the Automatically Detect My Printer check box in the Add Printer Wizard. If you don't select this option, Windows 2000 detects the printer the next time the system is rebooted and attempts to install the printer a second time.

**Figure 8-3.** The Local Or Network Printer screen of the Add Printer Wizard.

6. Click Yes. Windows 2000 displays the New Hardware Found dialog box when it locates the printer. If Windows 2000 has the appropriate drivers for the device, it installs them automatically.
7. If the printer wasn't detected, run the Add Printer Wizard again, but this time clear the Automatically Detect My Printer check box in the Local Or Network Printer screen, and then click Next.
8. In the Select The Printer Port screen, shown in Figure 8-4, choose the port the printer is attached to, and then click Next.
9. Select the manufacturer and model of the printer from the Manufacturers and Printers dialog boxes and click Next. Or, click Windows Update to view a list of updated drivers and click Have Disk to provide a driver disk.
10. Enter a name for the printer in the Printer Name text box. Enter the share name for the printer on the network.
11. Choose whether to share the printer by selecting either Do Not Share This Printer or Share As. If Share As is selected, provide a share name for the printer.

**Figure 8-4.** *The Select The Printer Port screen of the Add Printer Wizard.*

12. Enter the location name for the printer in the Location box. (See the [Creating Location-Naming Conventions](#) section earlier in this chapter for information on choosing a location-naming scheme.) Describe the capabilities of the printer in the Comments text box.
13. Print a test page by clicking Yes in the Print Test Page screen, and then click Next to display a summary of the printer installation. To change the installation choices, click Back; otherwise, click Finish to complete the installation.

## Sharing Printers on a Network

Adding local printers is obviously not the most efficient way to deploy printers. To share printers on a network, you have several options. As the following sections explain, you can add a printer shared by another computer, add TCP/IP printers on a TCP/IP printer port, add printers on an LPR printer port, or add an AppleTalk printing device.

### Adding Printers Shared by Another Computer

After using a direct physical connection, the next simplest way to connect to a printer is to use a shared printer on the network, although you can't turn around and share these connections out.

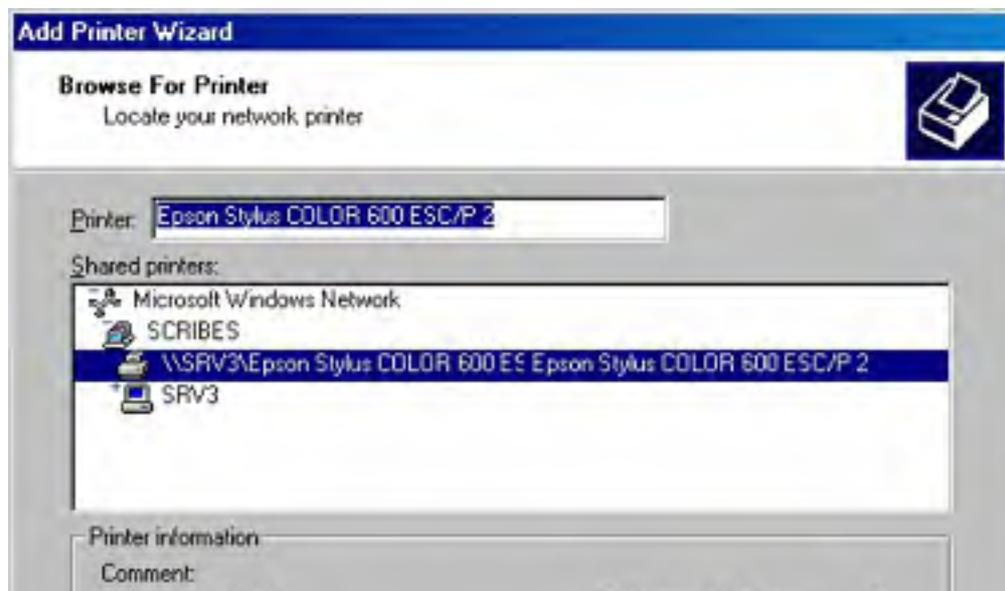

The computer that is sharing the printer might be a print server or simply a workstation with an attached printer. To add a printer to a Windows 2000 system that is already being shared by a server or workstation on the network, follow these steps:

1. Configure the computer sharing the printer with the proper protocol; make sure that the printer is shared on the network and that you have proper permissions to access it.
2. For a printer connected to a NetWare server, make sure that you have the NWLink IPX/SPX/NetBIOS Compatible Transport Protocol and Gateway Service for NetWare installed, enabled, and active on the Windows 2000 print server.

Using Gateway Service for NetWare requires a certain amount of processing power from the print server, decreasing the print server's throughput. Microsoft clients that use a NetWare printer heavily should install the Client Service for NetWare and print directly to the NetWare print server instead of printing through the Windows 2000 server.

3. Click Start, choose Settings, and then click Printers to open the Printers folder.
4. Double-click Add Printer to start the Add Printer Wizard.
5. Select the Network Printer option. Enter the printer name in the Name text box, or click Next to browse for the printer. If you choose to browse for a printer, Windows 2000 displays the Browse For Printer screen, shown in Figure 8-5.

If the printers are published in Active Directory, you can select Find A Printer In The Directory and click Next to search Active Directory by printer location or features.

**Figure 8-5.** The Browse For Printer screen of the Add Printer Wizard.

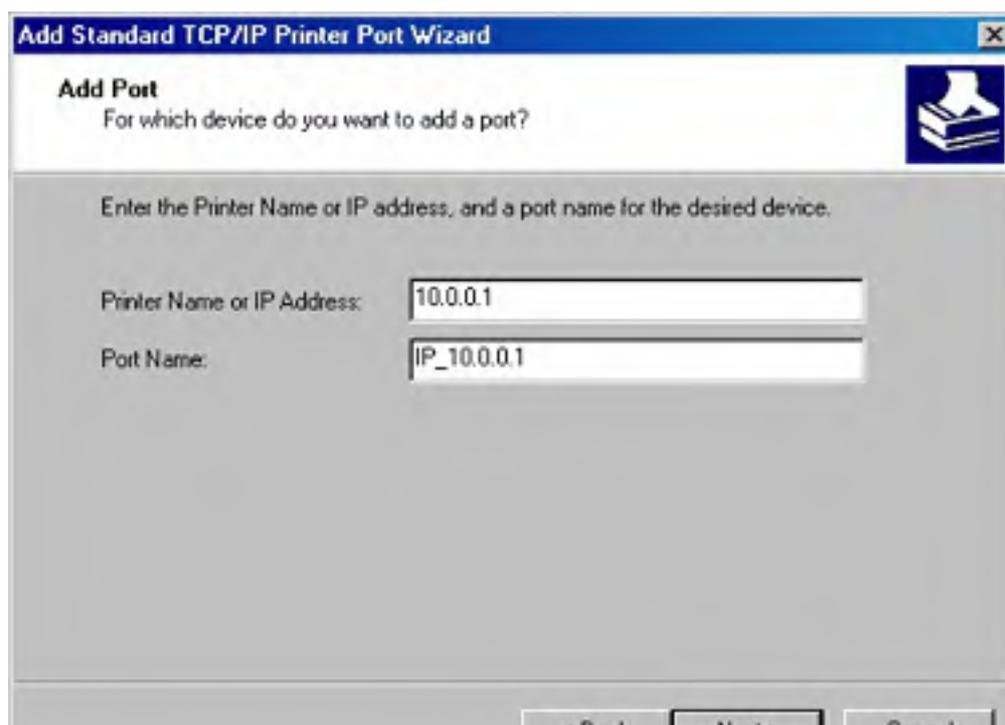

6. Choose the printer from the list of shared printers, and then click Next.
7. If you've already installed one or more printers on the server, choose whether this printer is to be the default printer by clicking Yes or No and then clicking Next. The Add Printer Wizard then displays a summary of the printer installation.
8. Click Finish, or click Back to make changes to the installation.

## Adding TCP/IP Printers on a TCP/IP Printer Port

The best solution for connecting to network printers is to use a standard TCP/IP printer port. The Windows 2000 standard TCP/IP printer port supports network printers that use TCP/IP, as well as printers connected to network devices such as the Hewlett-Packard JetDirect or the Intel NetPort.

To set up a network-based printer through a standard TCP/IP printer port—which Windows 2000 treats as a local port—follow these steps:

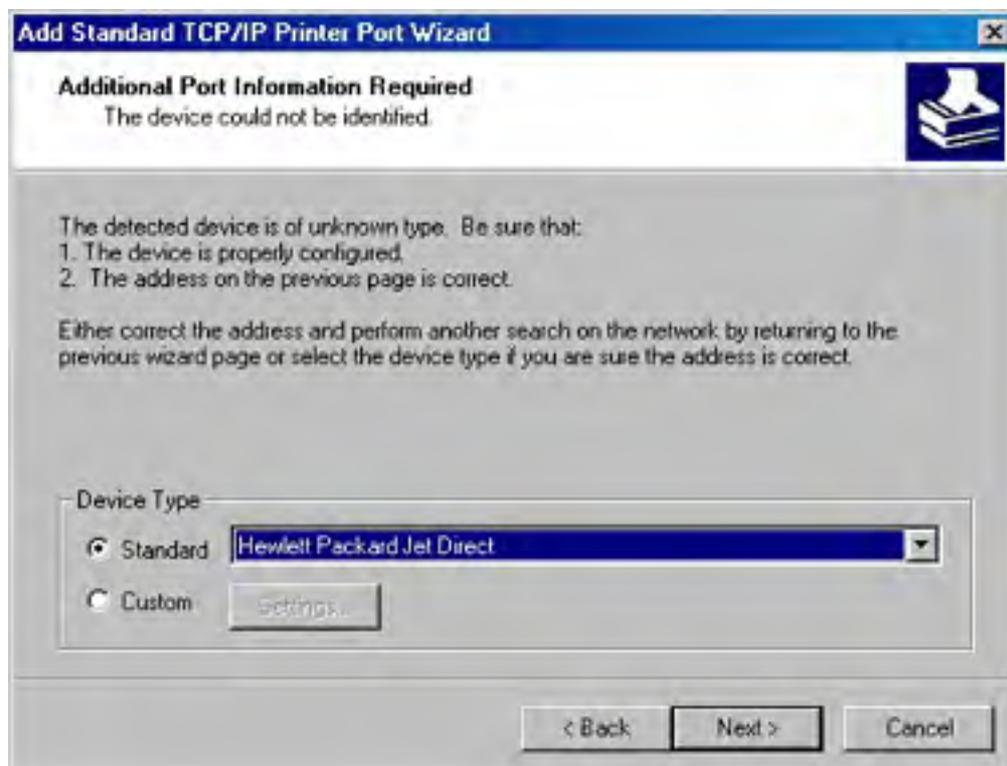

1. Connect the printer to the network and configure the printer with the proper TCP/IP settings for the network.
2. Click Start, choose Settings, and then click Printers to open the Printers folder.
3. Double-click Add Printer to start the Add Printer Wizard.
4. Click Next in the first screen to begin using the Add Printer Wizard.
5. Select the Local Printer option, and clear the Automatically Detect My Printer check box.
6. Select Create A New Port, and then select Standard TCP/IP Port from the drop-down list box. Windows 2000 then launches the Add Standard TCP/IP Printer Port Wizard.
7. Make sure that the printer is connected to the network and turned on, establish a network connection if you haven't already, and then click Next in the first screen of the Add Standard TCP/IP Printer Port Wizard to begin using the wizard.
8. Enter the printer name or IP address in the first text box, as shown in Figure 8-6.

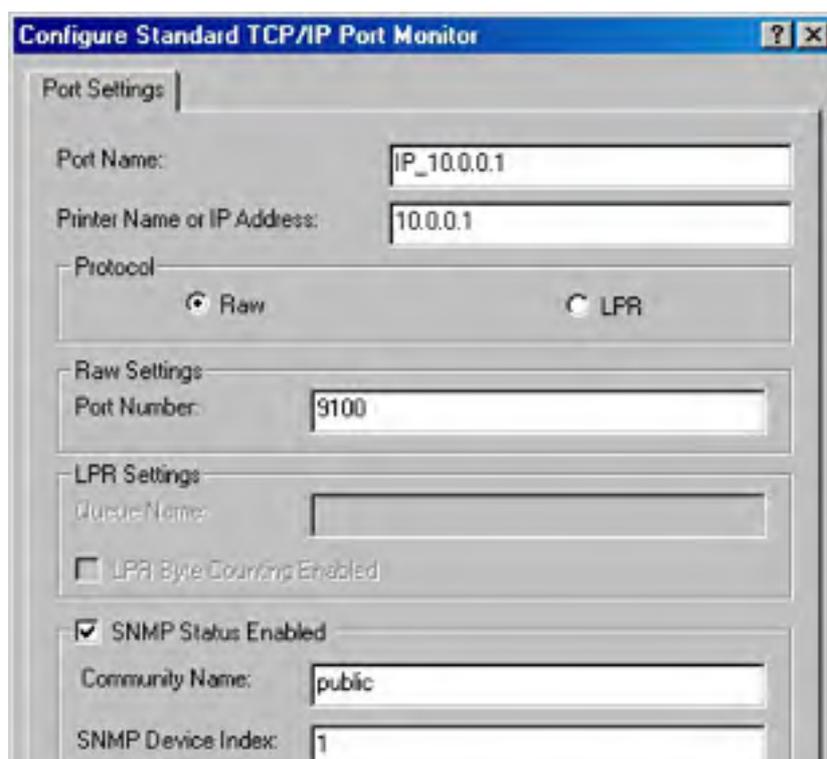

**Figure 8-6.** The Add Port screen of the Add Standard TCP/IP Printer Port Wizard.

9. If necessary, modify the TCP/IP port name that Windows 2000 automatically fills in and then click Next. Windows 2000 then attempts to connect to the printer.
10. If Windows can't detect the printer, you'll be asked for additional information (Figure 8-7).

**Figure 8-7.** The Additional Port Information Required screen of the Add Standard TCP/IP Printer Port Wizard.

11. Select the printer from the Standard list box, or select Custom and click Settings to display the Configure Standard TCP/IP Port Monitor dialog box, shown in Figure 8-8.

**Figure 8-8.** The Configure Standard TCP/IP Port Monitor dialog box of the Add Standard TCP/IP Printer Port Wizard.

12. Choose the protocol the printer uses, either raw or LPR. (For more information on configuring the server to use an LPR port to communicate with a printer that uses the LPD service, see the next section.)
13. Enter the port number for the printer if you're using the raw protocol. Use the default port number (9100) unless the printer documentation specifies that you must use a different port.
14. To use the LPR protocol, enter the queue name in the box provided.

Select the LPR Byte Counting check box if you're having problems with incomplete or missing documents. However, be aware that selecting this check box tells the server to count the number of bytes in a document before sending it to the printer, considerably slowing printing.

15. If the printer supports Simple Network Management Protocol (SNMP) as defined in RFC 1759, select the SNMP Status Enabled check box, and enter the Community Name (usually "public") and SNMP Device Index.
16. Click OK when you're finished configuring the TCP/IP port.
17. In the last screen of the TCP/IP Port Wizard, click Finish.
18. If Windows doesn't detect the printer, choose the printer model in the next screen, and then click Next.
19. Enter a name for the printer in the Printer Name text box. Click Next. We recommend that you choose a name with 31 characters or less that doesn't contain any spaces or special characters.
20. In the Printer Sharing screen, select Do Not Share This Printer if you do not want this printer to be accessible to users on the network. Select Share As and supply a share name for the printer if you want users on the network to be able to use this printer. Click Next.
21. Enter the location name for the printer in the Location box. (See the section entitled [Creating Location-Naming Conventions](#), earlier in this chapter, for information on choosing a location-naming scheme.) Describe the capabilities of the printer in the Comments box.
22. Print a test page by clicking Yes in the Print Test Page screen. Click Next to display a summary of the printer installation.

## Adding Printers on an LPR Printer Port

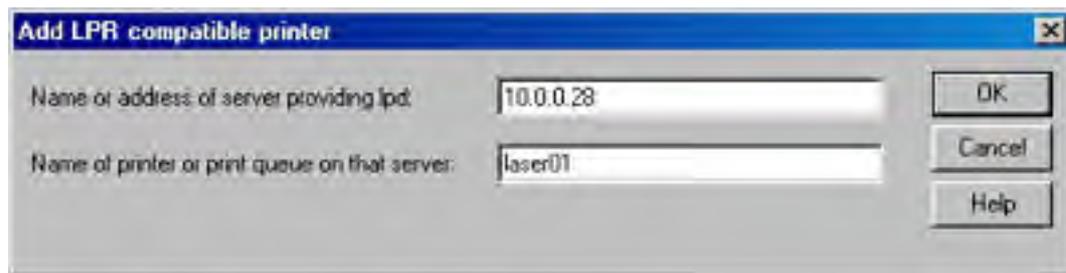

Another common way to connect to a network printer is to use an LPR port, allowing the print server to communicate with printers connected to UNIX computers or using the LPD service.

Follow these steps to set up a network-based printer through an LPR port:

1. Connect the printer to the network and configure the printer with the proper TCP/IP and LPD settings.
2. Install UNIX print services by using the Windows Component Wizard (accessible from the Add/Remove Programs Control Panel tool).
3. Click Start, choose Settings, and then click Printers to open the Printers folder. Double-click Add Printer to start the Add Printer Wizard.
4. Select the Local Printer option, and clear the Automatically Detect My Printer check box.
5. Choose the Create A New Port Type option, select LPR Port from the drop-down list box, and click Next.

6. Enter the name or address of the printer or print server running LPD in the first text box of the Add LPR Compatible Printer dialog box, shown in Figure 8-9.

**Figure 8-9.** The Add LPR Compatible Printer screen of the Add Printer Wizard.

7. In the second text box, enter the name of the printer or print queue on the LPD server, and then click OK. Windows adds the port to the list of ports.
8. If Windows doesn't detect the printer, choose the printer model in the next screen, and then click Next.
9. Give the printer a name in the Printer Name text box. Then enter the share name to use for the printer on the network.
10. Enter the location name for the printer in the Location box. Describe the printer's capabilities in the Comments text box.
11. To print a test page, click Yes in the Print Test Page screen. Click Next to display a summary of the printer installation.

## Adding AppleTalk Printing Devices

In a mixed computing environment with Macintosh clients, you might need to use one or more AppleTalk printing devices.

AppleTalk doesn't support client user names or passwords, eliminating the ability to set permissions for Macintosh users on the print server. However, you can set permissions for Macintosh users as a group, thus giving all Macintosh clients the same printer permissions. (For information on installing the AppleTalk protocol and AppleTalk networking, see [Chapter 23](#).)

To install an AppleTalk printer, follow these steps:

1. Connect and configure the printer.
2. Install Macintosh print services by using the Windows Component Wizard.
3. Open the Printers folder. Double-click Add Printer to start the Add Printer Wizard.
4. Select Local Printer, clear the Automatically Detect My Printer check box, and then click Next.
5. Select the Create A New Port option, and then select AppleTalk Printing Device from the drop-down list box and click Next. Windows 2000 searches the network for AppleTalk printers.
6. Choose a printer in the Available AppleTalk Printing Devices dialog box, and click OK to install the printer. When asked if you want to capture the port, click Yes. Windows adds the port to the list of ports.

When you capture the AppleTalk printing port, the printer is exclusively managed by the Windows 2000 print server and can't be simultaneously connected to a Macintosh print server. This limitation gives the administrator of the print server complete control over the printer.

7. Choose the printer model in the next screen if Windows doesn't detect the printer. Enter a name for the printer in the Printer Name text box. Enter the share name to use for the printer.

8. Enter the location name for the printer in the Location box. Describe the capabilities of the printer in the Comments text box, and then click Next.
9. Print a test page by clicking Yes in the Print Test Page window. Click Next to display a summary of the printer installation.

## Modifying Printer Properties

After you install printers on the print server, you'll need to set security, set various printer options, select the default printer and its options, and select the print server and its options. This section explains how to perform these tasks and more.

### Setting Security Options

Some people don't think about security when setting up printers, but this can be an important factor to consider. For example, you might not want everyone to print to the five-dollar-a-page dye sublimation printer purchased for the art staff. At a more basic level, you probably don't want most users to modify printer properties or change the priorities of documents in the print queue.

Setting permissions for groups (and occasionally individual users) and auditing the actions users and groups perform is how you handle printer security, just like access to a computer. Configure users to belong to groups, and then give the groups the level of permissions appropriate for those users. Turn on auditing for individual users or groups so that the person responsible for managing audit logs can track user actions in connection with the printer.

You must use an account with Manage Printers permissions to view and change printer security settings.

### Printer Permissions Levels

Printers are Windows 2000 resources and thus can be protected like any other resource by Windows 2000 security features. Printers in Windows 2000 have owners and access control lists (ACLs), which specify the permissions each user or group has. The creator of the printer is automatically made the owner of the printer, and only users with sufficient permissions (Manage Printers) can take the ownership of the printer from the creator. A user or group has three levels of control permissions for a printer: Print, Manage Documents, and Manage Printers.

Macintosh clients assume that if a client can physically send a document to a printer, it implicitly has permission to do so. Therefore, a Macintosh client has no printer security.

Members of the Everyone group are granted the Print permission by default. Users or groups with Print permission can connect to the printer and print documents. The Creator/Owner is granted the Manage Documents permission level by default. This means that the user who initiates a print job can pause, restart, and delete that job from the print queue. Separating the Creator/Owner permission from the Print permission allows permission to print to be widely granted while restricting users to managing only their own documents.

For additional security, you can remove the Print permission from the Everyone group and instead assign it to the built-in Users group. This permits only authenticated users to print.

The Manage Printers permission level is the Windows 2000 equivalent of Full Control permission in Windows NT. This level is granted by default to power users, print operators, and server operators on a domain controller and to administrators on a server. In addition to the Print and Manage Documents permissions, the Manage Printers permission level adds the ability to set printer sharing, modify printer properties, delete printers, change printer permissions, and take ownership of printers.

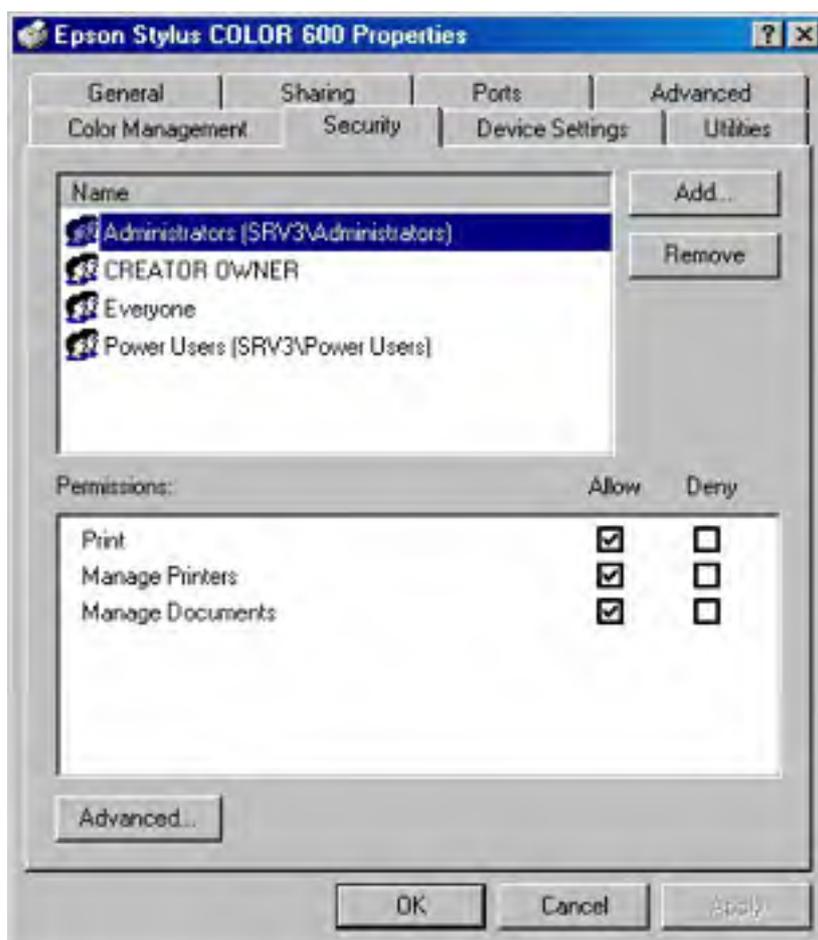

You should configure a printer according to the same guidelines you would follow for any shared resource. Create a local group with Print permissions, give it a name that matches the printer name, and then add global groups to the local group. If security isn't an issue, give Manage Documents or Manage Printers permission to the local group. For more on groups, see [Chapter 9](#).

### Changing Printer Permissions

To change the permissions on a printer, follow these steps:

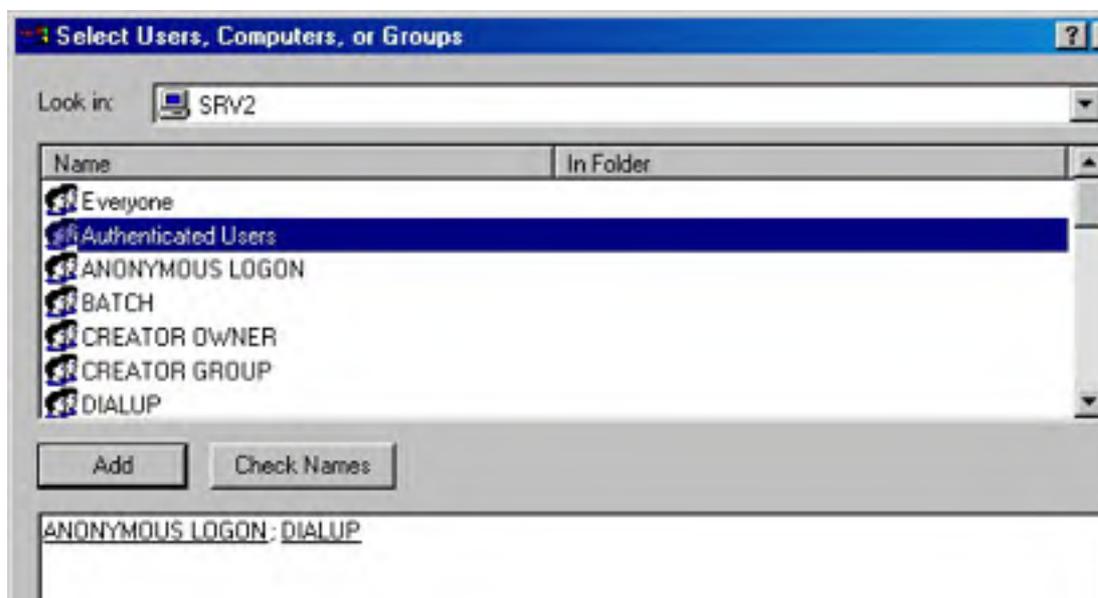

1. Open the Printers folder from the Start menu.

2. Right-click the printer to be modified, and then choose Properties from the shortcut menu.
3. Click the Security tab in the printer's Properties dialog box, shown in Figure 8-10.

**Figure 8-10.** The Security tab of a printer's Properties dialog box.

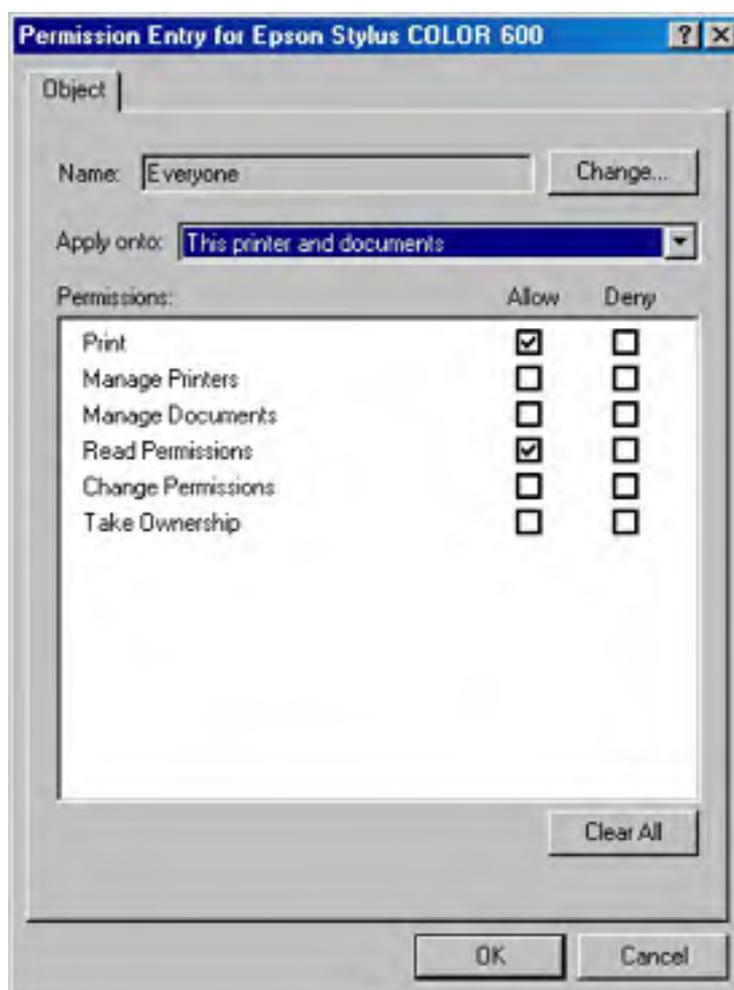

4. To change the permissions for a group, select the group from the list, and then select the check boxes in the Permissions section of the dialog box to choose which permissions to give to each group.
5. To add a user or group to the list, click Add, select a user or group from the list to add (as shown in Figure 8-11), and then click Add. When you're finished adding users or groups, click OK.

**Figure 8-11.** *The Select Users, Computers, Or Groups dialog box.*

6. To remove a user or group from the list of users and groups with permission to use the printer, select the user or group, and then click Remove.
7. To view or change more detailed security settings, click Advanced.
8. Use the Permissions tab of the Access Control Settings dialog box to view or change all permissions for each user or group. (Additional settings are Read Permissions, Change Permissions, and Take Ownership.)
9. To specify whether the permissions for a particular user or group apply to only the printer, only the documents, or both the printer and documents, select the user or group, click View/Edit, and then choose a setting from the Apply Onto drop-down list box. Click OK (Figure 8-12).

**Figure 8-12.** *The Permission Entry dialog box.*

### **Configuring Printer Auditing**

To audit actions for the printer (to record the occurrences of successful or unsuccessful printer-related actions by users or groups), follow these steps:

1. In the Printers folder (located on the Start menu), right-click the printer you want to modify, and then choose Properties from the shortcut menu.
2. Click the Security tab in the printer's Properties dialog box, and then click Advanced.
3. Click the Auditing tab. To add an auditing entry, click Add.
4. Select a group to audit, and then click OK.
5. In the Auditing Entry dialog box, select the actions that you would like to record, and then click OK.
6. To edit audits you create, select the auditing entry and click View/Edit.

You can view the results of the audit settings in the security log. After reviewing the log a few times, you might conclude that you're auditing too many or too few events. If you log too many actions, the log fills rapidly and events that are more serious can get lost in the long list of relatively trivial ones. If too few events are logged, you might miss a pattern of improper access to printers.

### Changing Printer Ownership

The owner of a printer is the person who has control over what level of permission users and groups have on the printer. To change the ownership for the printer, follow these steps:

1. In the Printers folder, right-click the printer you want to modify, and then choose Properties from the shortcut menu.
2. Click the Security tab in the printer's Properties dialog box, and then click Advanced.
3. Click the Owner tab to view the current ownership of the printer.
4. Select the user or group to be the new owner of the printer, and then click OK.

Only users or groups with the Manage Printers permission level appear in the list of users or groups available to take ownership of the printer.
--

### Setting Permissions for Macintosh Clients

Macintosh clients assume that if a client can physically send a document to a printer, it implicitly has permission to do so. This can put a damper on attempts to control access to printers. Fortunately, there is a way you can still control what level of access Macintosh clients have to printers, but only as a group: all Macintosh clients will receive the same permissions.

To limit the permissions of Macintosh clients you need to create a new user account and then configure Print Services for Macintosh to use this account. These are the actions you need to take:

1. Create a new user account, possibly named MacPrintClients (see [Chapter 9](#) for more information on creating users and assigning permissions).
2. Give the new account the permissions you want to assign all Macintosh clients.
3. Launch Services from the Administrative Tools folder on the Program menu, double-click Print Server For Macintosh, and click the Log On tab.
4. Select This Account and enter the account's user name and password in the boxes provided. Alternatively, click Browse, enter the user name, and click OK.

### Changing Printer Options

Windows 2000 installs new printers with printer options designed to work for most users, but frequently, you'll need to change them so the printer will work optimally. Some printer modifications to options that you might need to make include changing the default printer, changing print server printer drivers, specifying color profiles, changing printer availability, determining group printing priorities, and setting up printer pools. These features might not be available until you actively enable them. Security settings such as permissions, auditing, and ownership are covered separately in the section entitled [Setting Security Options](#), earlier in this chapter.

Depending on the printer driver you use, the dialog boxes and printer options that you have are probably different from those that we show. If you use a printer driver provided by the printer manufacturer, additional tabs and options might be unavailable in the standard Windows 2000 printer drivers.

## Changing the Default Printer

Applications on the computer that shares the printer automatically print to the default printer unless a different printer is specified. On a print server, it hardly matters which printer is the default printer, but it is important for clients. After a few users accidentally print their e-mail on the expensive plotter, you (or maybe just the finance department) begin to see the importance of having the default printer set correctly.

To change the default printer, follow these steps:

1. In the Printers folder, right-click the printer you want to modify.
2. Choose Set As Default Printer from the shortcut menu.

## Changing General Options and Printing Test Pages

To change general printer options such as the printer name, or to print a test page, follow these steps:

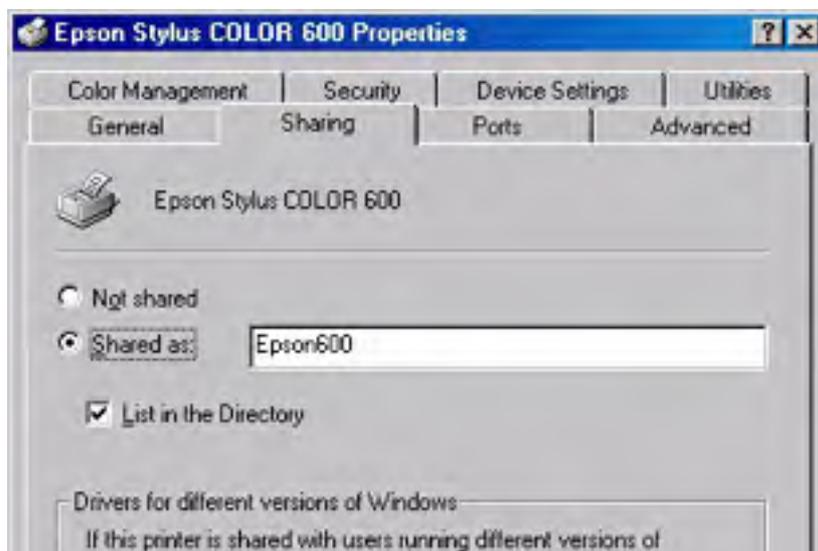

1. In the Printers folder, right-click the printer you want to modify, and then choose Properties from the shortcut menu.
2. Use the General tab of the Properties dialog box to view or modify the printer name, location name, or comments, as well as to view the printer capabilities.
3. To print a test page, click Print Test Page in the General tab.

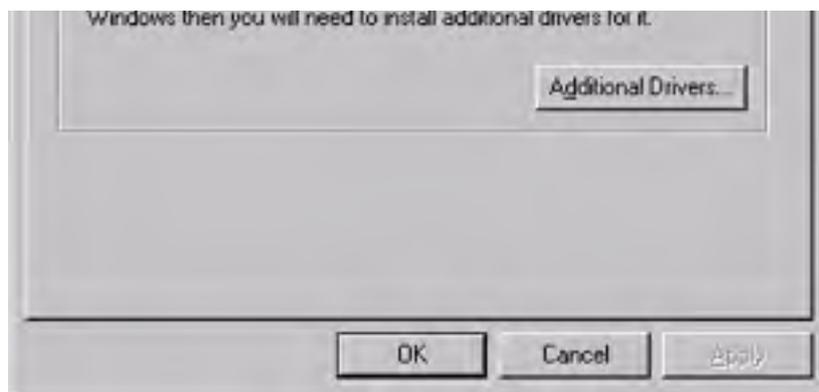

You can also print a test page by opening Windows Notepad and creating a simple document. In fact, printing in Notepad is an easy troubleshooting technique used to see whether basic printing is working.

## Sharing a Printer and Providing Client Drivers

To change the share name the printer uses on a network, to stop sharing the printer, or to install drivers that client machines can use for the printer, follow these steps:

1. In the Printers folder, right-click the printer you want to modify, and then choose Properties from the shortcut menu.
2. Click the Sharing tab. Click Shared As, and enter the share name for the printer in the text box provided (Figure 8-13).

**Figure 8-13.** The Sharing tab of a printer's Properties dialog box.

3. To publish the printer in Active Directory, select the List In The Directory check box, if available. (To change the way printers are published in Active Directory, use the Group Policy snap-in, discussed in detail in [Chapter 9](#).)
4. To add client drivers that are automatically downloaded and installed when a Windows 2000 or Windows NT client connects to the printer, click Additional Drivers.
5. In the Additional Drivers dialog box, select the check box next to any client drivers to be installed, and then click OK. To install additional client drivers, you need access to the Windows 2000 installation files, either on CD-ROM or across the network.

When client drivers are installed on a print server, many Windows clients automatically download the drivers when they are initially connected to the printer. Windows 2000 and Windows NT 4 clients automatically check for updated versions of the printer drivers at startup and download newer versions if necessary. Windows NT 3.x clients automatically check and update their drivers when they print to the server. Windows 95 and 98 clients don't automatically check for updated drivers and must be updated manually.

### Changing Print Server Printer Drivers

To change the driver that the print server uses for a printer, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the Advanced tab.
3. Choose a driver from the Driver drop-down list box, or click the New Driver option to start the Update Driver Wizard.

### Setting Up Printer Pools and Changing Port Settings

A printer pool is useful for handling a large volume of printing at a location, particularly when there is a mix of large and small documents. For example, someone with a single-page memo doesn't have to be stuck in the queue behind a print job that's the corporate equivalent of the *Encyclopedia Britannica*.

If printers share a single driver, they can appear to clients as one printer. The advantage of using a printer pool is that clients don't need to find which printer is available; they simply print to the single logical printer (print driver) on the print server, which then sends the print job to the first available printer. Administration of the printers is also simplified because they are all consolidated under one driver. If you modify the properties for the single logical printer, all physical printers in the printer pool use the same settings.

Printers in a printer pool should be located near each other to make finding a completed print job easier.

To set up a printer pool or simply change the port settings for a printer, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.

2. Click the Ports tab.
3. Select the Enable Printer Pooling check box.
4. To change the transmission retry settings for a port, select the port and click Configure Port.
5. To add additional printers to the printer pool, select the ports to which the additional printers are connected.

All printers in a printer pool must be identical or must at least be able to use the same printer driver, as they are all configured by one printer driver.

## Specifying a Color Profile

Windows 2000 includes the Integrated Color Management (ICM) 2 API for maintaining consistent colors across monitors, color printers, and scanners. When you need to achieve accurate color reproduction, it's useful to set up the printer, as well as the users' monitors and scanners, with an appropriate color profile. To do so, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the Color Management tab. Select the Automatic option to have Windows 2000 choose the best color profile.
3. To manually select a color profile, choose the Manual option, and then select a profile from the list or click Add to install an additional color profile from the device manufacturer. Click OK.

Color management in Windows has come a long way, but most graphics professionals still use third-party, hardware-based, color-matching solutions when color accuracy is important. However, ICM provides a good way to attain a reasonable measure of accuracy for noncritical work.

## Changing Printer Availability

To set up the printer to be available only during certain times—perhaps to discourage after-hours printing—perform the following steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the Advanced tab, and then click the Available From option.
3. Select the earliest and latest times the printer is to be available to users, and then click OK.

To dedicate a printer to large, high-priority print jobs after normal hours, install a duplicate logical printer (printer driver) for the printer. Make one logical printer available during normal hours to all users. Make the second one available after hours to only particular users or groups.

## Determining Group Printer Priorities

Sometimes you might want to make the printer available preferentially to a certain group of users so that they can jump straight to the head of the print queue. This ability can be extremely useful for users who face time pressures and need to take precedence over other users when printing.

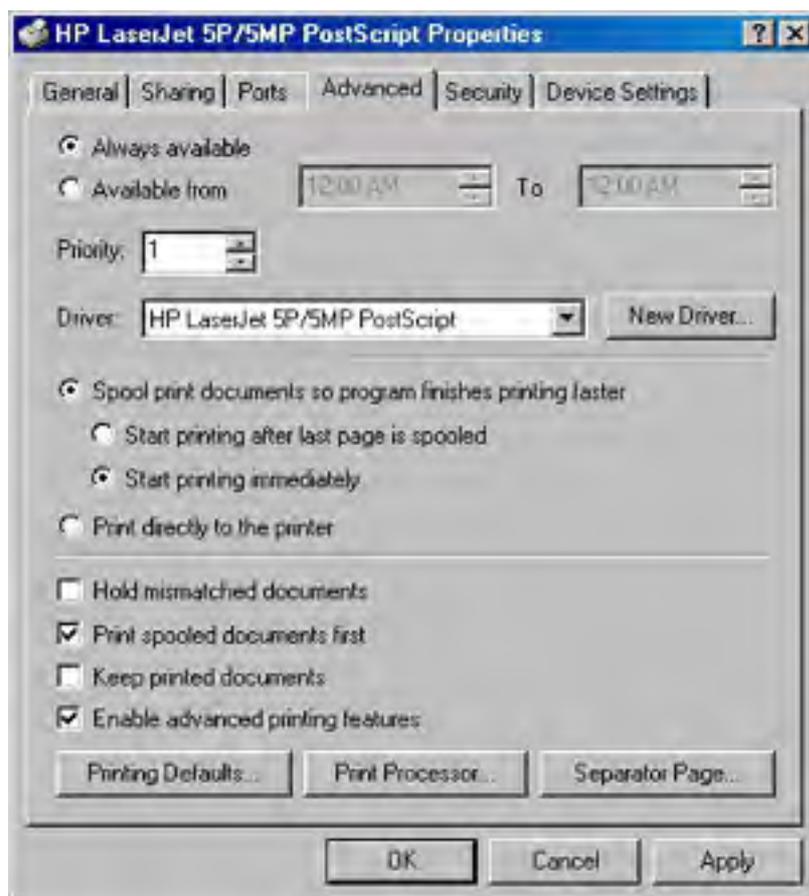

To set up groups to have different priorities on a printer, you need to set up two or more logical printers for the physical printer. Thus, you would have two or more printer drivers set up for a single printer, with each driver possessing a different priority level and a different set of users or groups. To do this, follow these steps:

1. In the Printers folder, click the Add Printer icon to add one or more duplicate logical printers for a physical printer already installed on the print server.
2. Right-click the logical printer you want to change the priority for, and then select Properties from the shortcut menu. Click the Advanced tab.
3. Change the priority to be assigned to the logical printer and the users and groups that use this printer driver by entering a number in the Priority text box. The priority range goes from 1, which is the lowest priority, to 99, which is the highest priority.
4. Click the Security tab and add the users and groups you want to allow to print at this priority level. Remove or deny print permissions to users whose printing should occur at a different priority level. Those users will utilize another printer with its own priority level.
5. Click OK, and repeat the process for all other logical printers created for the printer.

## Changing Spool Settings

Print spooling, or storing a print job on disk before printing, affects how clients perceive printing performance and the actual printing speed. You can change the way print spooling works to correct printing problems or to hold printed documents in the printer queue in case a user needs to print the document again. Follow these steps to change a printer's spool settings:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the Advanced tab to display the printer's spool settings, as shown in Figure 8-14.
3. To reduce the time it takes to print a document, select the Spool Print Documents option, and select the Start Printing Immediately option to begin printing as soon as enough data is spooled.

**Figure 8-14.** The Advanced tab of a printer's Properties dialog box.

4. To ensure that the entire document is available to the printer when printing begins, select the Start Printing After Last Page Is Spooled option. This step might correct some printing problems.
5. If you continue to have printing problems, choose the Print Directly To The Printer option to turn off spooling. Enabling this option causes a performance hit on the server.
6. Select the Hold Mismatched Documents check box to hold documents in the queue that don't match the current printer settings. Other documents in the print queue are unaffected by held documents.
7. Select the Print Spooled Documents First check box to print the highest priority document that is already spooled first, ahead of higher priority documents that are still spooling. This step speeds overall printer throughput by keeping the printer from waiting for documents.
8. Select the Keep Printed Documents check box to keep a copy of print jobs in the printer queue in case users need to print the document again. In this circumstance, the user can resubmit the document directly from the queue rather than printing from his or her application a second time.
9. Clear the Enable Advanced Printing Features check box if you experience printer problems. This turns off metafile spooling, which disables some printer options such as page order, booklet printing, and pages per sheet (if available on the printer).

### **Changing Print Processor Settings and Specifying a Separator Page**

The print processor determines the data format used with documents sent to the printer, generally either *raw* or *EMF*. (See the section entitled [Understanding the Printing Process](#), earlier in this chapter, for information on these data types and their advantages.) To change the type of print processor the print server uses for a printer or to specify a separator page to insert between print jobs, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the Advanced tab. Click Print Processor to change the print processor or to specify a data type to use. When you're finished setting options in the Print Processor dialog box, click OK.
3. Click Separator Page to select a page to insert between printed documents to help separate the print jobs. Click OK.

### **Setting Up a Printer to Use Both PostScript and PCL**

If you have a printer that supports printing in two printer languages (usually PostScript and PCL), you can set up the printer to simultaneously support both languages. To do this, set up two logical printers (printer drivers) for the printer: one for each data type. Clients with PostScript documents then use the PostScript-enabled logical printer, whereas users with PCL documents use the PCL logical printer.

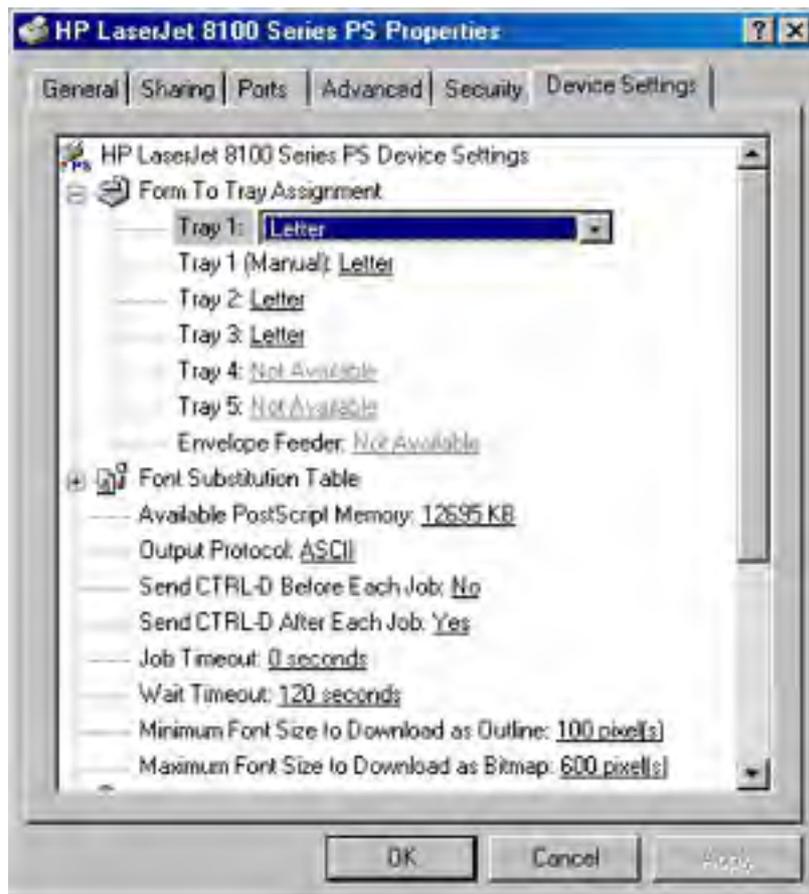

Open the Printers folder and click Add Printer to create a logical printer that supports the first data type (either PostScript or PCL). Then click Add Printer a second time to create a logical printer that supports the second data type.

### **Setting Installable Options and Printer Device Settings**

Each printer comes with several configurable device options, such as which paper tray to print from, whether a duplexer is installed, and how to handle downloadable fonts. Although the options that are configurable vary with the printer model, you can use the following procedure to change the printer device settings on any printer:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.

2. Select the Device Settings tab, and then click the underlined words to display a drop-down list box that you can use to configure an option, as shown in Figure 8-15.

**Figure 8-15.** The Device Settings tab of a printer's Properties dialog box.

If the printer has multiple trays with different forms, match the form to the tray so that documents using the form always print properly. Under the Form To Tray Assignment heading, select each tray and choose the form that the tray holds. If the printer supports Page Protection and has 1 MB or more of available optional memory, click the Device Settings tab and turn on this option to ensure that complex pages print properly. When you turn this option on, the printer creates each page in memory before beginning to print.

## Changing Default Print Settings

After you configure the printer options for the installed printer, you should set the default print settings that are used by clients. The default printer settings you specify on the print server are used as the defaults for all clients connecting to the printer (users can change printing preferences on their computers if you haven't disabled this ability using Group Policy).

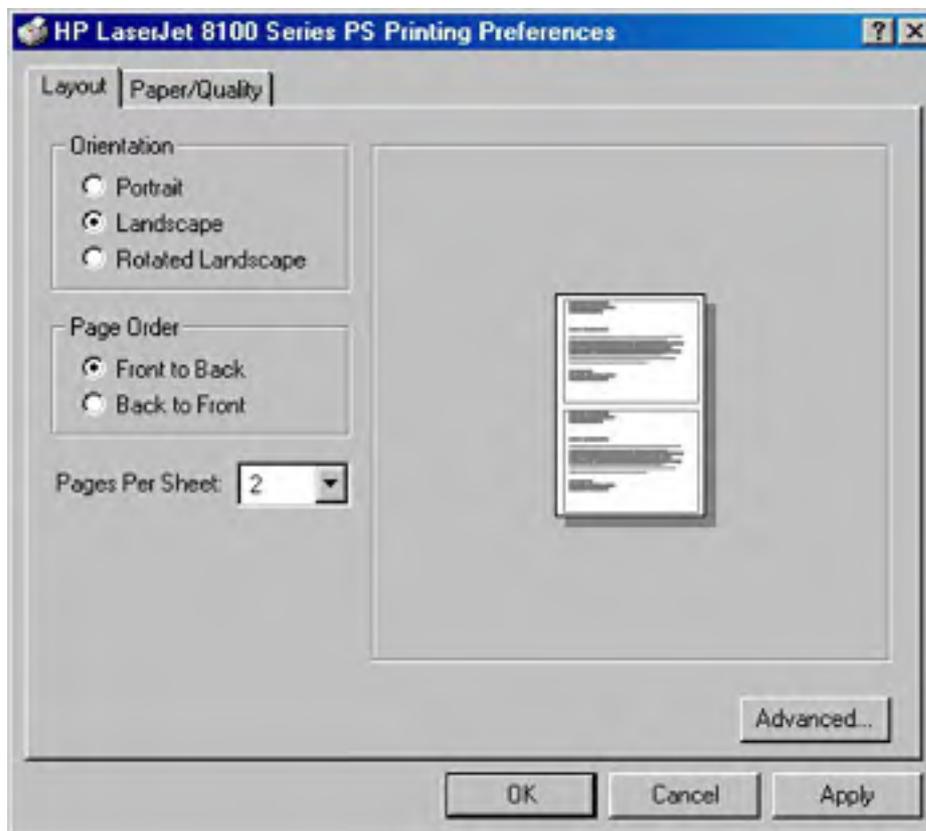

This section describes how to set layout options, how to set paper options, and how to set quality defaults for a print server and attached clients.

### Setting Layout Defaults

Layout involves such options as the orientation of documents and paper, the order in which pages are printed, and the number of pages per sheet of paper that are printed. To change these settings, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click the General tab, and then click Printing Preferences.

3. To change the paper orientation, select Portrait, Landscape, or Rotated Landscape, as shown in Figure 8-16. Note that the preview changes depending on the selection you choose.
4. To specify whether the printer should start with the last page of a document or the first page, select either the Front To Back option, which is good for face-down printing, or the Back To Front option, which is better for page-up printers.

**Figure 8-16.** The Layout tab of a printer's Printing Preferences dialog box.

5. To print multiple pages per sheet of paper, select the number of pages to print on a sheet from the Pages Per Sheet drop-down list box.

The Rotated Landscape orientation, if available, prints a page in the landscape format, but rotated 90 degrees counterclockwise.

## Setting Paper and Quality Defaults

Paper and quality options are important printing defaults because you generally want most users to print on a certain paper size from a particular paper tray with a certain quality setting. Most users change the default options only if their documents don't print the way they wanted, potentially causing a lot of waste if the defaults are inappropriate and the users don't correct them until after printing a copy (or more). Setting these defaults to a standard-size paper (most likely letter size) and at the quality setting most appropriate for the users can save the company a great deal of money over time. To specify paper options and quality settings, follow these steps:

1. In the Printers folder, right-click the printer you want to modify and select Properties from the shortcut menu.
2. Click Printing Defaults in the General tab. Click the Paper/Quality tab.
3. Use the Paper Source drop-down list box to select which tray (or other paper source) you want users to print from by default.
4. Select the type of paper the printer is usually stocked with from the Media drop-down list box.

5. If the printer driver has a Quality Settings section, use this part of the dialog box to choose a resolution or quality setting to use on the documents by default. In general, use the lowest quality settings that are acceptable to the users to increase printing speed, reduce waste, and lower costs.
6. If you have a color printer, choose whether the users should print black or color by default.
7. If the printer driver doesn't have Quality options in the Quality/Paper tab, click Advanced, and use the Advanced Options dialog box to set any layout, quality, or paper options that are available on the printer.

To set duplex printing, staples, and other advanced printer options, use Advanced Options—these settings might not be available elsewhere—depending on the printer driver and whether you've enabled these installable options.

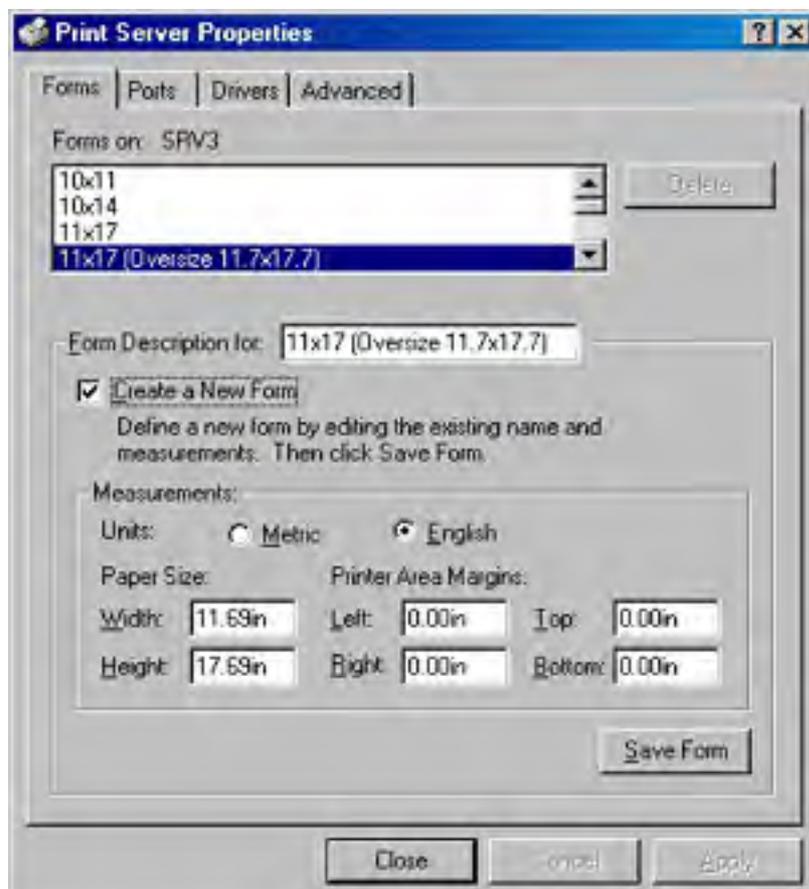

## Setting Print Server Options

Although most printer configuration occurs in the printer driver for a particular printer, you can configure some of the actual print server settings. These settings affect all printers hosted by the print server; they include determining which forms are available to print on and which ports and printer drivers are available to use, as well as some spool settings.

## Modifying the Forms Available on the Print Server

Forms are the media you put in a printer; basically if you can print on it, Windows considers it a form. Forms can be paper of various sizes, every sort of envelope, or other types of media such as film. Print servers are set up to handle a wide variety of standard forms by default, but occasionally it can be useful to set up additional forms that the printers can use, maybe because you use special company forms. Perhaps you want to modify or delete an existing form. To do so, follow these steps:

1. In the Printers folder, choose the Server Properties command from the File menu to open the Print Server Properties dialog box, shown in Figure 8-17.

---

**Figure 8-17.** *The Forms tab of the Print Server Properties dialog box.*

2. To modify a form, select the form and then use the Measurements boxes to alter it.
3. To create a new form, select the Create A New Form check box, enter a name for the form in the Form Description text box, use the Measurements boxes to define the form, and then click Save Form.

## Configuring Ports and Drivers

You can use the Ports and Drivers tabs in the Print Server Properties dialog box to configure the port and printer drivers that are available on the print server. You can add new ports for the printers or configure the printer drivers you want to make available to clients to download when they connect to the print server. To do so, follow these steps:

1. In the Printers folder, choose Server Properties from the File menu.
2. To view the ports available on the print server, click the Ports tab.
3. Select a port and click Configure Port to modify the port settings, or click Add Port or Delete Port to add or remove a port from the system.
4. Click the Drivers tab to view a list of currently installed drivers on the print server.
5. To view the driver details for a printer driver, select the driver and then click Properties to display the Driver Properties dialog box. Use this dialog box to view the properties for each file that makes up the printer driver.
6. To update a printer driver, select the driver and click Update.
7. To add a printer driver that you want to make available to clients to download, click Add to launch the Add Printer Driver Wizard, which walks you through the driver installation process.
8. To remove a printer driver, select the driver and click Remove.

## Configuring Advanced Print Server Settings

The Advanced tab of the Print Server Settings dialog box is extremely useful for configuring the print server for optimal performance and ease of use. You can and should specify where the spool folder is stored, and you can also control how the print server deals with printing events. To configure these settings, follow these steps:

1. In the Printers folder, choose Server Properties from the File menu.
2. Click the Advanced tab. In the Spool Folder text box, enter the location in which you want to store the spool folder.

For optimal performance, place the spool folder on a separate drive from Windows 2000, its applications, and especially its swap file. Also make sure that the drive is big enough to hold all the documents in the print queue. If you choose to enable the holding of printed documents, the drive needs to be even bigger.

3. Select the check boxes next to the events to be logged.

To be notified of errors while printing remote documents, select Beep On Errors Of Remote Documents. To send a message to the user when the document finishes printing, select Notify When Remote Documents Are Printed. To display a notification message on the computer the document was printed on (even if the user who printed it is currently logged on elsewhere) select Notify Computer, Not User, When Remote Documents Are Printed.

The Notify When Remote Documents Are Printed feature can be useful on busy print servers when a significant delay might occur between the time that a client sends off a document and the time when the document reaches the head of the queue and actually prints. However, on less busy print servers or for users who need to print frequently, this feature can be annoying. If this situation occurs for users, you can turn off the option to eliminate the problem.

## Printers and Active Directory

Windows 2000 print servers are thoroughly integrated with Active Directory, making it possible for clients to easily find a suitable printer on the network.

### How Printers Are Published

Printers are automatically published in Active Directory when you share them on the network, unless you clear the List In The Directory check box. You can control whether a printer is published by opening the printer's Properties dialog box and, in the Sharing tab, selecting or clearing the List In The Directory check box.

Printers are published to whatever domain controller the print server happens to find on its domain. The new printer objects (printQueue objects in Active Directory-speak) are then automatically propagated through Active Directory to the other domain controllers so that clients can find the printers regardless of which domain controller they're querying. The maximum propagation delay within a single site is about 30 minutes, but it's usually closer to 5 to 10 minutes.

When a print server updates the characteristics of its printers, Active Directory is automatically updated. If a print server goes offline, its printers are removed from Active Directory until it comes back online, at which point the print server republishes its printers.

#### Real World

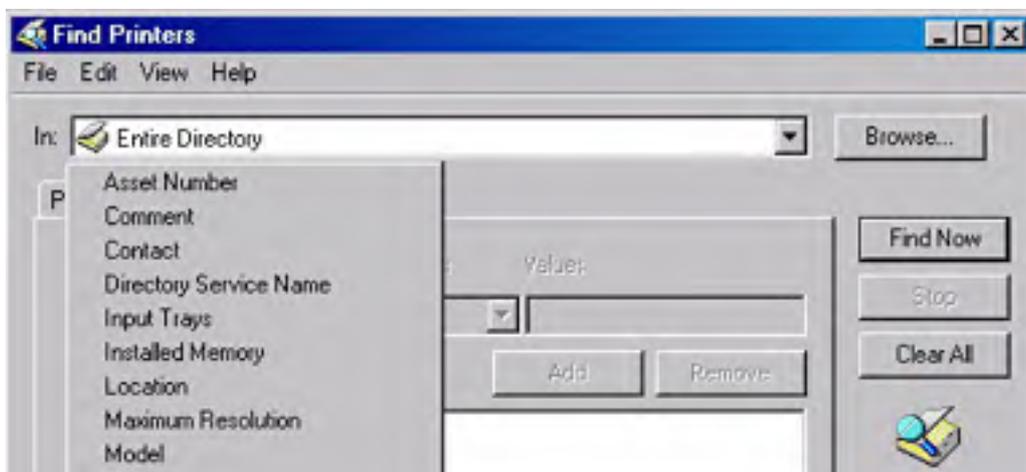

##### Publishing All Printers in the Active Directory

Most enterprises won't have all their printers hosted by Windows 2000 print servers, yet ideally, all printers that are available to clients should be listed in Active Directory. For this to happen, you'll need to specifically publish printers that are not hosted by a Windows 2000 print server in Active Directory.

To do so, launch Active Directory Users and Computers from the Administrative Tools folder, right-click the domain, subnet, or organizational unit in which you want to publish the printer, and choose New Printer from the shortcut menu. Enter the path of the printer to be published in the UNC Path Of Downlevel Print Server To Be Published text box, and then click OK.

### Using Active Directory to Find Printers

Active Directory makes it easy to search for printers to which you want to connect. To find a printer using Active Directory, point to Search on the Start menu and choose For Printers. Enter the name of the printer or its model in the Name and Model text boxes. Alternatively, click the Features tab to specify the particular features needed, or click the Advanced tab to fine-tune the search with a variety of values (Figure 8-18).

**Figure 8-18.** Possible features for designing a printer search.

If you're in a large organization, it might be difficult to identify a nearby printer without printer location tracking, discussed in the next section.

If printer location tracking is enabled, when the query form opens, the system determines the location of the computer from which the query is being run and fills in the Location box. Click Browse to change the location.

When location tracking is enabled, you can use the Group Policy snap-in (covered in [Chapter 9](#)) to define locations that don't depend on actual geographic locations.

## Using Printer Location Tracking

Finding a printer in a large enterprise can be tricky. Active Directory provides a useful alternative to wandering the halls: printer location tracking. Printer location tracking uses Active Directory to store the printer location, allowing users to search for printers based on names, locations, and a long list of features (as described in the next section).

To use printer location tracking, you need to publish the printers in Active Directory with the *Location* field filled out. This makes it easy for users to find printers that are physically near them when searching Active Directory for a printer.

This section covers the requirements for using printer location tracking and explains how to enable this feature. (It is turned off by default.)

### Meeting the Requirements for Printer Location Tracking

Printer location tracking requires a few conditions to work properly. These conditions are easy for most organizations to meet, but the network infrastructure of some companies will require modification. To use printer location tracking, the following conditions must be in place:

- Active Directory must be installed on the network and must contain more than one site or more than one IP subnet.
- The network must have an IP addressing scheme that matches the network's physical layout reasonably well.
- The client computers must be able to query Active Directory. (They must support LDAP 2 or later.)
- Each site should be on a separate subnet.

- Each subnet that clients need to access should have its own subnet object in Active Directory.

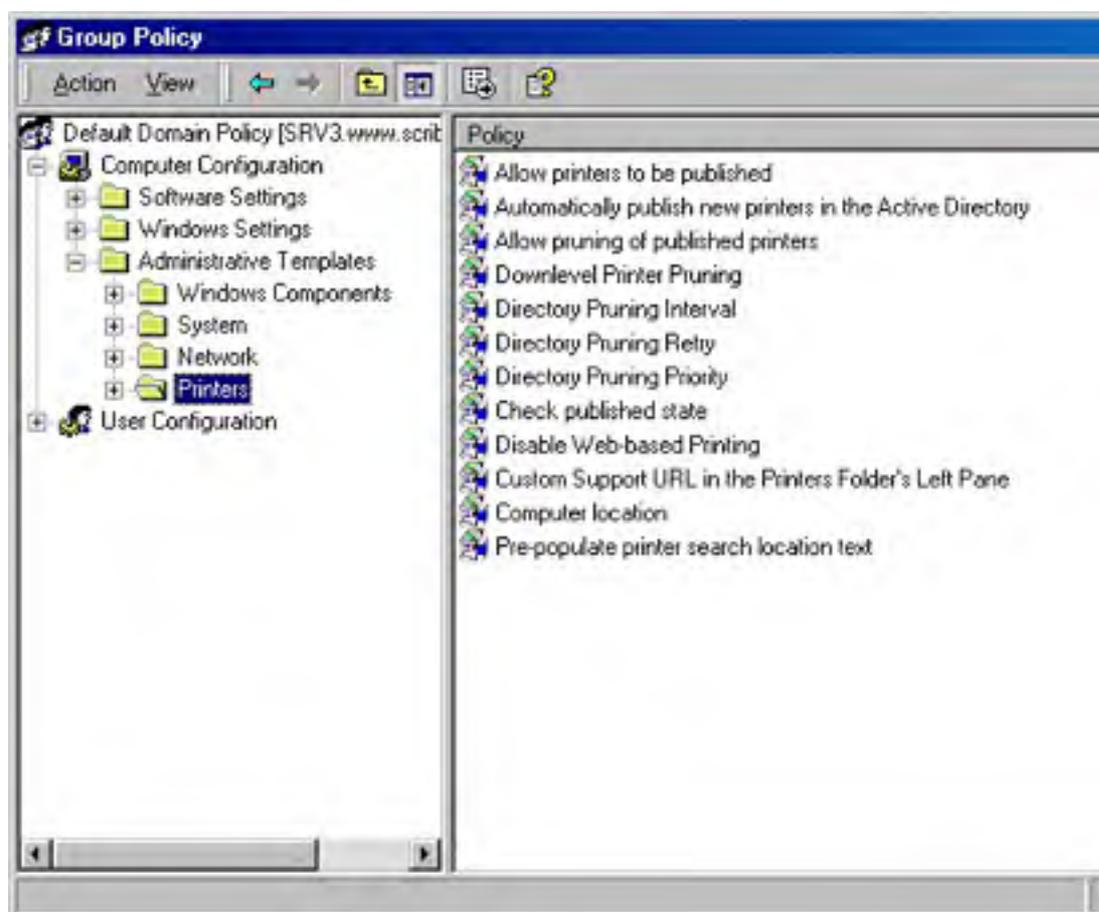

For information on how to install Active Directory and create the appropriate subnets for the enterprise using Active Directory Sites and Services, see [Chapter 12](#).

Printer location tracking isn't particularly useful until an enterprise is quite large. However, you should use a compatible naming convention so you can enable printer location tracking at some future time.

## Enabling Printer Location Tracking

Once you've prepped the network, follow these steps to set up printer location tracking:

1. Launch Active Directory Sites and Services from the Administrative Tools folder.
2. In the Sites folder, right-click the first site and choose Properties from the shortcut menu.
3. Click the Location tab and enter the location name for the site, or click Browse to select the location from the location tree for the enterprise.
4. Click OK and repeat steps 2 and 3 for each site and subnet on the network.
5. Open the Active Directory Users and Computers snap-in, right-click the domain for which you want to enable location tracking, choose Properties from the shortcut menu, and click the Group Policy tab.
6. Select the policy to edit, and then click Edit to open the Group Policy snap-in.
7. Open the Computer Configuration folder, open the Administrative Templates folder, and finally, open the Printers folders (Figure 8-19).

**Figure 8-19.** The Group Policy snap-in.

8. Double-click the Pre-Populate Printer Search Location Text policy, select Enabled, and click OK. Close the Group Policy window, and then close the domain's Properties dialog box. This automatically fills in the Location box for clients when searching Active Directory with the location of their subnet.
9. Right-click the first printer in the print server's Printer folder, and choose Properties from the shortcut menu.
10. Fill in the Location text box, or click Browse to select the location from the location tree for the enterprise.

You'll probably want to be more specific in the Location box for printers than simply providing the location of the subnet. For example, you might add a room number or name.

11. Repeat steps 9 and 10 for all printers in Active Directory.
12. Test the printer location tracking by searching for client machines to make sure that everything is configured properly.

## Managing Printers and Print Servers

Once the printers and print server are configured, it's tempting to consider the job finished, but in reality, managing printers and print servers is an ongoing process. Fortunately, Windows 2000 makes the job of managing printers and print servers fairly easy and flexible. A Windows 2000 print server or hosted printer can be managed by any Windows 2000 machine, or even from any system using a Web browser, as long as Internet Information Services (IIS) or Peer Web Services is installed and Web-based printing hasn't been disabled using the Group Policy snap-in.

This section focuses on some common management chores such as connecting to a printer and viewing the print jobs, managing print jobs in the queue, and transferring print jobs from one printer to another—all from either a Windows 2000 machine or a Web browser.

### Managing Printers from Windows 2000

You can use any machine running Windows 2000 to manage printers shared by a Windows 2000 or Windows NT print server. In fact, you'll probably administer the printers from a remote machine instead of the print server. Managing printers in Windows 2000 is similar to the process in Windows NT 4, so if you're familiar with managing printers in Windows NT, you can skip this basic information.

#### Viewing the Status of a Printer

To view the status of a printer and jobs in the printer's queue, follow these steps:

1. Open the Printers folder on the print server, or perform a search to locate the printer to manage.
2. Double-click the printer to open a monitoring window that you can use to view and manage the printer's queue (Figure 8-20).

You might want to create a folder containing shortcuts to all the print servers you manage. To do this, create a folder wherever it's convenient for you, and then drag the Printers folders for each print server into the newly created folder.

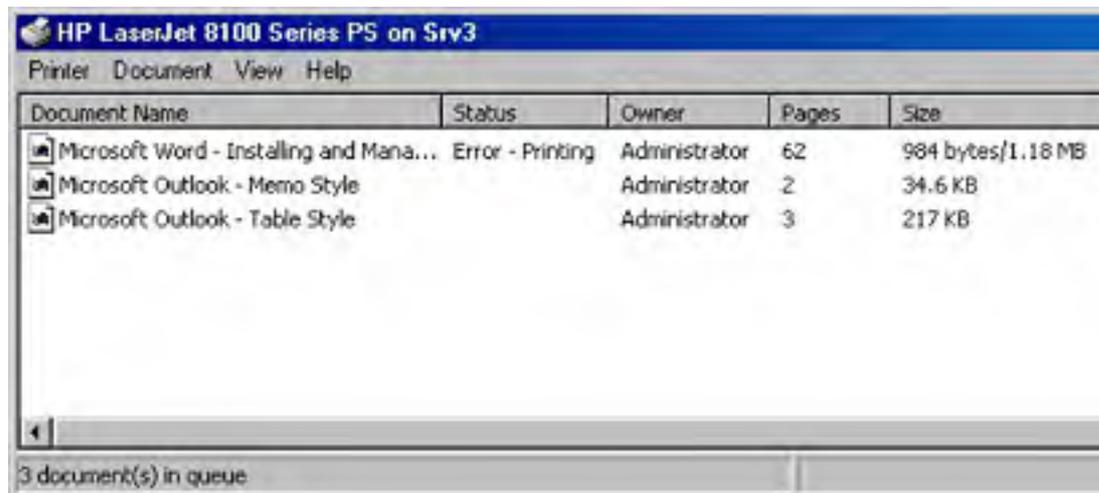

Figure 8-20. The print queue window.

#### Pausing, Canceling, and Restarting Print Jobs

Use the Print Monitor window to pause, cancel, or restart any or all documents waiting to print, provided you have Manage Printers permissions. (See the section entitled [Printer Permissions Levels](#), earlier in this chapter, for more information on permissions.) To do this, follow these steps:

1. Select the document or documents in the print queue that you want to work with.

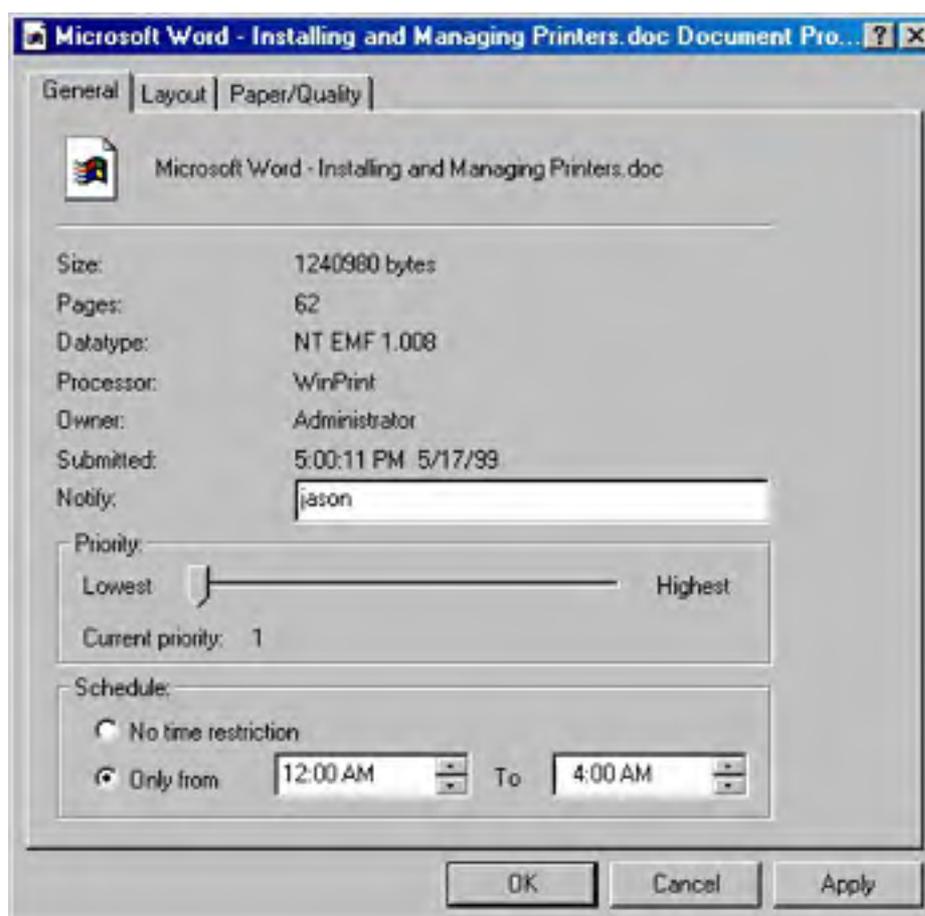

2. Right-click the document, and choose Pause from the shortcut menu to temporarily stop the document from printing. Right-click the document, and choose Resume to continue printing.
3. To cancel a print job, right-click the document and choose Cancel from the shortcut menu. You can also cancel print jobs by selecting them and pressing the Delete key.
4. To restart a print job (force the document to print from the beginning again), right-click the document, and choose Restart from the shortcut menu.
5. To pause the printer, causing all documents to be held, choose Pause Printing from the Printer menu. Select the command again to resume printing.
6. To cancel all print jobs in the print queue, go to the Printer menu and choose Cancel All Documents.

Sometimes a print job appears stuck in the queue and cannot be deleted. In that case, you can try turning the printer off and then on again, or you can stop the Print Spooler service on the print server and restart it.

### Modifying a Print Job's Properties

In addition to starting and stopping print jobs in a printer's queue, you can also change the priority and schedule of individual print jobs as well as the person who is notified when the document finishes printing. To do so, follow these steps:

1. Right-click the print job to be modified, and choose Properties from the shortcut menu.
2. To change the person who is notified when the document finishes printing, enter the user's name in the Notify text box, shown in Figure 8-21.

**Figure 8-21.** The General tab of a document's Properties dialog box.

3. Use the Priority slider to adjust the priority of the document, with 1 being the lowest priority and 99 the highest priority.

4. To specify that the document should be printed only during a certain period, select the Only From option and choose the time range to allow the document to print. Click OK.

Use the Schedule feature to set a large document to print only during times when you anticipate the printer to be free.

## Moving Documents from One Printer to Another

When a printer makes crackling sounds and zaps anyone who touches it, it's time to call the repair person and move all print jobs to another printer that can use the same driver. To move all documents from one printer (usually because the original printer encountered problems) to another printer that can use the same printer driver, follow these steps:

1. Double-click the printer from which you want to move documents in the print server's Printers folder.
2. From the File menu, choose Properties, and then click the Ports tab.
3. If the printer to which you want to transfer documents is on the same print server, select the port that the second printer is on, clear the check box next to the original port, and click OK.
4. If the printer is elsewhere on the network, click Add Port, select Standard TCP/IP Port, and then click New Port.
5. Click Next in the first screen of the Add Standard TCP/IP Printer Port Wizard, and then enter the DNS name or IP address of the printer in the first text box.
6. If necessary, modify the TCP/IP port name that Windows 2000 automatically fills in and then click Next. Windows 2000 then attempts to connect to the printer.
7. If Windows doesn't detect the printer, choose a device type in the next screen, and then click Next.

To connect to a printer using LPR instead of using the Standard TCP/IP Port Monitor, select the Custom option, click Settings, choose LPR, enter the name of the print queue on the LPD server in the Queue Name box, and then click OK. This procedure is covered in greater detail in the section entitled [Adding Printers on an LPR Printer Port](#), earlier in this chapter.

8. Review the settings and then click Finish to add the Standard TCP/IP port.
9. Click Close in the Printer Ports dialog box, verify that the correct port is selected, and then click Close.

A currently printing document can't be moved.

## Managing Printers from a Web Browser

Windows 2000 lets you manage the printers from any browser, provided you have IIS installed on the print server and have sufficient privileges; Peer Web Services works if you're using Windows 2000 Professional as the print server. (In either case, you might be prompted for the user name and password.) This feature can be extremely useful, providing the ability to manage printers from remote locations.

You can also print across the network or Internet from a Web browser, but to use this feature, you need to use Microsoft Internet Explorer 4 or later. Print to an Internet Printing-enabled printer by opening the printer in the Web browser and then clicking the Connect hyperlink to download and install the appropriate drivers for the printer on the computer. Then use the newly downloaded printer drivers to print the documents. To prevent clients from using Web-based printing, use the Group Policy snap-in, discussed in [Chapter 9](#).

## Viewing the Status of a Printer

To view the status of a printer and jobs in the printer's queue, follow these steps:

1. Enter the URL of the print server followed by `/printers` in the browser's Address window.
2. To display the printer's queue, click the hyperlink to the printer you want to manage.

You can add print servers or printers to the Favorites folder or add a bookmark just as you can with a Web page.

## Pausing, Canceling, and Restarting Print Jobs

You can use the Document List page to pause, cancel, or restart any or all documents waiting to print. To do this, follow these steps:

1. Click a hyperlink under the Printer Actions heading to pause, resume, or cancel the printing of all documents in the print queue.
2. To pause or cancel a specific print job, select the option button to the left of the document, and then click the Pause hyperlink or the Cancel hyperlink under the Document Actions heading, as shown in Figure 822.
3. To view the properties for the printer, click the Properties hyperlink under the View heading. Note that you can only view properties in the browser; to change them, you must use a Windows 2000 machine.

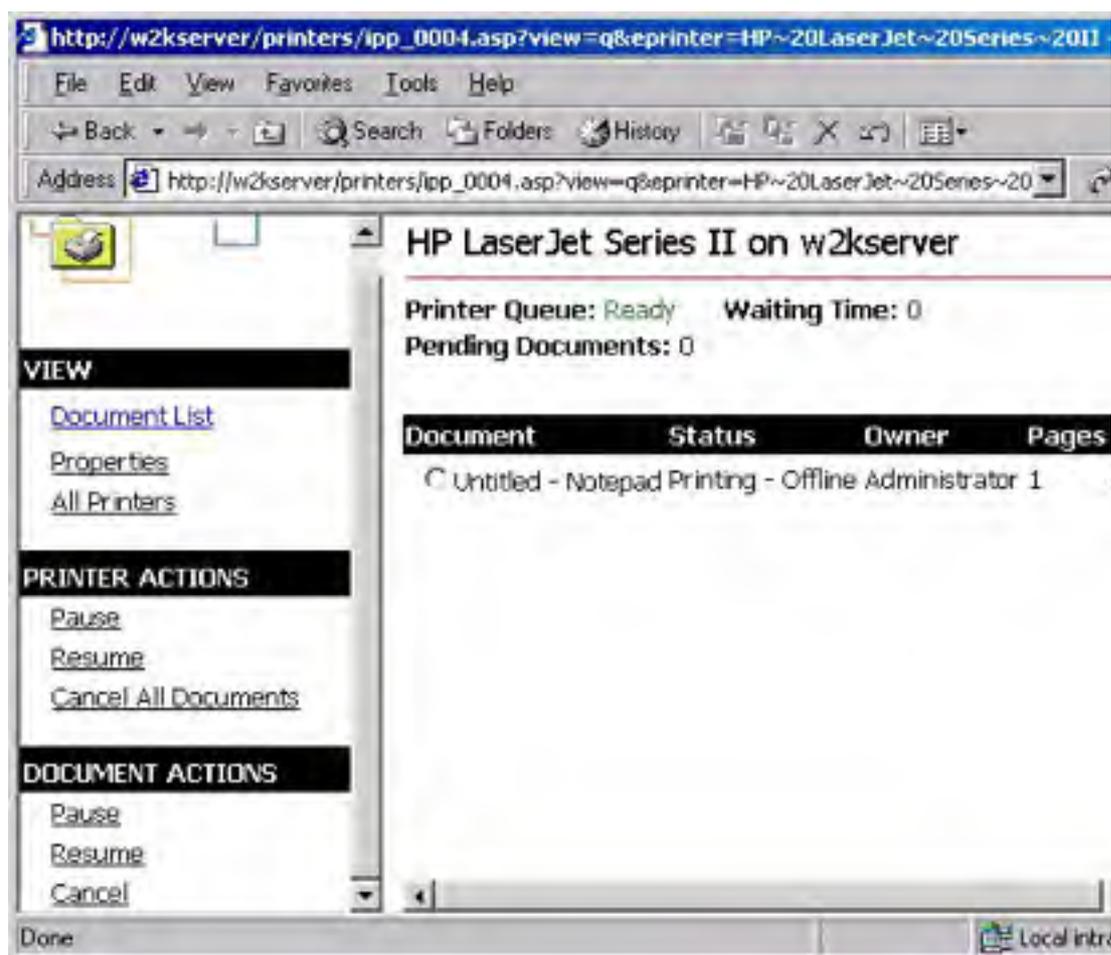

Figure 8-22. The Document List page for a printer.

## Troubleshooting Printing Problems

The goal in troubleshooting printing problems, as in troubleshooting any type of problems, is first to isolate and identify the problem and then to determine a course of action to fix it. This section helps you diagnose the printer problems, locate the printing subsystem where the error is occurring, and give you some specific tips for solving the problems. The most likely printing problem you'll encounter is a user who can't print, so we present the troubleshooting procedures with this task as the focus.

This section is somewhat condensed, with all client troubleshooting steps presented together and all server steps presented together. In reality, you would often perform basic troubleshooting on the client before you move on to verifying that the print server is working, and you would move on to the most advanced troubleshooting tasks only after you ascertain for sure where the problem is.

Because no set technique exists to identify where a problem lies, the real difficulty in troubleshooting is determining the cause of the problem. To be able to do this, you must understand the various components involved in printing. A little intuition doesn't hurt, either. (For background about the printing process, you might want to reread the [Understanding the Printing Process](#) section before you continue.)

Printing problems usually fall into the following categories:

- **Physical problems** Including problems with the printer and the transmission media.
- **Print server problems** Including problems with printer drivers, permissions levels, and software status.
- **Network connectivity problems** Including not being able to communicate between the server and the clients because of incorrect protocols, network settings, or hardware failures. (These problems can be handled on either the client or the server, depending on which is experiencing the connectivity problem.)
- **Client problems** Including problems with printer drivers, permissions, and applications.

Try to determine which category the problem is in before getting into details. A process of elimination usually works. Try printing from a couple of client machines. If only one doesn't work, you've narrowed the problem down to that client machine; if all clients fail, try printing from the print server. If this succeeds, you know that the problem lies either in the print server configuration or in network connectivity. Keep trying alternatives until you've isolated the problem as precisely as possible, and then start applying the most common fixes until you solve the problem.

If you've already partially isolated the problem, jump straight to the heading in this section that applies and continue. If you can't solve the problem by following the guidelines provided here, you should at least be able to isolate the problem to a greater degree.

### More Info

If you can't resolve the problems by using the information provided here, check out the Microsoft Knowledge Base. Go to <http://support.microsoft.com>, and click the Search link.

## Printing from the Client Machine Experiencing the Problem

Attempting to print from the client machine allows you to see any error messages generated while printing. These messages often uncover the cause of the problem or at least indicate some possibilities.

If the document prints properly, you probably have a user error, in which case you might need to educate the users as to the proper printing procedure. Otherwise, you might have a problem with a particular program, or the printer driver might be improperly configured for the users.

Many administrators use this step later in their troubleshooting process to minimize the number of times they need to visit client systems. To understand whether the problem affects only the client or clients reporting the problem or whether it's more generalized, they start by checking the print server or printing from another client computer such as the one they're currently using.

## Document Prints Incorrectly

When a document prints but appears garbled or has some other defect, a compatibility problem exists between the client, the printer driver, and the printer. Make sure that the client is using the proper client printer driver and that the server is also using the proper printer driver.

You might want to try installing a duplicate logical printer to test whether the printer driver is corrupt. If this isn't the problem, try changing the spool settings on the client driver (or, if multiple clients experience the same problem, the server's printer driver). Specifically try changing the following options in the Advanced tab of the printer's Properties dialog box. (See the section entitled [Changing Spool Settings](#), earlier in this chapter, for a more detailed procedure.)

- To ensure that the entire document is available to the printer when printing begins, select the Start Printing After Last Page Is Spooled option.
- If you continue to have printing problems, choose the Print Directly To The Printer option to turn off spooling. This action causes a performance reduction on the server.
- Clear the Enable Advanced Printing Features check box on the print server to turn off metafile spooling, which disables some printer options such as page order, booklet printing, and pages per sheet (if available on the printer).

## Document Fails to Print

If the document doesn't print properly, error messages frequently appear that might help you identify the problem. Here are some solutions to try:

- If you receive an error stating that the appropriate printer driver wasn't available for download, you need to install the appropriate client drivers on the print server.
- If you receive an error stating that the print device was unavailable, you might have a network connectivity problem, or the client might lack sufficient permissions.
- If you hear a lot of disk access and the document fails to print, verify that the drive holding the client's spool folder contains enough free disk space to hold the spooled document.
- Determine whether you can see and connect to the print server across the network. Try copying a file to the print server to see whether you can access the print server. (Generally, if you can't access the print server, you can't access any attached printers.)
- Try creating a new local printer with the share name `\\<servername>\<printername>` of the printer as the port name. This tests whether you can copy print files to the print server.
- Print a test document from Notepad. If you can print with Notepad and not with the user's application, the printer drivers are correct and the application is likely the problem.
- If you can't print with Notepad, you can also try printing from the command line by typing the following command: `dir > [the printer port name]`, using the share name of the network printer as the printer port name.

## Printing from Some Applications Doesn't Work

Some applications experience problems when printing in Windows 2000. Some of the issues you might encounter are listed here:

- **Printing from Microsoft Outlook on a system with multiple languages is slow.** This occurs if languages are installed on the client that aren't available on the server. To remedy this, copy the fonts to the `%SystemRoot%\Fonts` folder on the print server, and open the Fonts folder (or reboot the server).

- **"Access denied" error message occurs when configuring a printer inside an application.** This occurs when you don't have sufficient privileges to change the printer's configuration. To configure a printer, you need to have Manage Printers permissions.
- **"Out-of-memory" error message occurs on application load on Windows 3.x client.** This can occur if a default printer isn't selected. Install a printer and configure it as the default printer.
- **MS-DOS program doesn't print on Windows 2000 or Windows NT.** This can occur if you're using an MS-DOS-based program that won't print until it is exited. Try quitting the program. Also, when setting up the printer driver using the Add Printer Wizard, choose Yes when asked whether you print from MS-DOS programs.

#### More Info

More Info For other issues, consult the Printers.txt file on the installation CD for the client operating system if the system is Windows 2000, Windows NT 4, or Windows 95/98. You might also want to check the Microsoft Knowledge Base at <http://support.microsoft.com>.

## Checking the Print Server Status

Administrators often check the print server status before actually going to the client machine because they can do it remotely. Here are some matters to check:

- The print monitor might show stalled documents or error messages. If the printer is out of paper or toner or if there's a paper jam, an error message frequently appears here.
- Check that sufficient free disk space exists on the drive holding the spool folder.
- If documents print garbled, the printer might be using the wrong data type (*EMF* or *raw*). Try using the *raw* data type to see if this corrects the problem. You might also want to clear the Enable Advanced Printing Features check box in the Advanced tab of the printer's Properties dialog box. (See the section entitled [Changing Spool Settings](#) earlier in this chapter for more information.)
- Check to see whether any documents are printing. If no documents exist in the print queue to observe, print a test page or document from the print server to verify that the print server is printing properly.
- If some documents in the print queue don't print and you can't delete them, the print spooler might be stalled. Restart the Print Spooler service to see whether this corrects the problem. You might also want to add another logical printer (printer driver) for the printer to try to rule out the possibility of a corrupt printer driver.
- Check that the proper services are installed and started for any non-Microsoft clients on the network. For example, if a Macintosh client is having printing problems, check to make sure that the Macintosh print services are installed and running.

To prevent documents with certain languages from printing slowly, install on the print servers the fonts for all languages that the clients will use to print. To do this, copy the fonts to the `%SystemRoot%\Fonts` folder on the print server and open the Fonts folder (or reboot the server).

## Printing from Another Client Machine

Attempting to print from another client machine helps determine whether the problem lies on the server or on the original client machine. Print a test document from the client system, and then use these guidelines to address the results of the print attempt.

- **Second client prints** If the second client you attempt to print from prints properly, you need to go back to the original client and perform more in-depth troubleshooting, such as reinstalling the printer drivers and testing the printing subsystem.
- **Second client fails to print** If the second client can't print to the specified printer, you

most likely have a problem with the print server or printer. If the print server shows no problems, check the printer.

## Checking the Printer

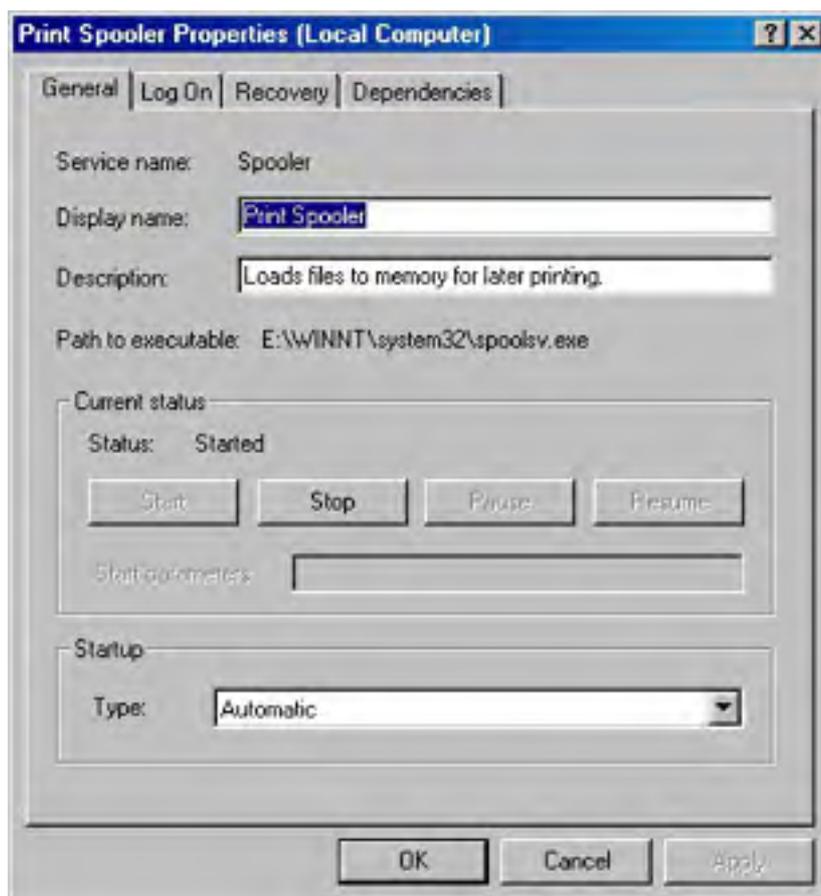

If you've ruled out the clients and the server as the source of the problem but you still can't print any documents on the printer, you need to take a close look at the printer. Pause the print queue, and then go check the actual printer. Are any errors reported on the printer? If you find any paper jams or if the printer is low on toner or needs servicing, the printer usually reports an error message. Make sure that the ready or online light is illuminated and that the printer cable is securely attached, or that the network cable is properly plugged in and the light next to the network port is illuminated (if available).

If you still can't print to the printer, attempt to print a test page directly from the printer. Most printers support this capability. If this works, try configuring a different print server with the printer. If you can print from a different print server, you have a problem with the original print server. If this doesn't work, try pinging the printer to see if you can communicate with it.

## Deleting Stuck Documents

If you can't delete documents in the print queue or if documents don't print, the print spooler might be stalled. This also affects any fax services the server is running. To restart the Print Spooler service, follow these steps:

1. Launch the Computer Management snap-in from the Administrative Tools folder, expand System Tools in the console tree, and then select Services.
2. Double-click the Print Spooler service in the right pane to open the Print Spooler Properties dialog box, shown in Figure 8-23.

**Figure 8-23.** The General tab of the Print Spooler Properties dialog box.

3. Click Stop to stop the service, and then click Start to restart the service.

4. To view the services (such as remote procedure call) on which the print spooler depends, click the Dependencies tab. You can also use this tab to view the services that depend on the print spooler to function properly.
5. To configure a recovery process to take place should the Print Spooler service fail, click the Recovery tab, and then specify whether you want to restart the service, reboot the computer, or run a program after each print spooler failure.

Restarting the service is usually a good option—it saves time. Automatic rebooting of the computer is a last option because of other processes that might be interrupted or stopped by a reboot.

## **Troubleshooting Printer Location Tracking**

Printer location tracking can have its own set of problems, although these are usually related to the way the printers and network are set up. The rest of this section discusses some common problems that you might encounter when using printer location tracking and suggests some courses of action.

### **Clients Can't Locate Some Printers in Active Directory**

This problem usually occurs when a printer isn't named according to the printer location name conventions the company decided to implement. When printer location tracking is enabled, clients by default can locate only printers with location attributes that match the naming convention. To fix the problem, enter the correct location name in the missing printer's *Location* field.

### **Naming Scheme Needs to Be Changed**

If the company changes its organizational structure or if you find that the current location-naming scheme needs to be changed, use the following procedure. (Windows 2000 doesn't ship with any tools for bulk editing of objects in Active Directory.)

Use Active Directory Sites and Services to update the sites and subnet names. Enter the new location names in the *Location* field of each printer that is affected by the location name restructuring. You can also do this with an Active Directory Services Interface (ADSI) script.

## **Summary**

As this chapter demonstrates, printing is a much bigger subject than most people imagine. Furthermore, almost all networks need comprehensive and reliable print services. You must plan how to meet present printing needs while also preparing for expansions and changes. Contingency plans are essential because even a brief disruption in printing is not only inconvenient, it's costly. In the next chapter, we'll cover the day-to-day tasks that network administrators perform and how to customize the tools in Windows 2000 Server to make your work easier and more efficient.

# Chapter 9

## **Managing Users and Groups**

The central task of a network is to make sure that the customers (the users) have everything they need and nothing they don't. What they need includes access to the files, folders, applications, printers, and Internet connections that they require to do their jobs. What they don't need is any trouble getting at what they *do* need.

The network administrator has additional needs, such as shielding need-to-know material from those who don't need to know and protecting the users from themselves. The key to all of these needs is the configuration of groups, users, and group policies—the topic of this chapter.

## Understanding Groups

By definition, groups in Microsoft Windows 2000 are Active Directory service or local computer objects that can contain users, contacts, computers, or other groups. In general, though, a group is usually a collection of user accounts. The point of groups is to simplify administration by allowing the network administrator to assign rights and permissions by group rather than to individual users.

Windows 2000 allows two group types: security and distribution. *Security groups* are essentially the only groups used by Windows 2000 because they're the only groups through which permissions can be assigned. Each security group is also assigned a *group scope*, which defines how permissions are assigned to the group's members. Programs that can search Active Directory can use security groups for nonsecurity purposes, such as sending e-mail to a group of users. *Distribution groups* are not security enabled and can be used *only* with e-mail applications to send e-mail to sets of users.

Later in the chapter, you'll find sections on user rights and how they are defined and assigned to groups. [Chapter 10](#) includes discussion of permissions and how they are assigned.

## Assigning Group Scopes

When a group is created, it is assigned a group scope that defines how permissions will be assigned. The three possible group scopes—global, domain local, and universal—are defined in the following sections.

### Global Scope

A group with a global scope is truly global in the sense that permissions can be granted for resources located in any domain. However, members can come only from the domain in which the group is created, and in that sense it is not global. Global groups are best used for directory objects that require frequent maintenance, such as user and computer accounts. Global groups can be members of universal and domain local groups in any domain, and they can have the following members:

- Other global groups in the same domain
- Individual accounts from the same domain

### Domain Local Scope

A domain local group is the inverse of a global group in that members can come from any domain but the permissions can be only for resources in the domain in which the group is created. The members of a domain local group have a common need to access certain resources in a particular domain. Domain local groups can have one or more of the following members:

- Other domain local groups in the same domain
- Global groups from any domain
- Universal groups from any domain
- Individual accounts from any domain

The nesting rules (that is, the storage of groups within other groups) apply fully only in native mode—that is, when all of the controllers in the domain are Windows 2000 servers. In mixed-mode domains, security groups with global scope can contain only individual accounts, not other groups. Security groups with domain local scope can contain both global groups and accounts. For more on native vs. mixed mode, see [Chapter 7](#).

### Universal Scope

A universal security group can have members from any domain and can be assigned permissions to resources in any domain. Although the universal scope sounds like an ideal solution in a multiple-domain enterprise, it's available only in domains that are running in native mode. Universal groups can have the following members:

- Other universal groups
- Global groups
- Individual accounts

Even in native mode, universal groups must be used with discretion because of the negative impact they can have on network performance, as described in the Real World sidebar, "How Groups Affect Network Performance."

## **Real World**

### **How Groups Affect Network Performance**

The importance of planning groups becomes even more apparent when you consider the negative effect that your group organization can have on network performance. When a user logs on to the network, the domain controller determines the user's group memberships and assigns a security token to the user. The token includes the security identifiers of all of the groups to which the user belongs, in addition to the user account ID. The more security groups the user belongs to, the longer it takes to assemble the token and the longer it takes the user to log on.

In addition, the security token, once assembled, is sent to every computer the user accesses. The target computer compares all of the security identifiers in the token against the permissions for all of the shared resources available at that computer. A large number of users added to a large number of shared resources (including individual folders) can take up a lot of bandwidth and processing time. One solution is to limit membership in security groups. Use distribution groups for categories of users that don't require specific permissions or rights.

Groups with universal scope will have a performance impact of their own because all such groups, along with their members, are listed in the Global Catalog. When there's a change to the membership in a group with universal scope, this fact must be relayed to every Global Catalog server in the domain tree, adding to the replication traffic on the network. Groups with global or domain local scope are also listed in the Global Catalog, but their individual members are not, so the solution is to limit the membership of universal groups primarily to global groups.

## Planning Organizational Units

Organizational units (OUs) are, as their name implies, organizing tools for collections of objects within a domain. An OU can contain any collection of Active Directory objects such as printers, computers, groups, and so forth.

In the past, a domain that became very complicated was usually sorted out by splitting the domain into multiple domains. Organizational units provide an alternative administrative substructure that is infinitely more flexible. They can be arranged hierarchically within a domain and administrative control can be delegated for functions in a single OU or an entire subtree of OUs. (An OU is the smallest entity to which you can delegate administrative control.) At the same time, organizational units can be modified, moved, renamed, and even deleted easily. Another plus is that, unlike a domain, a subtree of organizational units doesn't require a domain controller.

Organizational units are only containers; they don't confer membership and aren't security principals. Rights and permissions are granted to users through group membership. After your groups are constructed, use OUs to organize group objects and assign Group Policy settings. The use of Group Policy is covered in [Chapter 9](#).

### Real World

#### Organizational Units or New Domain?

Unfortunately, there's no firm rule that you can apply to decide when an expanding network should be divided into separate domains and when new OUs are called for. If any of the following applies, multiple domains might be the answer:

- Decentralized administration is needed.
- The network encompasses competing business units or joint ventures.
- Parts of the network are separated by *very* slow links, so complete replication would create severe traffic problems. (If the link is merely slow, you can use multiple sites within a single domain because replication is less frequent.)
- Different account policies are needed. Because account policies are applied at the domain level, greatly differing policies might call for separate domains.

Situations that call for the use of OUs include the following:

- Localized or tightly controlled administration is needed.
- Structure of the organization requires the arrangement of network objects into separate containers.
- The structure that you wish to separate is likely to change at some point.

So in general, when the situation calls for a flexible or even fluid structure, OUs are the answer.

## Creating Organizational Units

Organizational units are easily created and appear as folders in a domain structure. To create an OU, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the domain and choose New and then Organizational Unit from the shortcut menu.
3. In the Organizational Unit dialog box, enter the name for the unit and then click OK.

## Moving Organizational Units

One of the most useful aspects of organizational units is that they can be moved from one container or even one domain to another. To move an OU, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the OU to be moved and choose Move from the shortcut menu.
3. In the Move dialog box, select the new location for the OU and click OK.

## **Deleting Organizational Units**

Organizational units can also be deleted easily. However, exercise caution when deleting an OU because its contents will also be removed. That means you can inadvertently delete all the resources and user accounts contained in an OU if you act too hastily. Follow these steps to delete an organizational unit:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the OU you want to remove and choose Delete from the shortcut menu.
3. Confirm the deletion by clicking Yes twice.

## Planning a Group Strategy

Looking at your network and the various group types, and then factoring in your specific needs and what you want to accomplish, you might end up feeling as though you're working on a logic puzzle: Claire lives in a blue house, Luisa collects stamps, Sam drives a Toyota, and Ross eats cheese. Which one has red hair?

Nevertheless, as in so many other aspects of network administration, planning is *the* essential step. The domain mode determines the types of groups available to you. A mixed-mode domain can't support groups with universal scope. Thus, as long as you have Microsoft Windows NT backup domain controllers, you are limited to groups with global and domain local scopes. However, with some thought and the use of nesting, these two types of security groups can suffice for almost all purposes.

## Determining Group Names

In planning your groups, you should determine a naming scheme that is appropriate for your organization. Two factors should be considered:

- **Group names should be instantly recognizable.** If they are, administrators searching Active Directory don't have to guess at their meaning.
- **Comparable groups should have similar names.** In other words, if you have a group for engineers in each domain, give all of the groups parallel names, such as NorAmer Engineers, SoAmer Engineers, and Asia Engineers.

## Using Global and Domain Local Groups

You'll need to develop a strategy for using the different groups. For example, users with common job responsibilities belong in a global group. Thus, you'd add user accounts for all graphic artists to a global group called Graphic Artists. Other users with common needs would be assigned to other global groups. Then you must identify resources to which users need access and create a domain local group for that resource. If, for example, you have several color printers and plotters that are used by specific departments, you could make a domain local group called Printers&Plotters.

Next you should decide which global groups need access to the resources you've identified. Continuing the example, you'd add the global group Graphic Artists to the domain local group Printers&Plotters, along with other global groups that need access to the printers and plotters. Permission to use the resources in Printers&Plotters would be assigned to the Printers&Plotters domain local group.

Keep in mind that global groups can complicate administration in multiple-domain situations. Global groups from different domains have to have their permissions set individually. Also, assigning users to domain local groups and granting permissions to the group does not give members access to resources outside the domain.

Remember that the nesting rules apply only in native mode. In mixed-mode domains, security groups with global scope can contain only individual accounts, not other groups. Security groups with domain local scope can contain global groups and accounts.

## Using Universal Groups

When you're able to use universal groups (that is, when your domain is running in native mode), keep the following guidelines in mind:

- Avoid adding individual accounts to universal groups, to keep replication traffic down.
- Add global groups from multiple domains to universal groups to give members access to resources in more than one domain.
- Universal groups can be members of domain local groups and other universal groups, but they can't be members of global groups.

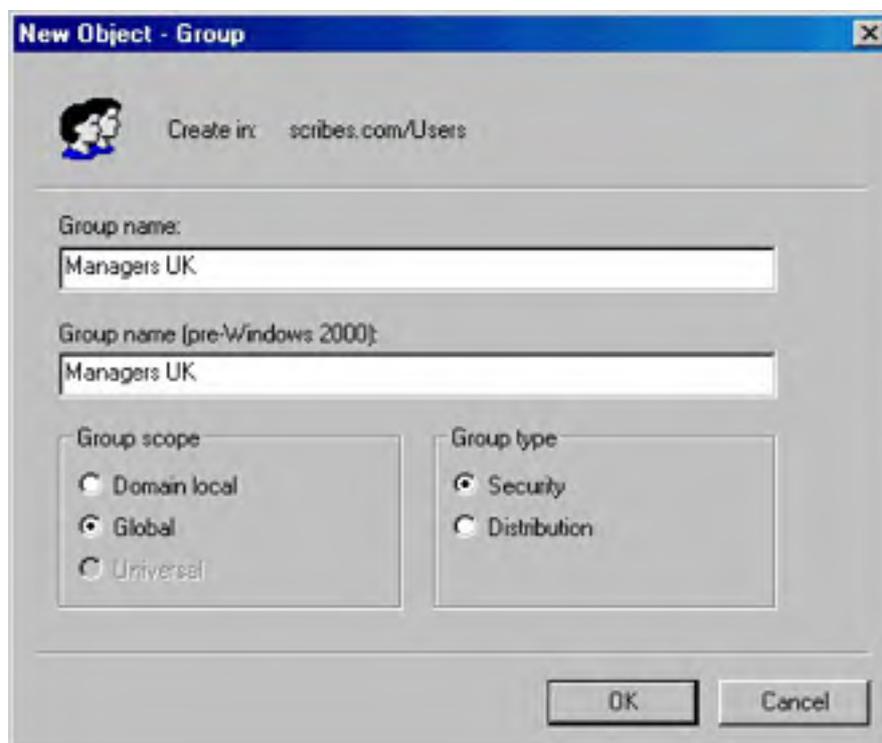

## Implementing the Group Strategy

Once you've planned your strategy and tested it using a variety of scenarios, you're ready to begin putting the structure into place.

### Creating Groups

Use Active Directory Users and Computers to create and delete groups. Groups should be created in the Users container or in an OU that you've created for the purpose of containing groups. To create a group, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Expand the domain in which the group will be created.
3. Right-click the Users container, point to New, and choose Group from the shortcut menu to open the dialog box shown in Figure 9-1.
4. Fill in the required information:
  - The group name must be unique in the domain.
  - The group name as it will be seen by pre-Windows 2000 operating systems will be filled in automatically. (In native mode, this field will be Downlevel Name Of New Group but will still be filled in automatically based on the name you provide as the group name.)
  - For Group Scope, click Domain Local, Global, or Universal.
  - For Group Type, click Security or Distribution.
5. Click OK when you're finished. The new group will appear in the Users container. You might have to wait a few minutes for the group to be replicated to the Global Catalog before adding members.

**Figure 9-1.** Creating a new group.

### Deleting Groups

When groups are no longer needed, be sure to delete them from the system promptly. Unnecessary groups are a security risk because it is all too easy to grant permissions unintentionally.

Each group, like each user, has a unique security identifier (SID). The SID is used to identify the group and the permissions assigned to the group. When the group is deleted, the SID is deleted and not used again. If you delete a group and decide later to re-create it, you will have to configure the users and permissions as if for a new group.

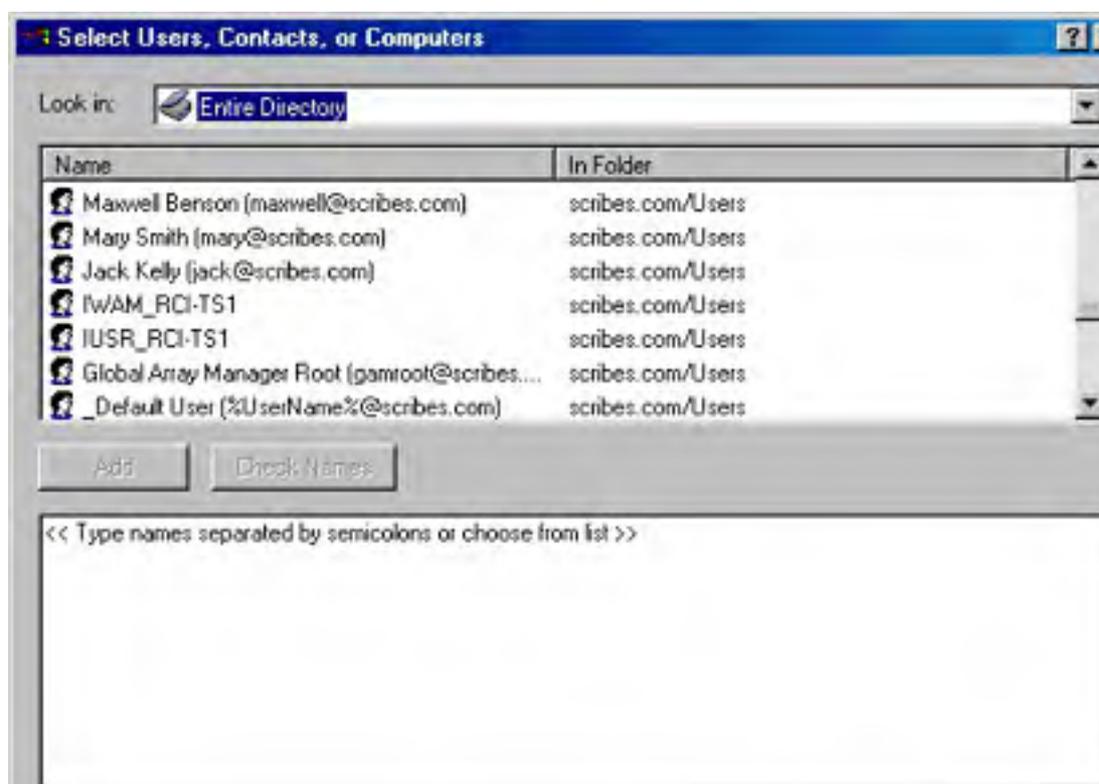

To delete a group, merely right-click its name in Active Directory Users and Computers and choose Delete from the shortcut menu. Deleting a group deletes only the group and the permissions associated with the group. It has no effect on the accounts of users who are members of the group.

## Adding Users to a Group

Once you've created a group, you'll need to add members to it. As mentioned earlier in the chapter, groups can contain users, contacts, other groups, and computers. To add members to a group, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. In the console tree, click the container that includes the group to which you will be adding members.
3. Right-click the group and choose Properties from the shortcut menu.
4. Click the Members tab, and then click Add to open the Select Users, Contacts, Or Computers dialog box (Figure 9-2).
5. Select the accounts you want to add. (You can use the Shift and Ctrl keys to select multiple accounts.)
6. Click Add. This returns you to the group's Properties dialog box with the users added. Click OK.

A contact is an account without security permissions and is typically used to represent external users for the purpose of e-mail. You can't log on to the network as a contact.

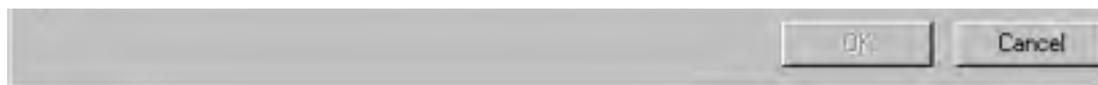

Figure 9-2. Adding an account to a group.

## Changing the Group Scope

Over time, you might find that you need to change the scope of a particular group. For example, you might need to change a global group to a universal group so that users from another domain can be part of the group. However, the types of changes that can be made to a group scope are quite limited, and you might need to delete the group and create a new one to get the configuration you need.

To change a group scope, right-click the group name in Active Directory Users and Computers and choose Properties from the shortcut menu. Make the necessary changes in the General tab, and click OK when you're finished. The rules for changing a group scope are as follows:

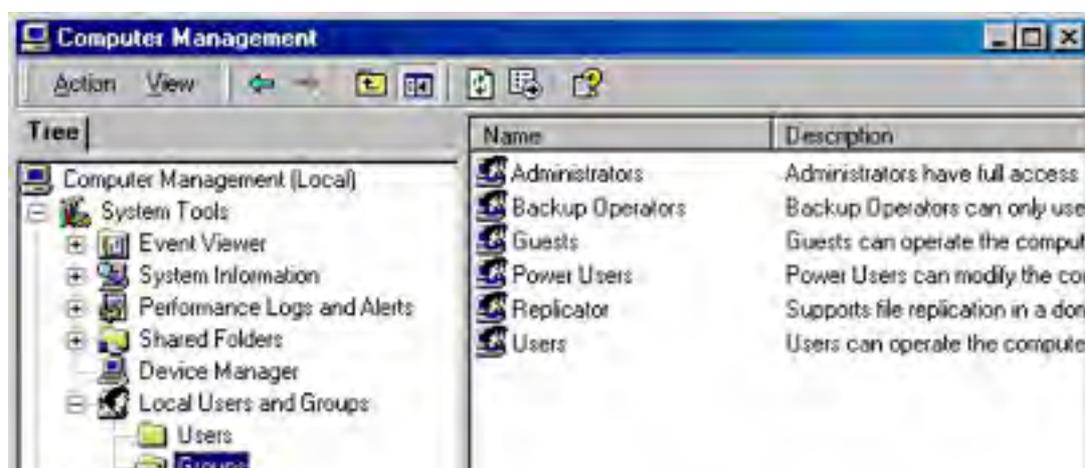

- In mixed mode, a security group cannot have universal scope.
- A global group can be changed to a universal group if the global group is not already a member of another global group.
- A domain local group can be changed to a universal group if the domain local group does not already contain another domain local group.
- A universal group cannot be changed.

## Creating Local Groups

A local group is a collection of user accounts on a single computer. The user accounts must be local to the computer, and members of local groups can be assigned permissions for resources only on the computer where the local group was created.

Local groups can be created on any Windows 2000 computer except domain controllers. In general, you don't want to use local groups on a computer that's part of a domain or, at least, you want to do so sparingly. Local groups don't appear in Active Directory, so you must administer local groups separately on each individual computer. To create a local group, follow these steps:

1. Right-click the My Computer icon on the desktop and choose Manage from the shortcut menu.
2. In the console tree, expand System Tools and then Local Users And Groups, as shown in Figure 9-3.
3. Right-click the Groups folder and select New Group from the shortcut menu.
4. In the New Group dialog box, enter the group name. You can include a description if you like.
5. Click Add to add members to the group. (You can add members now or later.)
6. Click Create when you're finished, and the new group is added to the list of groups in the details pane.

**Figure 9-3.** Viewing local groups in the Computer Management MMC snap-in.

## Managing Built-in Groups and User Rights

Windows 2000 creates four types of built-in groups: local, domain local, global, and system. Each type of built-in group has a predetermined set of user rights. Everyone assigned to the group automatically possesses those rights.

### Built-in Local Groups

Member servers, stand-alone servers, and computers running Windows 2000 Professional have built-in local groups that give rights to perform tasks on a single computer. Table 9-1 shows the built-in local groups.

**Table 9-1.** *Built-in local groups*

Local Group	Description
Administrators	Members can perform all administrative tasks on the computer. Use this group with caution. The built-in Administrator account that's created when the operating system is installed is a member of the group. When a stand-alone server or a computer running Windows 2000 Professional or Microsoft Windows XP Professional joins a domain, the Domain Admins group is made part of this group.
Backup Operators	Members can log on to the computer, back up and restore the computer's data, and shut down the computer. Members cannot change security settings. There are no default members in the group.
Guests	Members can perform only tasks for which an administrator has granted rights. Members can use only those resources for which an administrator has specifically granted permission.
Power Users	Members can create and modify user accounts and install programs on the local computer but cannot view other users' files.
Replicator	Do not add user accounts of actual users to this group. If necessary, you can add a "dummy" user account to this group to permit you to log on to Replicator services on a domain controller to manage replication of files and directories.
Users	Members of this group can log on to the computer, access the network, save documents, and shut down the computer. Members cannot install programs or make system changes. When a member server or Windows 2000 Professional machine joins a domain, the Domain Users group is added to this group.

If you don't want members of the Domain Users group to have access to a particular workstation or member server, remove Domain Users from that computer's local Users group. Similarly, if you don't want the members of Domain Admins group to administer a particular workstation or member server, remove Domain Admins from the local Administrators group.

### Built-in Domain Local Groups

The Windows 2000 built-in domain local groups provide users with rights and permissions to perform tasks on domain controllers and in Active Directory. The domain local groups have predefined rights and permissions that are granted to users and global groups that you add as members. Table 9-2 shows the most commonly used of the built-in domain local groups.

**Table 9-2.** *Commonly used built-in domain local groups*

Domain Local Group	Description
Account Operators	Members can create, delete, and manage user accounts and groups. Members cannot modify the Administrators group or any of the Operators groups.

Administrators	Members are automatically granted every right and permission on all domain controllers and the domain itself. The Administrator account, Enterprise Admins group, and Domain Admins group are members.
Backup Operators	Members can back up and restore data on all domain controllers using Windows 2000 Backup.
Guests	Members can perform only tasks for which an administrator has granted rights. Members can use only those resources for which an administrator has specifically granted permission. The Guest User and Domain Guests groups are members by default.
Print Operators	Members can manage all aspects of printer operation and configuration in the domain.
Server Operators	Members can perform most administrative tasks on domain controllers, except the manipulation of security options.
Users	Members can log on to the computer, access the network, save documents, and shut down the computer. Members cannot install programs or make system changes. The Domain Users group is a member by default.

### Real World

#### Just Who Is Everyone?

In Windows NT, all domain users are members of the Everyone group. This group is controlled by the operating system and appears on any network with Windows NT servers. In Windows 2000, the equivalent group is called Authenticated Users. Unlike Everyone, Authenticated Users contains no anonymous users or guests. The Everyone group survives as a *special identity*. You don't see it when you administer groups, and it can't be placed in a group. When a user logs on to the network, the user is automatically added to Everyone. You can't see or change the membership of the special identities, which also include the Network and Interactive groups. Use the Authenticated Users group in place of the Everyone group when assigning permissions to resources to ensure that anonymous users and guests are restricted from accessing network resources.

## Built-in Global Groups

Built-in global groups are created to encompass common types of accounts. By default, these groups do not have inherent rights; an administrator must assign all rights to the group. However, some members are added to these groups automatically, and you can add more members based on the rights and permissions you assign to the groups. Rights can be assigned directly to the groups or by adding the built-in global groups to domain local groups. Table 9-3 describes the built-in global groups that are commonly used.

**Table 9-3.** Commonly used built-in global groups

Global Group	Description
Domain Admins	This group is automatically a member of the domain local Administrators group, so members of Domain Admins can perform administrative tasks on any computer in the domain. The Administrator account is a member of this group by default.
Domain Computers	All controllers and workstations in the domain are members.
Domain Controllers	All domain controllers in the domain are members.
Domain Guests	The Guest account is a member by default. This group is automatically a member of the domain local Guests group.
Domain Users	All domain users and the Administrator account are members. The Domain Users group is automatically a member of the domain local Users group.

Enterprise Admins	This group is for users who are to have administrative rights for the entire network. Enterprise Admins is automatically a member of the domain local Administrators group in the domain in which it is created. You need to add it to the domain local Administrators group for other domains.
Group Policy Admins	Members can create and modify group policy for the domain.

If you have users who should have fewer rights and/or permissions than the typical user, add these users to Domain Guests and remove them from Domain Users.

## Defining User Rights

What users can and cannot do depends on the rights and permissions that have been granted to them. *Rights* generally apply to the system as a whole. The ability to back up files or to log on to a server, for example, is a right that the administrator giveth or taketh away. Rights can be assigned individually, but most often they are characteristics of groups, and a user is assigned to a particular group on the basis of the rights that the user needs.

*Permissions* indicate the access that a user (or group) has to specific objects such as files, directories, and printers. For example, the question of whether a user can read a particular directory or access a network printer is a permission. Permissions are discussed at length later in this chapter.

*Rights*, in turn, are divided into two types: privileges and logon rights. *Privileges* include such things as the ability to run security audits or force shutdown from a remote system—obviously not things that are done by most users. *Logon rights* are self-explanatory; they involve the ability to connect to a computer in specific ways. Rights are automatically assigned to the built-in groups in Windows 2000, although they can be assigned to individual users as well as groups. Assignment by group is preferred, so whenever possible, you should assign rights by group membership to keep administration simple. When membership in groups defines rights, rights can be removed from a user by simply removing the user from the group. Tables 9-4 and 9-5 list the logon rights and privileges and the groups to which they are assigned by default.

**Table 9-4.** Logon rights assigned to groups by default

Name	Description	Groups Assigned the Right by Default
Access this computer from the network	Permits connection to the computer through the network.	Administrators, Power Users, Everyone
Logon as a batch job	Allows logging on using a batch queue.	Administrators
Logon as a service	Allows logging on as a service using a specific user account and security context.	None
Logon locally	Permits logon at the computer's keyboard.	Administrators, Account Operators, Backup Operators, Print Operators, Server Operators

**Table 9-5.** Privileges assigned to groups by default

Privilege	Description	Groups Assigned the Privilege by Default
Act as part of the operating system	Allows a process to authenticate as any user. A process that requires this privilege should use the LocalSystem account, which already includes this privilege.	None

Add workstations to domain	Allows a user to add new workstations to an existing domain.	Administrators
Backup files and directories	Allows backing up the system; overrides specific file and folder permissions.	Administrators, Backup Operators
Bypass traverse checking	Allows a user to go through directory trees (folder structures) even if the user doesn't have permission to access the directories being passed through.	Everyone
Change the system time	Allows the setting of the computer's internal clock.	Administrators, Power Users
Create a pagefile	Allows the creation and modification of a pagefile.	Administrators
Create a token object	Allows a process to create a token that can be used to access any local resource. A process that requires this privilege should use the LocalSystem account, which already includes this privilege.	None
Create permanent shared objects	Allows a process to create a directory object. Used by kernel-mode components to extend the Windows 2000 object namespace. Components running in kernel mode already have this privilege.	None
Debug programs	Allows the user to attach a debugger to a process.	Administrators
Enable computer and user accounts to be trusted for delegation	Permits a user to set the Trusted for Delegation setting on an object.	Administrators
Force shutdown from a remote system	Allows the shutdown of a computer from a remote location on the network.	Administrators
Generate security audits	Allows a process to make entries in a security log.	None
Increase quotas	Allows a process with write property access to another process to increase the processor quota assigned to that process.	None
Increase scheduling priority	Allows the use of Task Manager to change the scheduling priority of a process.	Administrators, Power Users
Load and unload device drivers	Install and remove device drivers.	Administrators
Lock pages in memory	Allows a process to keep data in physical memory. This is an obsolete privilege that can have a seriously negative effect on system performance. Do not use it.	None
Manage auditing and security log	Allows a user to specify auditing options and to view and clear the security log in Event Viewer. Audit Directory Service Access must be turned on for object access auditing to be performed. (See <a href="#">Chapter 10</a> .) Administrators can always view and clear the security log.	Administrators
Modify firmware environment	Allows the configuration of nonvolatile RAM on computers that support such function.	Administrators variables

Profile a single process	Allows performance sampling on a process.	Administrators, Power Users
Profile system performance	Allows performance sampling of the system.	Administrators
Remove computer from docking station	Allows the removal of a laptop from a docking station using the Windows 2000 interface.	Administrators, Users
Replace a process level token	Allows the replacement of the default token associated with a subprocess.	None
Restore files and directories	Allows restoring files and folders to a system; overrules specific file and folder permissions.	Administrators, Backup Operators
Shut down the system	Shuts down Windows 2000.	Administrators, Backup Operators, Everyone, Power Users, Users
Synchronize directory service data	Allows a user to initiate a synchronization of Active Directory.	Administrators
Take ownership of files or other objects	Allows a user to take ownership of any security object including files and folders, printers, registry keys, and processes. Overrules specified permissions.	Administrators

### Assigning User Rights to a Group

Rights are assigned and removed most easily at a domain level using group policy. Suppose you have a group of users whom you want to allow to log on locally to Windows 2000 servers, but you don't want them to be members of any of the groups that have this logon right by default. One way to approach this situation would be to create a group called Logon Rights, add the users to the group, and assign the right to log on locally to the Logon Rights group. To assign a right to a particular group, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder. Right-click the domain name and choose Properties from the shortcut menu.
2. Click the Group Policy tab, select the Default Domain Policy, and then click Edit. Open Computer Configuration, and then open Windows Settings.
3. Under Security Settings, click Local Properties and then User Rights Assignment (Figure 9-4). In the details pane, double-click Log On Locally.
4. Place a check mark next to Define These Policy Settings and then click Add.
5. Enter the name of the group to be granted this right (or click Browse to search for the group). Click OK twice and close the Default Domain Policy.

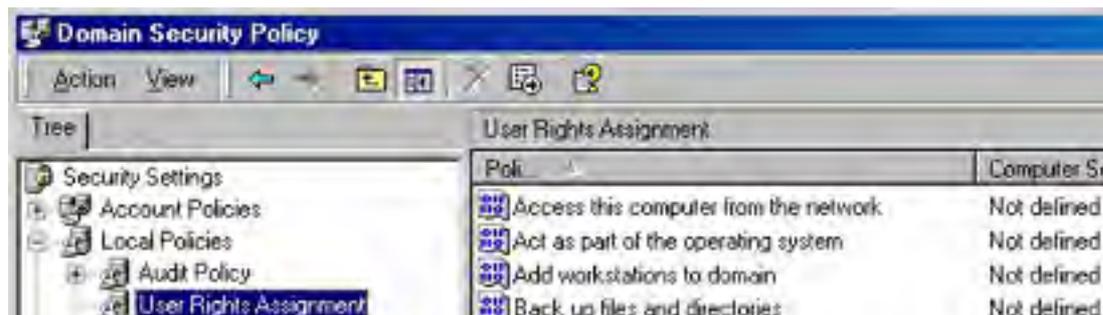

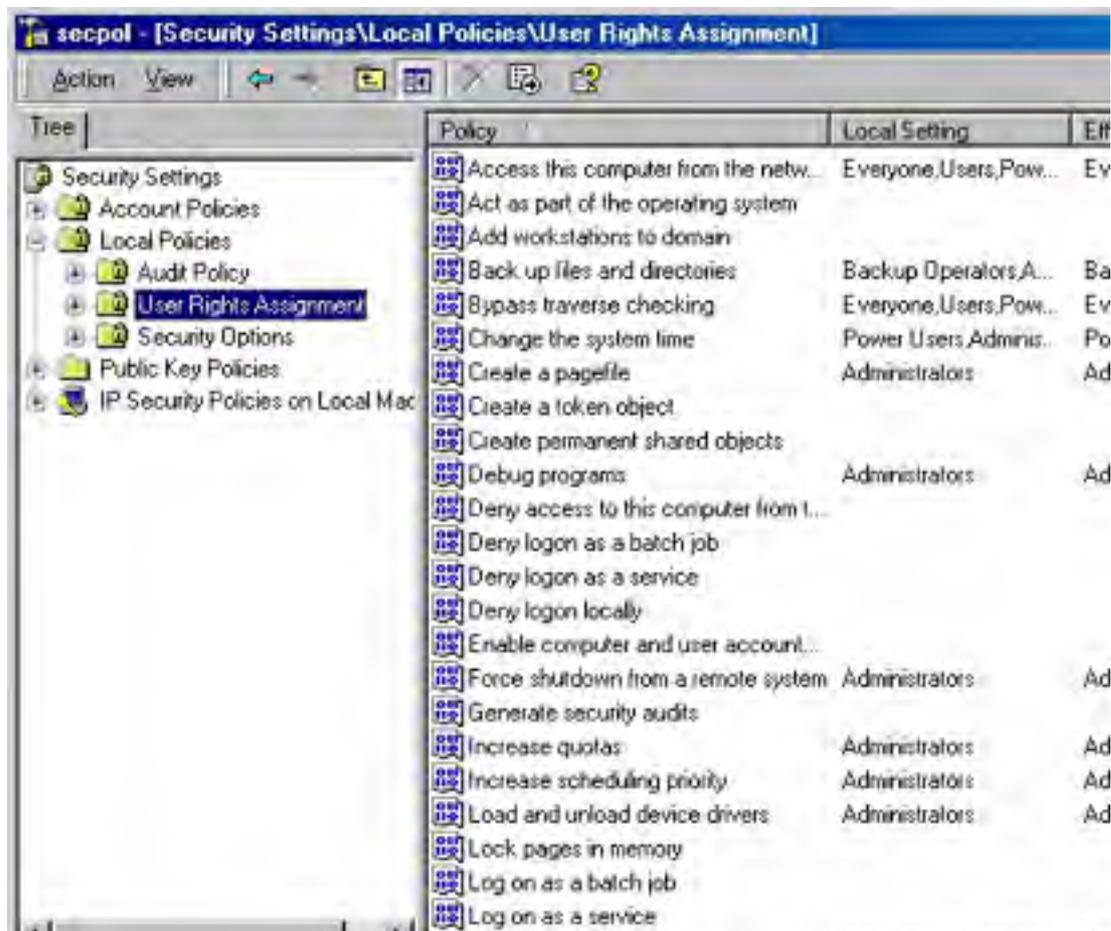

Figure 9-4. User rights listed under group policy.

The same process can remove rights, except that you'd click Remove in step 4. Rights can also be assigned to an individual user using this method.

### Assigning Rights Locally

Rights can be assigned or removed locally, though you must bear in mind that a defined domain-level policy will override a local policy setting. To assign a policy locally, follow these steps:

1. Launch Local Security Policy from the Administrative Tools folder.
2. Under Security Settings, click Local Policies and then User Rights Assignment (Figure 9-5). As you can see, the local settings are shown in addition to the *effective* settings. (Effective policy settings are the policy settings in effect after domain policy settings are applied.)

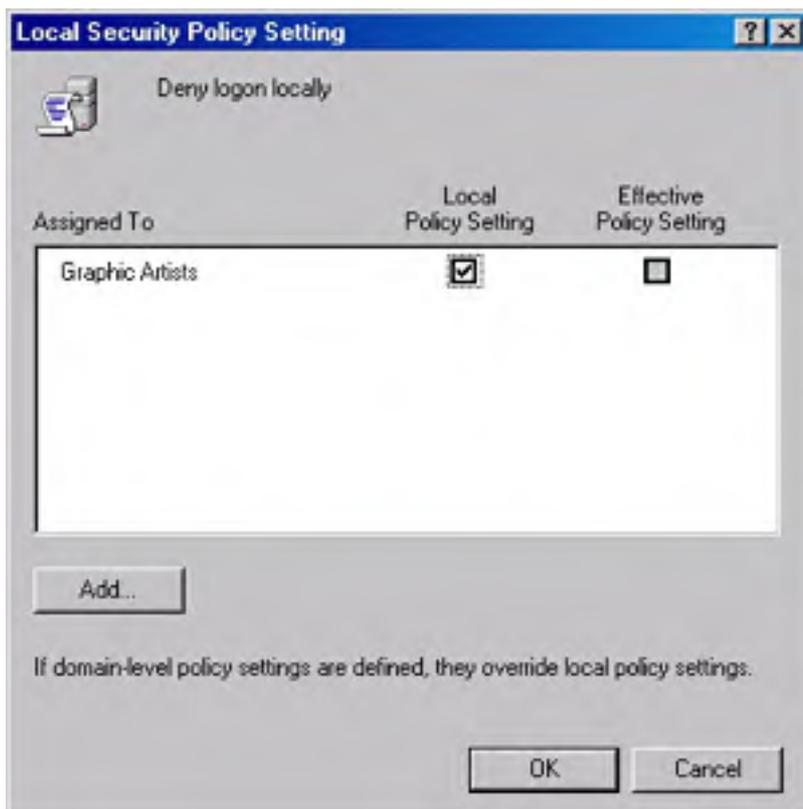

**Figure 9-5.** Local policy settings.

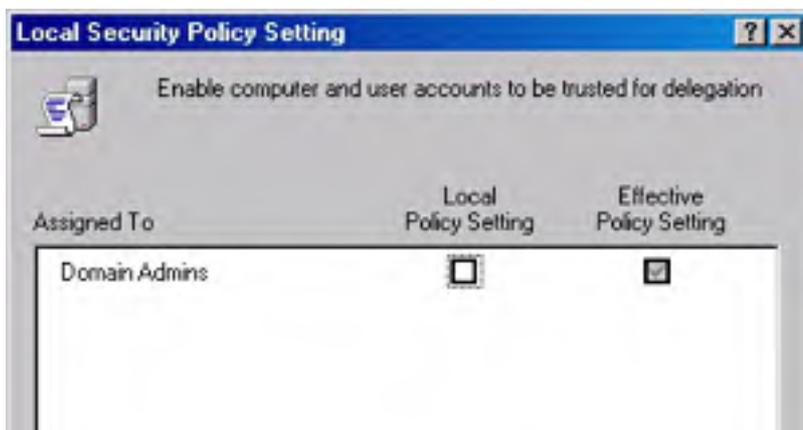

3. In the details pane, double-click the policy you want to assign to open the Local Security Policy Setting dialog box.
4. Click Add to select a group (or individual) in the Select Users Or Groups dialog box. Select the group, click Add, and then click OK.

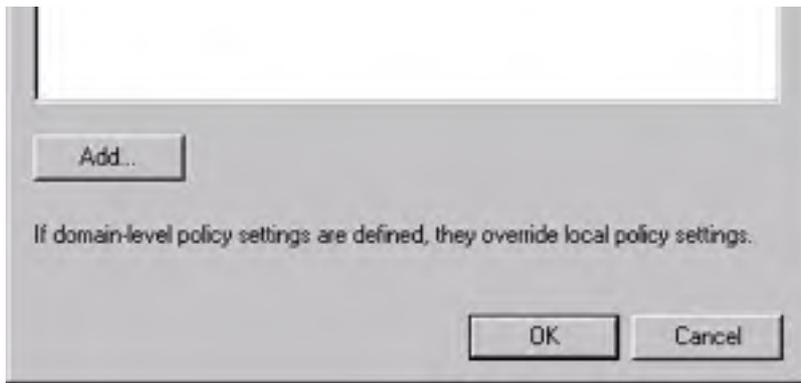

As you can see in Figure 9-6, the policy setting Deny Logon Locally has been assigned to the Graphic Artists group. The policy is shown as local only—that is, there is no domain policy in effect. The net result is that members of the Graphic Artists group will not be able to log on to this local computer. Their ability to log on or not log on to other computers in the domain is neither specified nor affected.

**Figure 9-6.** Defining the local policy that denies local logon.

Figure 9-7 shows another local policy window. In this case, the right to Enable Computer And User Accounts To Be Trusted For Delegation is assigned to Domain Admins through a domain-level policy. A domain-level policy applies whether the local policy is defined or not. Group Policy is covered in more detail later in this chapter.

**Figure 9-7.** *Domain-level policy as the effective policy.*

## Creating User Accounts

Every person who will have access to the network requires a user account. A user account makes it possible to

- Authenticate the identity of the person connecting to the network
- Control access to domain resources
- Audit actions performed using the account

Windows 2000 creates only two predefined accounts: the Administrator account, giving the user all rights and permissions, and the Guest account, which has limited rights. All other accounts are created by an administrator and are either domain accounts (valid throughout the domain by default) or local accounts (usable only on the machine where they are created).

## Naming User Accounts

In Active Directory, each user account has a *principal name*. The name consists of two parts, the *security principal name* and the *principal name suffix*. For existing Windows NT user accounts, the security principal name is by default the same as the name used to log on to the Windows NT domain. For new Windows 2000 user accounts, an administrator assigns the security principal name. The default principal name suffix is the DNS name of the root domain in the domain tree. So a user identified as EduardoP in a Windows NT domain would have a principal name such as EduardoP@scribes.com.

## Account Options

Planning account options for users simplifies the process of creating accounts. The account options to consider include the following:

- **Logon Hours** By default, a user can log on at any hour of the day or night. For security reasons, you might want to restrict access by some or all users to certain times of the day or certain days of the week.
- **Log On To** By default, users can log on to all workstations. For security reasons, you can limit logon access to a particular machine or machines if you have the NetBIOS protocol installed in the domain. Without NetBIOS, Windows 2000 is unable to determine a specific logon location.
- **Account Expiration** You can decide whether you want to set accounts to expire. For obvious reasons, it makes sense to set an expiration date for temporary employees to coincide with the end of their contracts.

Other options—*many* other options—can be set in user accounts and are detailed in the section entitled [Setting User Account Properties](#), later in this chapter. The three options just listed are the most likely to be applied across large numbers of users.

### Real World

#### Establishing a Naming Convention

The security principal name should be assigned using a consistent naming convention, so that you and your users can remember user names and find them in lists. Some options for user names include the following:

- **First name plus last initial** Examples are MichaelG and SusanM. In the case of duplicate first names, you can add numbers (MichaelG1 and MichaelG2) or enough letters to provide identification (IngridMat and IngridMur).
- **First name plus a number** Examples are Dave112 and Dave113. This approach can be a problem, especially for people with first names that appear frequently in the population. It makes it hard to remember your *own* user name and even harder to identify those of others.

- **First initial plus last name** An example would be LSmith. If you have both a Linda Smith and a Louise Smith, you could use LiSmith and LoSmith or LSmith1 and LSmith2.
- **Last name plus an initial** This convention is useful in a large network. When you have multiple users with the same last name, add a few letters, as in SmithLi or SmithLo.

No matter which approach you choose, you must not only accommodate the existing users on your network, but you must also be able to integrate future users. Then, even if the company's next hire is U Ti or Chomondely St. J. Montgomery-Glossup, your user name convention will still be able to handle it.

## Passwords

All of your users should have well-chosen passwords and should be required to change them periodically. Passwords should be chosen according to the guidelines in the sidebar "Rules for Good Passwords." Accounts should be set to lockout when invalid passwords are entered. (Allow three to five attempts, to leave room for typographical errors.)

### Rules for Good Passwords

A good password has the following characteristics:

- It is not a rotation of the characters in a logon name. (How many brain cells would it take to figure this one out?)
- It contains at least two alphabetic characters and one nonalphabetic character.
- It is at least six characters long, but seven characters is even better. Short-term memory is capable of remembering a maximum of roughly seven "chunks" of information, so seven is the longest password you can reasonably expect users to remember. Also, the LAN Manager hash algorithm used by Windows NT and Windows 2000 breaks passwords down into seven-character chunks before encrypting them. These chunks can often be cracked because they're short (as little as one character long for an eight-character password—seven plus one), and the cracked portion might provide a clue to the remainder of the password, allowing a hacker to guess the complete password.
- It isn't the user's name or initials, the initials of his or her children or significant other, or any of these items combined with other commonly available personal data such as a birth date, telephone number, or license plate number.

Among the best passwords are alphanumeric acronyms of phrases that have a meaning to the user but are not likely to be known to others. This makes the password easy for the user to remember while making it hard for an outsider to guess.

It pays to educate your users about passwords and password privacy, and you might want to occasionally verify that the message is getting through by checking your office for passwords written on sticky notes next to monitors, under keyboards, or in desk drawers. But most of all, it pays to heed your own advice: make sure that the password you have selected for administration is a good password, and change it frequently. Doing so helps you avoid the consequences of having somebody break into your system and wreak havoc in your very own kingdom. If users will be dialing into the network from home or other remote sites, you might want to include more security than domain-level password authorization.

Of course, the ultimate in password security is use of smart cards (which combine a credit-card-like card with a PIN) or biometrics (such as fingerprint scanners, which are now fairly inexpensive).

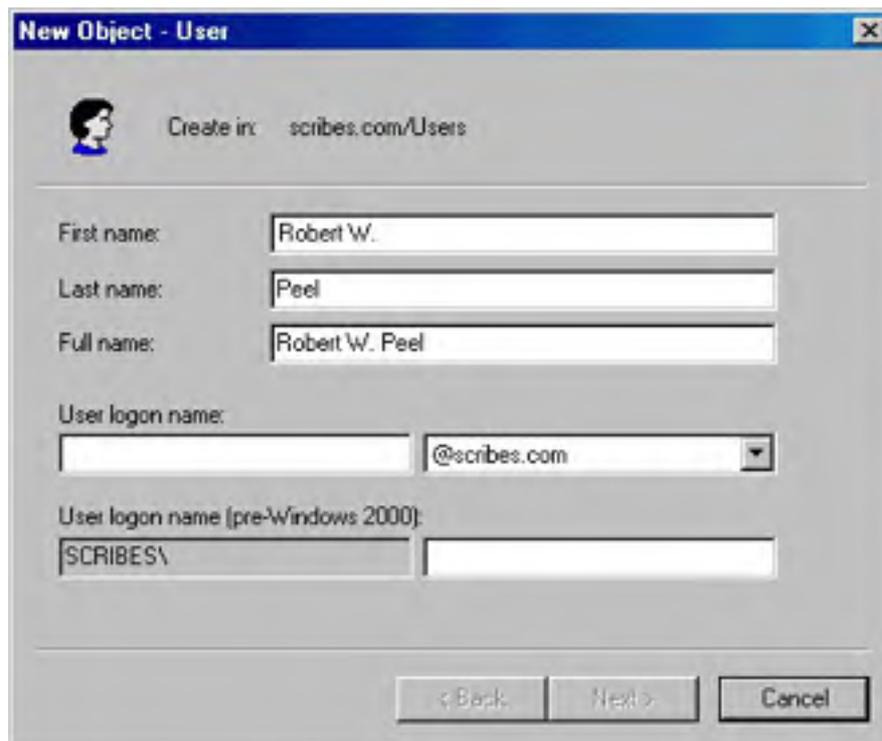

Administrators should have three accounts on the system: one administrative account (renamed from Administrator), a fake Administrator account (as a decoy), and one normal user account (this is discussed in the section entitled [Securing the Administrator Account](#), later in this chapter). You

should use the normal user account unless you are performing administrative tasks. Because of the privileges associated with administrative accounts, they are prime targets for intruders. [Chapter 10](#) includes information on using the secondary logon to keep the administrative account safe.

## Creating a Domain User Account

Domain user accounts can be created in the default Users OU, or you can make another OU to hold them. To add a domain user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Select the domain name and, on the Action menu, point to New and then choose User to open the dialog box shown in Figure 9-8.
3. Provide the user's first and last name. The Full Name box is filled in automatically. The full name must be unique in the OU where the user account is created.

The screenshot shows the 'New Object - User' dialog box. At the top, it says 'Create in: scribes.com/Users'. Below that are several input fields: 'First name' with 'Robert W.', 'Last name' with 'Peel', and 'Full name' with 'Robert W. Peel'. There are also fields for 'User logon name' (empty) and 'User logon name (pre-Windows 2000)' with 'SCRIBES\'. A dropdown menu next to the 'User logon name' field shows '@scribes.com'. At the bottom, there are three buttons: 'Back', 'Next', and 'Cancel'.

**Figure 9-8.** Creating a new domain user account.

4. Provide the user logon name based on your naming convention. This name must be unique in Active Directory. The pre-Windows 2000 logon name is filled in automatically. This is the name used to log on from computers running Windows operating systems such as Windows NT. Click Next.
5. Provide a password and set password policies. Click Next.
6. A confirmation screen opens, showing the details of the account you are about to create. If the details are correct, click Finish. Otherwise, use the Back button to make corrections.

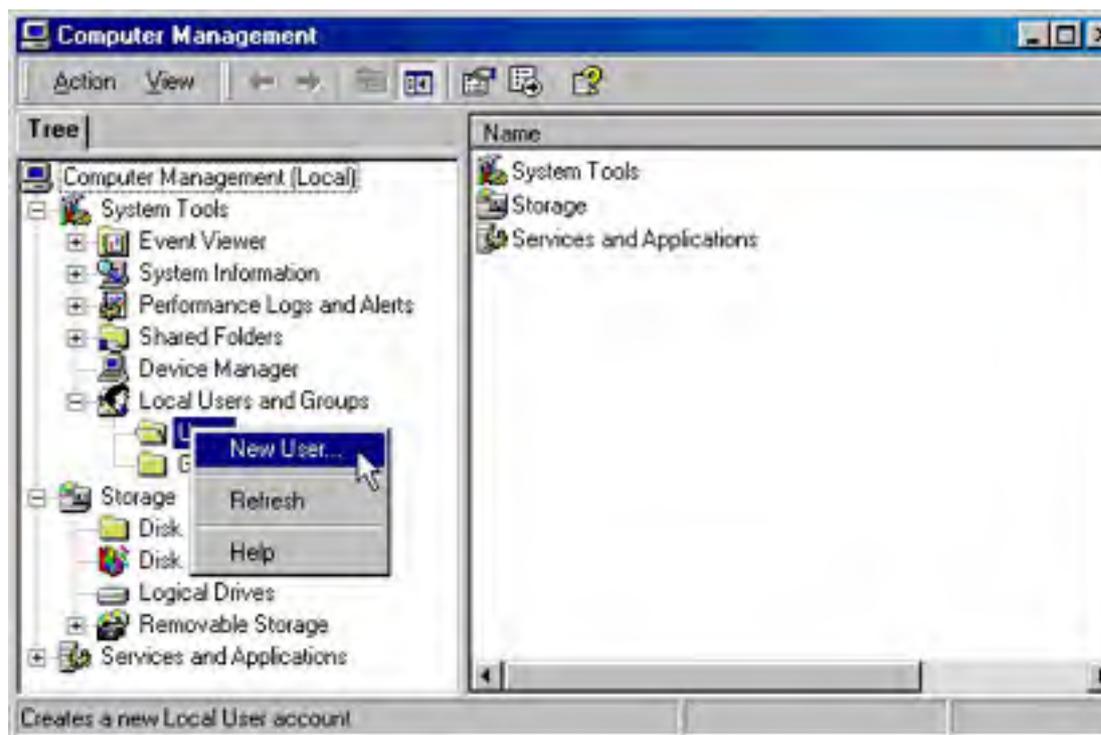

At this point, the new user account is added to the OU with default settings. It's unlikely that the default settings are exactly what you want, so you'll need to adjust the properties of the new account, as described in the section later in this chapter entitled [Setting User Account Properties](#).

## Creating a Local User Account

A local account cannot access the domain and therefore has access only to the resources on the computer where it's created and used. To create a local user account, follow these steps:

1. Right-click My Computer and choose Manage from the shortcut menu.
2. In the console tree, click Local Users And Groups. Right-click Users and choose New User from the shortcut menu (Figure 9-9).

3. In the New User dialog box, supply the user name, full name, and description.

**Figure 9-9.** Creating a local user account.

4. Provide a password and set password policies. Click Create. At this point, the new user account is created with default settings. Local accounts can belong to locally created groups (on the single computer).

Domain controllers cannot have local users or groups but local security settings can be configured using Local Security Settings from the Administrative Tools folder.

## Setting User Account Properties

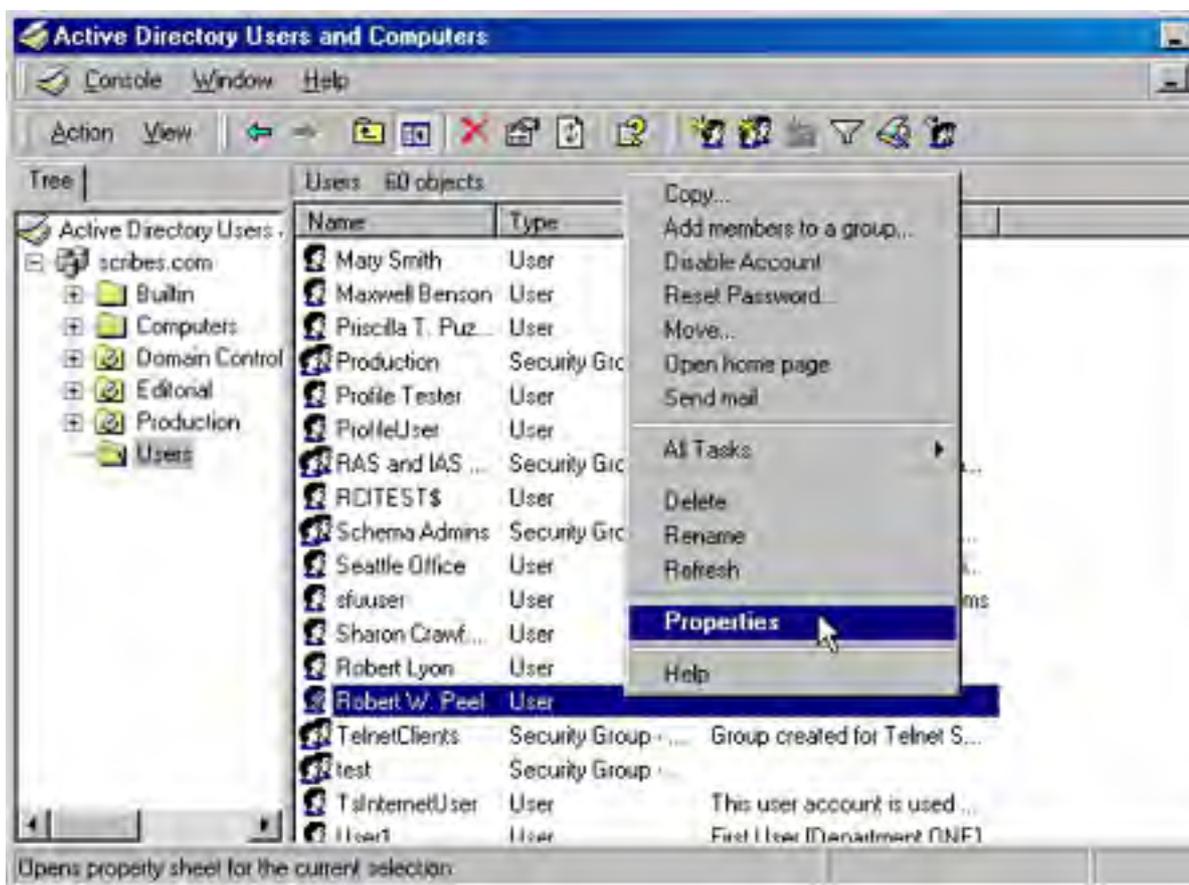

The Properties dialog box for a domain user can have up to a dozen tabs, depending on the domain's setup; Table 9-6 describes these tabs. All of the information entered in the Properties dialog box can be used as the basis for a search in Active Directory. For example, you can find a user's telephone number or department by searching for the user's last name. To set the properties for a domain user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Open the OU where the domain user account was created.
3. Right-click the user account and choose Properties from the shortcut menu (Figure 9-10).
4. Click the tab for the properties you want to set. Make the changes and click OK when you're finished.

**Table 9-6.** Tabs in the Properties dialog box for a domain user account

Tab	Description
General	Documents the user's name, description, office location, telephone number, e-mail address, and Web page address
Address	Documents the user's physical address
Account	Documents the logon name, logon restrictions, password options, and whether the account expires

Profile	Shows the user's profile path, the path of any script that runs at logon, the path to a home folder, and any automatic drive connections
Telephones	Lists additional telephone numbers such as for a pager, cellular phone, or Internet phone
Organization	Documents the user's title, department, company, manager, and direct reports
Member Of	Lists the user's group memberships
Dial-In	Documents the user's dial-in access
Terminal Services, Environment, Sessions, Remote Control	Documents the user's Terminal Services profile

**Figure 9-10.** Selecting the properties for a domain user account.

## Testing User Accounts

As you develop different types of user accounts, it's advisable to test them. Create a dummy account with the memberships and restrictions you're planning on using. Then log on to a client machine and see whether the account produces the results you expect. You should test the following items:

- Test restrictions to logon hours and passwords by attempting to bypass them.
- Test home folders and profiles (discussed in the section [Using Home Folders](#), later in this chapter) to see whether they are actually created.
- Test roaming profiles by logging on from various machines.

- Test group memberships by performing a task that membership in the group is supposed to allow (or deny), such as logging on to a server.

If unexpected results occur, the time to discover them is before you've deployed a thousand users with the wrong settings.

## Managing User Accounts

Especially on a large, busy network, managing user accounts is an ongoing process of additions, deletions, and changes. These tasks aren't difficult, but they can be time-consuming and need to be managed carefully.

### Disabling and Enabling a User Account

If you need to deactivate a domain user account for some period of time but not delete it permanently, you can disable it. To disable a user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Open the container that holds the user account.
3. Right-click the user name and choose Disable Account from the shortcut menu (Figure 9-11). An informational box opens telling you that the object has been disabled, and a red circle with an "X" appears over the user account's icon.

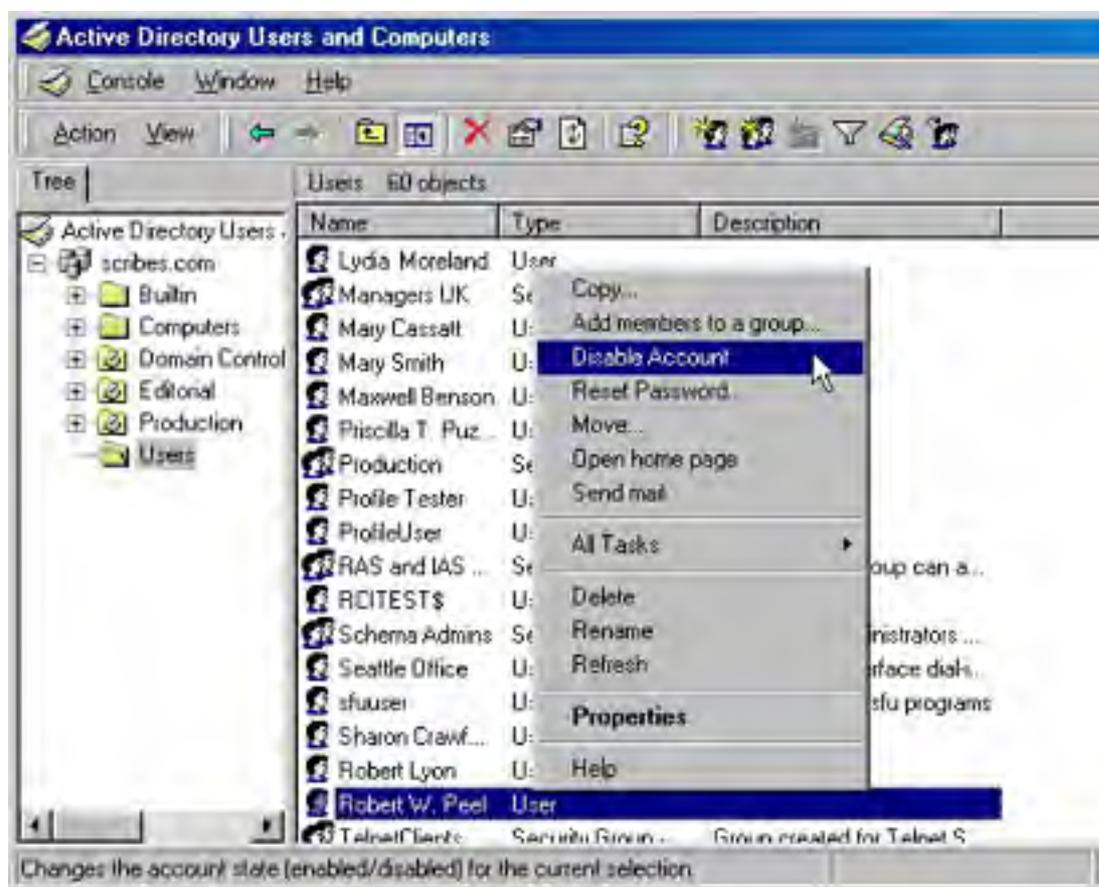

Figure 9-11. Disabling a user account.

To enable a previously disabled account, you perform the same steps, choosing Enable Account from the shortcut menu.

Double-check that the Guest account is disabled (it is by default). Enabling the Guest account exposes an unnecessary security risk for most companies.

### Deleting a User Account

Each user account in the domain has an associated security identifier that is unique and never reused, which means that a deleted account is completely deleted. If you delete Jeremy's account and later change your mind, you have to re-create not only the account but also the permissions, settings, group memberships, and other properties that the original user account possessed. For that reason, if there's any doubt about whether an account might be needed in the future, it's best to disable it and not perform the deletion until you're sure it won't be needed again.

However, accounts do have to be deleted at regular intervals. To delete a domain user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Open the container that holds the user account.
3. Right-click the user name and choose Delete from the shortcut menu.
4. An Active Directory dialog box opens, asking you to confirm the deletion. Click Yes and the account is deleted.

## Finding a User Account

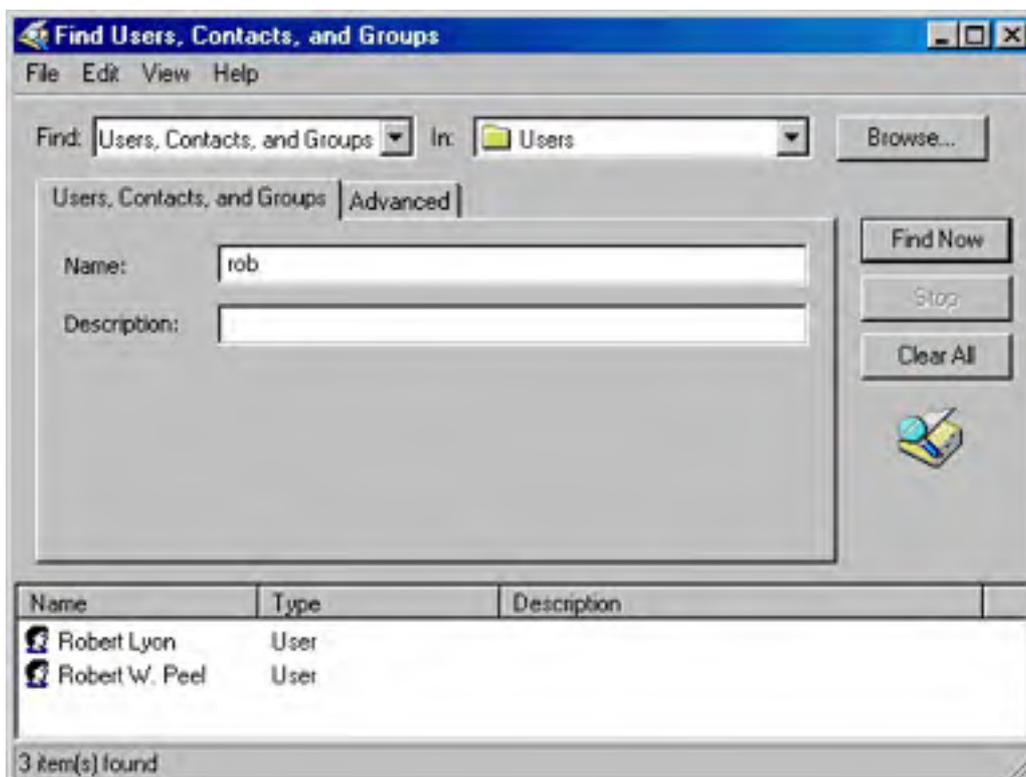

To search for a particular user account, launch Active Directory Users and Computers from the Administrative Tools folder and on the toolbar, click the Find icon, shown here:

This opens the Find Users, Contacts, And Groups dialog box. Don't be misled, though. Open the drop-down list in the Find box and you'll see that you can use this tool to search for computers, printers, shared folders, organizational units, and much more.

To find a specific user, select the scope of your search in the In box. Type a name, part of a name, or some other descriptive element that's part of the user's profile, and click Find Now. As you can see in Figure 9-12, a search for a portion of a name returns all users with that element in their names.

The larger the network, the more specific your search needs to be. In a large network environment, you can narrow your search to a specific organizational unit. Launch Active Directory Users and Computers from the Administrative Tools folder and choose Find from the shortcut menu. Right-click the OU you are interested in.

**Figure 9-12.** Searching for a user by name.

## Moving a User Account

To move a user account from one container to another, follow these steps:

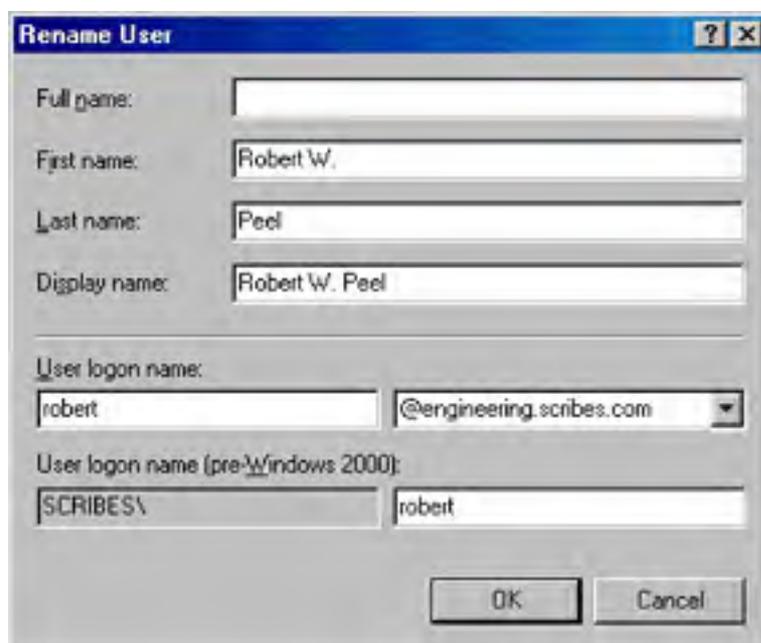

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. In the console tree, click the OU that contains the user account.
3. Right-click the user account to be moved and choose Move from the shortcut menu.
4. In the Move dialog box, select the destination container and click OK.

## Renaming a User Account

On occasion, a user account might need to be renamed. For example, if you have an account configured with an assortment of rights, permissions, and group memberships for a particular position and a new person is taking over that position, you can change the first, last, and user logon names for the new person. It's a good practice to rename the Administrator account for security reasons.

To rename an existing user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. In the console tree, click the OU that contains the account.
3. Right-click the user name, and choose Rename from the shortcut menu. (You can also slowly click the user name twice.)
4. Press the Delete key and then the Enter key to open the Rename User dialog box (Figure 9-13).
5. Enter the changes and click OK. The account is renamed, and all permissions and other settings remain intact. Any other personal data in the account's Properties dialog box has to be changed as well.

**Figure 9-13.** Renaming an existing user account.

## Securing the Administrator Account

The Administrator account is an obvious and highly attractive target to hackers, and thus requires special care to protect. The following tactics are useful for securing the Administrator account:

- Rename the Administrator account to something that a hacker wouldn't be able to guess (avoid admin, root, boss, and so on). A standard user name is appropriate.
- Create a decoy Administrator account that has no privileges whatsoever, and then regularly scan the event log to see if anyone has attempted to log on using this account.
- Set a lockout policy for the real Administrator account (which you've renamed). Use the Passprop utility from the *Microsoft Windows 2000 Server Resource Kit* to do so.

## Resetting a User's Password

For passwords to be effective, they must not be obvious or easy to guess. However, when passwords are not obvious or easy to guess, they will inevitably be forgotten. When a user forgets his or her password, you can reset it. The best policy is to reset it to a simple password and require the user to change the password at the next logon to the network.

To reset a password, just launch Active Directory Users and Computers from the Administrative Tools folder and find the container for the account whose password you need to reset. Right-click the account name and choose Reset Password from the shortcut menu. In the Reset Password dialog box (Figure 9-14), enter the new password twice, and select the User Must Change Password At Next Logon option.

**Figure 9-14.** Resetting a user's password.

Windows XP provides the ability to create an encrypted password reset disk, enabling a user to reset his or her password without having to call the Help Desk. (In any organization, the Help Desk personnel spend a large portion of their time resetting passwords.) Just make sure that users know to store these disks in a secure physical location, such as a locked desk drawer.

## Unlocking a User Account

If a user violates a group policy, such as exceeding the limit for bad logon attempts, Group Policy locks the account. When an account is locked, it cannot be used to log on to the system. To unlock a user account, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. In the console tree, click the OU that contains the locked account.
3. Right-click the user account in the details pane and choose Properties from the shortcut menu.
4. In the Properties dialog box, click the Account tab.
5. Clear the check box next to Account Is Locked Out. Click OK.

By default, Group Policy does not lock accounts due to failed logon attempts. You should make this setting for security reasons. See the section entitled [Understanding Group Policies](#), later in this chapter.

For instructions on how to delegate the right to unlock locked accounts, see [Chapter 10](#).

## Using Home Folders

Home directories or folders are repositories that you can provide on a network server for users' documents. Placing home folders on a network file server has several advantages:

- Backup of user documents is centralized.
- Users can access their home folders from any client computer.
- Home folders can be accessed from clients running any Microsoft operating system (including MS-DOS and all versions of Windows).

The contents of home folders are not part of user profiles, so they don't affect network traffic during logon. (A home folder can also be on a client computer, but that defeats much of its purpose.)

## Creating Home Folders on a Server

To create a home folder on a network file server, follow these steps:

1. On the server, create a new folder for the home folders. Right-click the new folder, and choose Properties from the shortcut menu.
2. Click the Sharing tab, and select Share This Folder (Figure 9-15).

**Figure 9-15.** Sharing the new Home Folders folder.

3. Click the Security tab, and remove the default Full Control from the Everyone group and assign Full Control to the Users group. (This setting prevents anyone other than domain user accounts from accessing the folder.)

Home folders should be stored on a partition formatted with NTFS. Home folders on a FAT partition can be secured only by assigning shared folder permissions on a user-by-user basis.

## Providing Home Folders to Users

To provide a user with a home folder, you must add the path for the folder to the user account's properties. Follow these steps to give a user access to a home folder:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Click the OU containing the user account. Right-click the user name, and choose Properties from the shortcut menu.
3. Click the Profile tab.
4. In the Home Folder area, click the Connect option and specify a drive letter to use to connect to the file server.
5. In the To box, specify the UNC name for the connection—for example, `\\server_name\shared_folder\user_logon_name`. If you use the variable `%username%`, as shown in Figure 9-16, a home folder is given the user's logon name, and all user accounts except the designated user and the local Administrator account are blocked access (all permissions are removed).

Figure 9-16. Specifying a home folder.

## Maintaining User Profiles

A *profile* is an environment specifically customized for a user. The profile contains the desktop and program settings for the user. Every user has a profile, whether the administrator configures one or not, because a default profile is automatically created for each user who logs on to a computer. Profiles offer a number of advantages:

- Multiple users can use the same computer, with the settings for each user restored at logon to the same state as when he or she logged off.
- Desktop changes made by one user do not affect any other user.
- If user profiles are stored on a server, they can follow users to any computer on the network running Windows 2000 or Windows NT 4.

From an administrator's standpoint, the information in the profile can be a valuable tool for setting up default user profiles for all users on the network or for customizing default profiles for different departments or job classifications. You can also set up *mandatory* profiles that allow a user to make changes to the desktop while logged on but not to save any of the changes. A mandatory profile always looks exactly the same every time a user logs on. The types of profiles are as follows:

- **Local profiles** Profiles made on a computer when a user logs on. The profile is specific to a user, local to that computer, and stored on the local computer's hard disk.
- **Roaming profiles** Profiles created by an administrator and stored on a server. These profiles follow a user to any Windows 2000 or Windows NT 4 machine on the network.
- **Mandatory profiles** Roaming profiles that can be changed only by an administrator.

### Real World

#### What's Stored in a Profile?

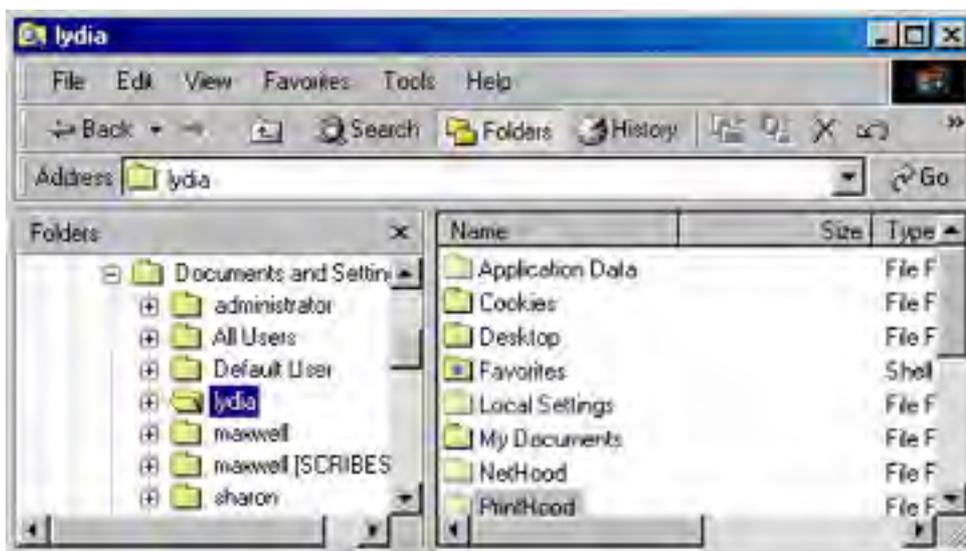

All profiles start out as a copy of the Default User profile that is installed on every computer running Windows 2000. Registry data for Default User is in the Ntuser.dat file contained in the Default User profile. Inside each profile are the following folders:

- **Application Data** Program-specific settings determined by the program manufacturer plus specific user security settings
- **Cookies** Messages sent to a Web browser by a Web server and stored locally to track user information and preferences
- **Desktop** Desktop files, folders, shortcuts, and the desktop appearance
- **Favorites** Shortcuts to favorite locations, particularly Web sites
- **Local Settings** Application data, History, and Temporary files
- **My Documents** User documents and My Pictures, which contains user graphics files
- **NetHood** Shortcuts to My Network Places
- **PrintHood** Shortcuts to items in the Printers folder
- **Recent** Shortcuts to the most recently accessed folders and files
- **SendTo** Items on the Send To menu
- **Start Menu** Items on the user's Start menu
- **Templates** Application templates

By default, only the Cookies, Desktop, Favorites, My Documents, and Start Menu folders are visible in Windows Explorer. The other folders are hidden; to see them you'll need to select Folder Options, click the View tab, and select Show Hidden Files And Folders.

## Local Profiles

Local profiles are created on computers when individual users log on. On a computer upgraded from Windows NT 4, the profile is stored in the Profiles folder on the system root partition. On a computer with a new installation of Windows 2000, the user profile is in the Documents And Settings folder (Figure 9-17).

**Figure 9-17.** A user's local profile.

The first time a user logs on to a computer, a profile folder is generated for the user, and the contents of the Default User folder are copied into it. Any changes made to the desktop by the user are saved in that user's profile when he or she logs off.

If a user has a local account on the computer as well as a domain account and logs on at different times using both accounts, the user will have two profile folders on the local computer: one for when the user logs on to the domain using the domain user account and one for when the user logs on locally to the computer. The local profile will be shown with the logon name. The domain profile will also be shown with the logon name but will have the domain name appended to it.

## Roaming Profiles

Roaming profiles are a great advantage for users who frequently use more than one computer. A roaming profile is stored on a server and, after the user's logon is authenticated in the directory service, is copied to the local computer. This allows a user to have the same desktop, application configuration, and local settings at any machine running Windows 2000 or Windows NT 4.

Here's how it works. You assign a location on a server for user profiles and create a folder shared with users who are to have roaming profiles. You enter a path to that folder in the user's Properties dialog box. The next time the user logs on to a computer, the profile from the server is downloaded to the local computer. When the user logs off, the profile is saved both locally and in the user profile path location. Specifying the user profile path is all it takes to turn a local profile into a roaming profile, available anywhere in the domain.

When the user logs on again, the profile on the server is compared to the copy on the local computer, and the more recent copy is loaded for the user. If the server isn't available, the local copy is used. If the server isn't available and this is the first time the user has logged on to the computer, a user profile is created locally using the Default User profile. When a profile isn't downloaded to a local computer because of server problems, the roaming profile is not updated when the user logs off.

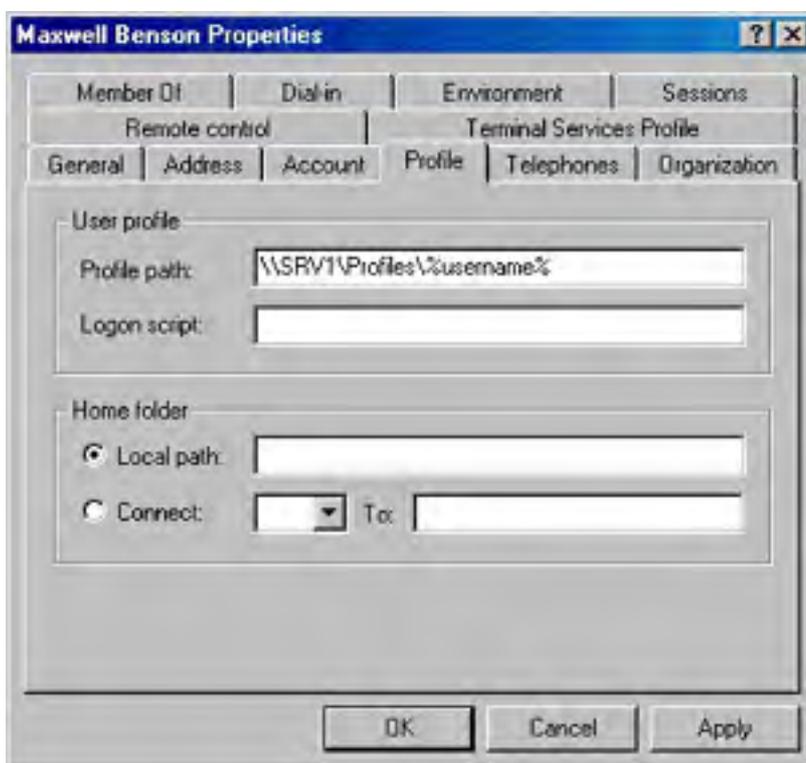

Put user profiles on a member server rather than on a domain controller to speed up the process of authentication and to avoid using a domain controller's processing power and bandwidth for the downloading of profiles. In addition, place the profiles on a server that is backed up regularly so that copies of roaming profiles are as recent as possible.

## Setting Up Roaming Profiles

Setting up roaming profiles is very easy. Simply assign a location on a server and complete the following steps:

1. Create a shared folder for the profiles on the server.
2. In the Profile tab in the user account Properties dialog box, provide a path to the shared folder, such as `\\server_name\shared_profile_folder\%username%`.

Figure 9-18 shows an example of a path for a roaming profile. When you use the variable `%username%`, Windows 2000 automatically replaces the variable with the user account name.

**Figure 9-18.** Setting a path for a roaming profile.

Once you've created a shared profile folder on a server and supplied a profile path in the user account, a roaming profile is enabled. The user's configuration of his or her desktop is copied and stored on the server and is available to the user from any computer. Most of the time, though, you won't want to send your users off to fend for themselves. Life is easier for users and for you if they are assigned a customized profile that is already set up with appropriate shortcuts, network connections, and Start menu items. For this, you'll need to set up customized profiles.

## Creating Customized Roaming Profiles

Creating customized roaming profiles is a simple—albeit multistep—process:

1. Create a user account with a descriptive name such as District Managers or Sales Staff. This is just a "blank" user account that you'll use to create a template for the customized configuration.
2. Log on using the template account and create the desktop settings you want, including applications, shortcuts, appearance, network connections, printers, and so forth.

3. Log off the template account. Windows 2000 creates a user profile on the system root drive in the Documents And Settings folder. Figure 9-19 shows the user account named Editors that has been created to be a template.

**Figure 9-19.** Creating a template for configuring profiles.

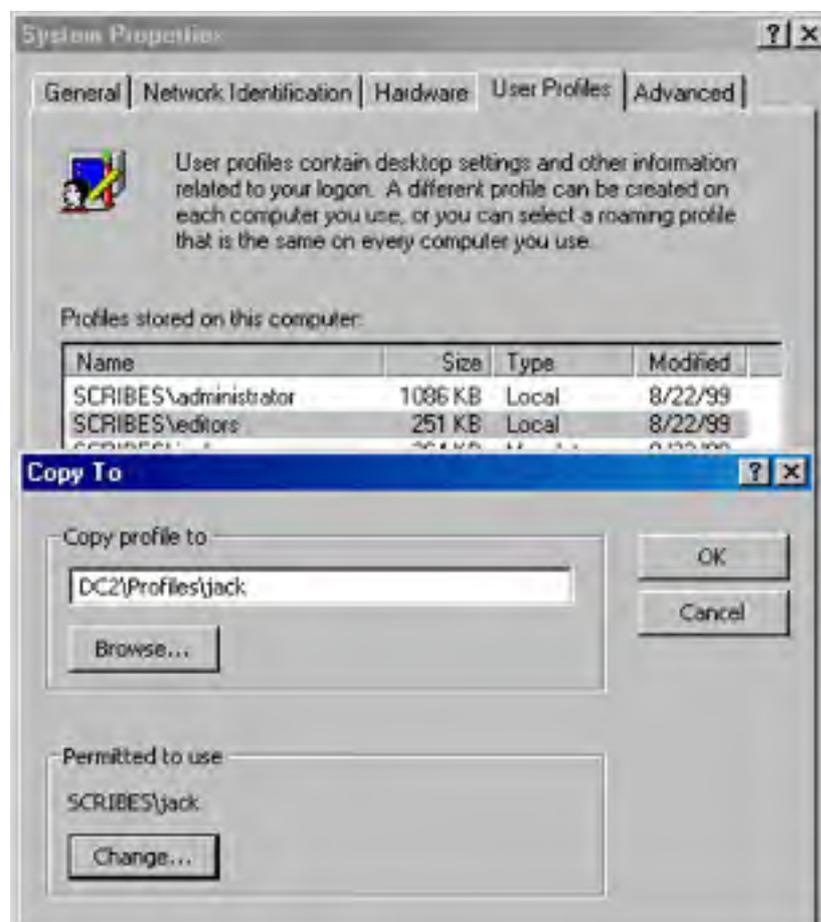

4. Log on using an administrator account. Launch Active Directory Users and Computers, and find the account for which you want to assign the customized roaming profile.
5. Right-click the account and choose Properties from the shortcut menu. Click the Profile tab.
6. In the Profile Path box, type `\\server_name\profile_folder\username`. (Figure 9-20 shows an example.) Click OK.

**Figure 9-20.** *Providing a path to the roaming profiles folder.*

7. In Control Panel, open System.
8. Click the User Profiles tab, and highlight the template profile. Click Copy To.
9. In the Copy To dialog box, type the path of the profiles folder on the server, such as **\\server\_name\shared\_folder\_name\username**.
10. In the Permitted To Use area, click Change to give the user permission to use the profile (Figure 9-21). Click OK to copy the template profile.

**Figure 9-21.** *Copying a template profile to a user's profile folder.*

## Using Mandatory Profiles

If you're going to all the trouble of assigning customized profiles, you'll undoubtedly want to make the profiles mandatory. A mandatory profile can be assigned to multiple users. When you make a change to a mandatory profile, that change is made to the environments of all of the users to whom you've assigned the mandatory profile. To change a profile into a mandatory profile, you must rename the hidden file `Ntuser.dat` to `Ntuser.man`.

If you don't see the `Ntuser` file in the individual's Profiles folder, choose Folder Options from the Tools menu and click the View tab. In Advanced Settings, select Show Hidden Files And Folders.

## Assigning a Logon Script to a User Profile

Logon scripts can be assigned by profile or through Group Policy. (Group Policy is covered later in this chapter.) To assign a script to a profile, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.

2. In the console tree, click Users. Right-click the user account and choose Properties from the shortcut menu.
3. Click the Profile tab and enter the name of the logon script in the Logon Script box.
4. Click OK when you're finished.

Windows 2000 always looks for logon scripts in the same place—on the authenticating domain controller at the path `%SystemRoot%\SYSVOL\sysvol\domain_name\scripts`. Scripts in this folder can be entered in the Logon Script path by name only, as shown in Figure 9-22. If you use folders inside the Scripts folder, you must show that part of the path in the Logon Script path (Figure 9-23). Table 9-7 shows the special variables that can be used when creating logon scripts. Logon scripts can also be created in VBScript and JScript. Replication of logon scripts to all domain controllers is automatic on NTFS volumes on Windows 2000 servers. Other types of files, such as FAT files, must be replicated manually.

Figure 9-22. A logon script located inside the Scripts folder.

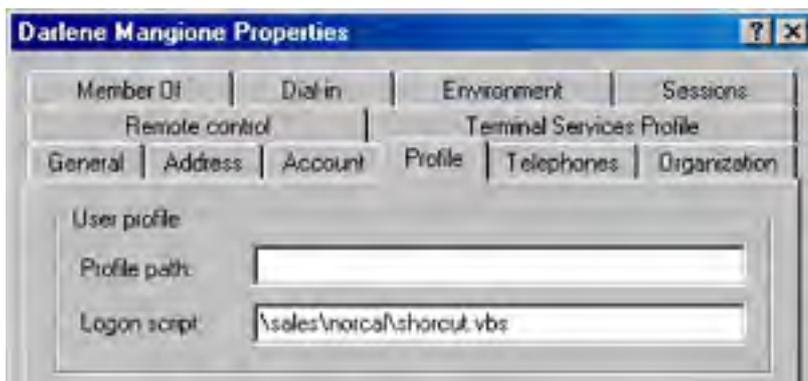

Figure 9-23. A logon script in subfolders inside the Scripts folder.

Table 9-7. Logon script variables

Variable	Description
<code>%homedrive%</code>	Letter of the drive containing the user's home directory on the user's local workstation
<code>%homepath%</code>	Full path of the user's home directory
<code>%os%</code>	User's operating system
<code>%processor_architecture%</code>	Processor type on the user's workstation
<code>%processor_level%</code>	Processor level of the user's workstation
<code>%userdomain%</code>	Domain where the user's account is defined
<code>%username%</code>	Account user name

## Configuring Shares and Permissions

As has been mentioned before, the whole point of a network is to share resources among the users. However, sharing is also an extension of the security features that begin with user accounts and passwords. Your goal as a system administrator is to make sure that everyone can use the resources they need without compromising the security of files and other resources. Users can have three types of capabilities, as follows:

- **Rights** Assigned to built-in groups but the administrator can extend rights to groups or individuals. (Rights are covered earlier in this chapter.)
- **Shares** Directories or drives that are shared on the network.
- **Permissions** File system capabilities that can be granted to individuals or to groups.

In the normal course of events, you'll deal with rights only rarely. However, shares and permissions are at the heart of an administrator's responsibilities.

On an NTFS volume, Windows 2000, like Windows NT Server, allows security that's so granular it's practically microscopic. Permissions of various types can be set, including permissions on individual files. This presents quite a temptation to the administrator to micro-manage every resource. Our best advice is to not give in to this temptation. Start with the least restriction possible and add restrictions only when required.

### Real World

#### Differences Between Shares and Permissions

Shares and permissions, although they sound very much alike, are not at all the same, and it's important to understand the differences. Shares apply to drives and directories. Until a drive or folder is shared over the network, users can't see it or gain access to it. Once a folder is shared, everyone on the network has, by default, access to all files in the folder, and to all subfolders of that folder, and so on.

On a FAT volume, a drive or folder can be shared and then additional restrictions added in the form of share permissions. These permissions apply only at the drive or folder level—not at the file level—and are limited to allowing or denying Full Control, Read, and Change.

On NTFS volumes, directories have the same share permissions as those on a FAT volume, but another layer of permission is available beyond that. Each folder has a Security Properties dialog box that allows more precise restrictions. Each file also has a Security Properties dialog box, allowing access to be granted or denied for individual files. These *folder permissions* and *file permissions* can restrict access both across the network *and* locally. For example, you can leave the share permission for a folder at the default setting, allowing Full Control to Everyone, and use the Security Properties dialog boxes to set more restrictive permissions by group or individual—whether for the folder as a whole or file-by-file within the folder.

Share permissions determine the maximum access over the network. This means if you set share permissions to allow Read but deny Change, all users will be restricted to Read only when they access the share over the network. You can, however, grant a user more extensive access through folder or file permissions, and this expanded access will be available when the user logs on *locally*. Or you can block the inheritance of permissions on a subfolder and give a user Full Control of the subfolder over the network—while the parent folder remains Read only.

Shares have no effect on users who can log on locally. For users who will be logging on locally to an NTFS partition, you can restrict access by using permissions.

## Using Special Shares

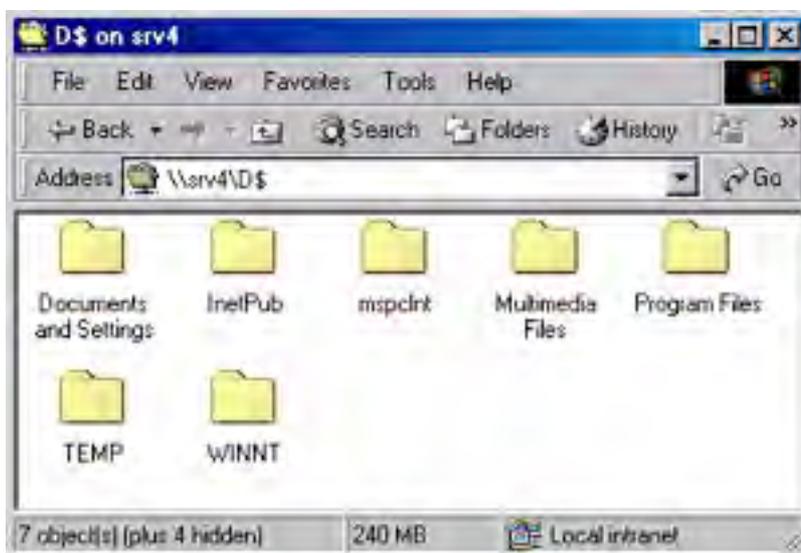

In addition to shares created by a user or administrator, the system creates a number of special shares that shouldn't be modified or deleted. The special share you're most likely to see is the ADMIN\$ share, which appears as C\$, D\$, E\$, and so on. These shares allow administrators to connect to drives that are otherwise not shared.

Special shares exist as part of the operating system's installation. Depending on the computer's configuration, some or all of the following special shares might be present. None of them should be modified or deleted.

- **ADMIN\$** Used during the remote administration of a computer. The path is always the location of the folder in which Windows was installed (that is, the system root). Only Administrators, Backup Operators, and Server Operators can connect to this share.
- **driveletter\$** The root folder of the named drive. Only Administrators, Backup Operators, and Server Operators can connect to these shares on a Windows 2000 server. On a Windows 2000 Professional computer, only Administrators and Backup Operators can connect to these shares.
- **IPC\$** Used during remote administration and when viewing shared resources. This share is essential to communication and you do not want to change, modify, or delete it.
- **NETLOGON** Used by the Net Logon service of a server running Windows NT Server while processing domain logons. This resource is provided for servers only, not for Windows NT Workstation.
- **PRINT\$** A resource that supports shared printers.
- **REPL\$** Created on a server when a fax client is sending a fax.

To connect to an unshared drive on another computer, use the address bar in any window and enter the address (Figure 9-24), using the syntax

```
\\computer_name\[driveletter]$
```

**Figure 9-24.** Connecting to an unshared drive on a remote computer.

To connect to the system root folder (the folder in which Windows is installed) on another computer, use the syntax

```
\\computer_name\admin$
```

Other special shares such as IPC\$ and PRINT\$ are created and used solely by the system. NETLOGON is a special share on Windows 2000 and Windows NT servers and is used while processing domain logon requests.

Adding a \$ sign to the end of a share name hides the share from all users. To access a hidden share, you will need to explicitly specify it; you will not be able to browse the network for that share.

## Shares and Permissions on NTFS vs. FAT

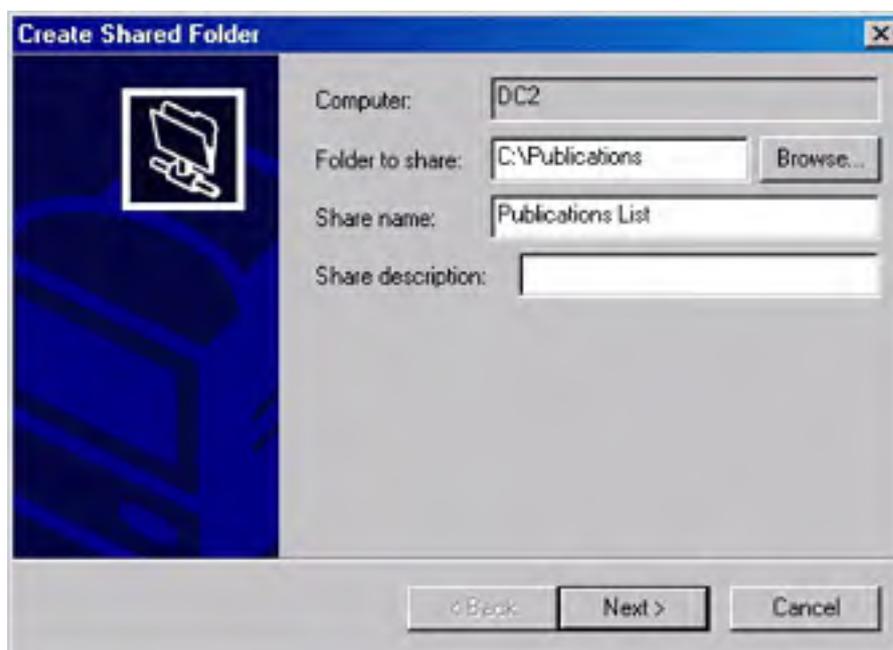

On partitions formatted using FAT, you can restrict files only at the folder level, only over the network, and only if the folder is shared. For someone who logs on locally, the shares have no effect. Needless to say, this security is inadequate for most companies.

On an NTFS volume, folders can be shared and also restricted further by means of permissions. Also, use folder and file permissions for security control both locally and over the network and allow Full Control access to Authenticated Users on the share (we recommend that you replace the Everyone permission with Authenticated Users).

## Sharing a Folder

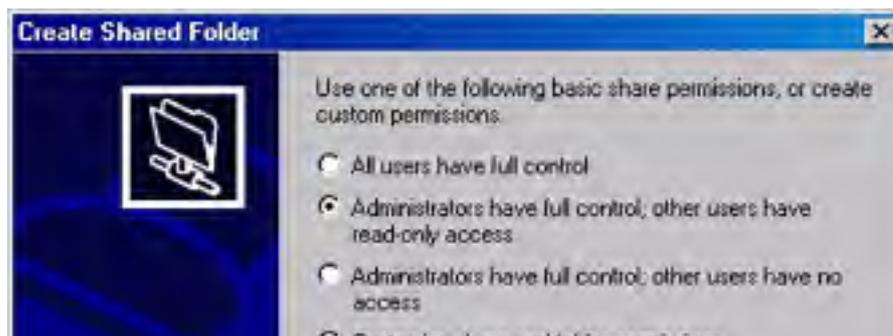

The easiest way to create shared folders is to use the Configure Your Server tool from the Administrative Tools folder. To do so, follow these steps:

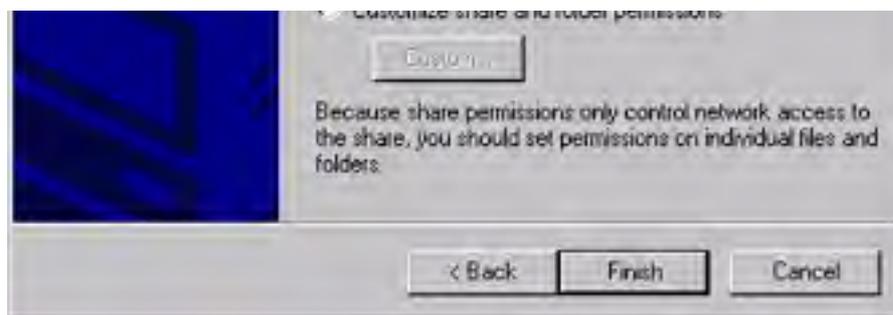

1. Open Configure Your Server and click File Server in the left column.
2. Click the link Start The Shared Folder Wizard to open the Create Shared Folder dialog box.
3. Enter the name and path of the folder and a share name (Figure 9-25).

**Figure 9-25.** Selecting a folder to be shared.

4. Select the share permissions you want to assign to the folder (Figure 926), bearing in mind that it's usually better to control access through permissions rather than shares. Click Finish when you're done.

**Figure 9-26.** Selecting share permissions.

You can set shares directly by right-clicking a folder, choosing Properties from the shortcut menu, and then clicking the Sharing tab.

### Real World

#### Share Names and Filenames in MS-DOS

If you have MS-DOS-based machines on your network (that includes Windows versions through 3.11) that will be accessing a shared folder, you must follow the 8.3 naming convention in the *share* name. A share name that doesn't conform to the MS-DOS 8.3 naming standard will not be seen at all by users with MS-DOS or Windows 3.x machines.

The names of files or folders can have up to 255 characters. MS-DOS users connecting to the file or folder over the network will see the name in the 8.3 format. Windows NT truncates the long names down to a size that an MS-DOS machine can recognize but does not do so for share names. Yes, it's odd. Windows 2000 converts long names to short names using the following rules:

- Spaces are removed.
- Characters not allowed in MS-DOS names are replaced by underscores ( \_ ).
- The name is shortened to its first six remaining characters, and then a tilde (~) and a digit are added. For the first file, the digit is 1. For a second file using the same six characters, the digit is 2. For example, your file named Budget Figures for March will be shortened to BUDGET~1. A second file, called Budget Figures for the Second Quarter, will be shortened to BUDGET~2.
- If the long name has any periods followed by other characters, the last period and the next three characters are used as the file extension in the short version of the filename. So a file called December.Sales.Presentation will be shortened to DECEMB~1.PRE.

As you can see, long filenames when truncated can be quite mysterious. If your network includes MS-DOS computers, you may want to continue using MSDOS naming conventions for the first six characters. The budget files just used as examples would then be MARBUD~Budget Figures for March.XLS and 2NDQTR~Budget Figures for the Second Quarter.XLS. To the MS-DOS computer, the files would appear as MARBUD~1.XLS and 2NDQTR~1.XLS.

### Creating a New Share for a Shared Folder

A single folder might be shared more than once. For example, one share might include Full Control for Administrators and another share for users might be more restricted. To add a new share, follow these steps:

1. Find the shared folder in Windows Explorer, and right-click on it. Choose Sharing from the shortcut menu.
2. In the dialog box that opens, click New Share.
3. In the New Share dialog box (Figure 9-27), enter a new Share Name. (Each share must have a unique name.) Set a user limit, if necessary.

4. Click Permissions to restrict access. Again, by default, the shared folder gives Full Control to all users.

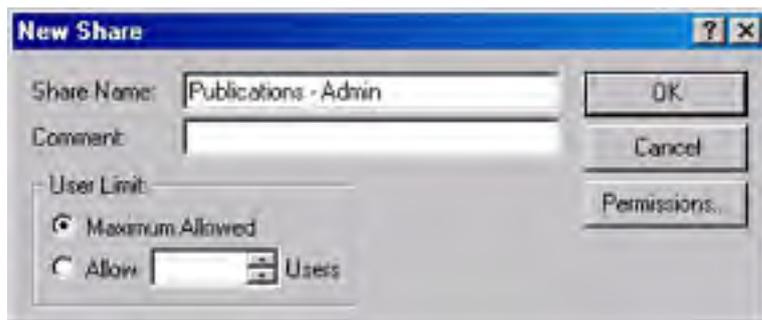

Figure 9-27. Adding a new share.

## Stopping Folder Sharing

To remove a folder from being shared, launch Computer Management from the Administrative Tools folder. Expand System Tools, then Shared Folders, and then Shares. Right-click the shared folder in the details pane, and choose Stop Sharing from the shortcut menu.

In Windows NT, when users are connected to a folder you are about to stop sharing, you are warned in a dialog box. This doesn't happen in Windows 2000. If you stop sharing a folder that users are connected to, the users are dropped out of the folder without warning and they might lose data.

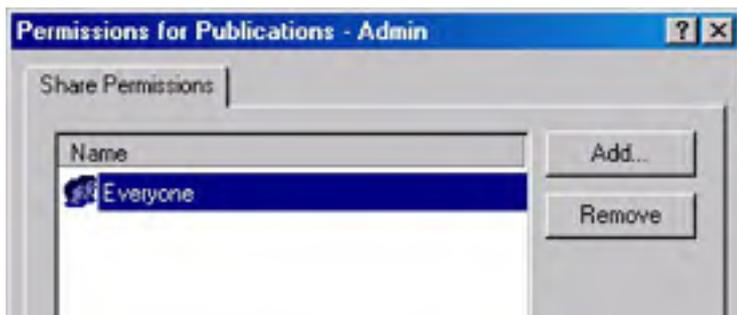

## Share Permissions

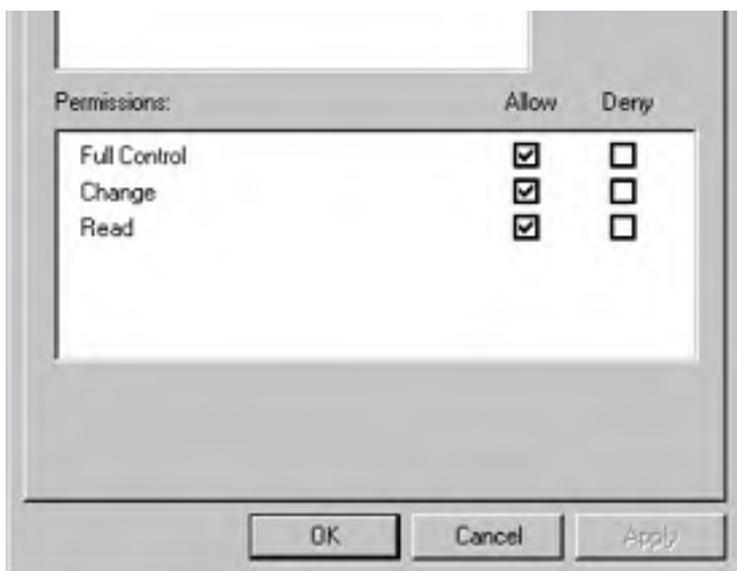

Share permissions establish the maximum range of access available. Other permission assignments (on an NTFS volume) can be more restrictive but can't expand beyond the limits established by the share permissions. Table 9-8 summarizes the three types of access, from most restrictive to least restrictive.

Table 9-8. Types of share permissions

Share Permission	Type of Access
Read	Allows viewing of file and subfolder names; can always view and clear the security log.
Change	Allows the access under Read, plus allows adding files and subdirectories to the shared folder, changing data in files, and deleting files and subdirectories.
Full Control	Allows all the access under Change plus allows changing permissions (NTFS volumes only) and taking ownership (NTFS volumes only).

To set share permissions for a folder, right-click the folder and choose Sharing from the shortcut menu. Click Permissions to open the dialog box shown in Figure 9-28. The type of access is set by the list at the bottom. Use the Add and Remove buttons to change who has access. Share permissions can be assigned to individual users, to groups, and to the special identities Everyone, System, Interactive, Network, and Authenticated Users.

**Figure 9-28.** Setting share permissions.

## Mapping Shared Folders and Drives

After traipsing through My Network Place's various windows to find a shared folder, users can simply double-click the folder to open it and access its contents. For easier access, right-click the shared folder and drag it to the desktop. Select Create Shortcut Here after releasing the mouse button.

For frequent use, it's simple to map a folder or drive so that it appears in Windows Explorer (or My Computer) as simply another local drive. The following sections cover mapping network folders to drive letters, as well as disconnecting from mapped drives.

A mapped drive is even better than a shortcut in one important respect: if you're using older programs, they're not going to recognize the network places and will not be able to open or save files anywhere other than your own computer. If you map a drive, the program cooperates because the drive on the other computer appears (to the program at least) to be local.

## Connecting to a Network Share

You can link a network share to a drive letter using the following procedure:

1. Open My Network Places and find the shared resource you want to map.
2. Right-click the object and choose Map Network Drive from the shortcut menu. The dialog box that appears (Figure 9-29) has three adjustable entries:
  - **Drive** This is the letter that the new folder or drive will be assigned on the local computer.
  - **Connect Using A Different User Name** If the mapping is for anyone other than the current user, click this link and supply the user name and password.
  - **Reconnect At Logon** Select this box to automatically make the connection at logon to the computer where this resource physically resides.
3. Click Finish when you're done.

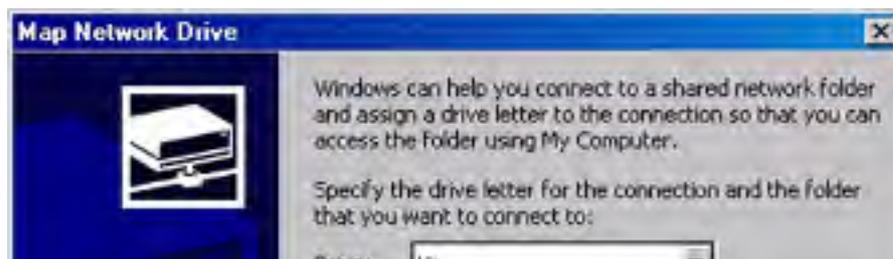

Figure 9-29. Mapping a network resource.

## Disconnecting from Mapped Resources

To get rid of a mapped drive or folder, you can select it and right-click. Choose Disconnect from the shortcut menu (Figure 9-30).

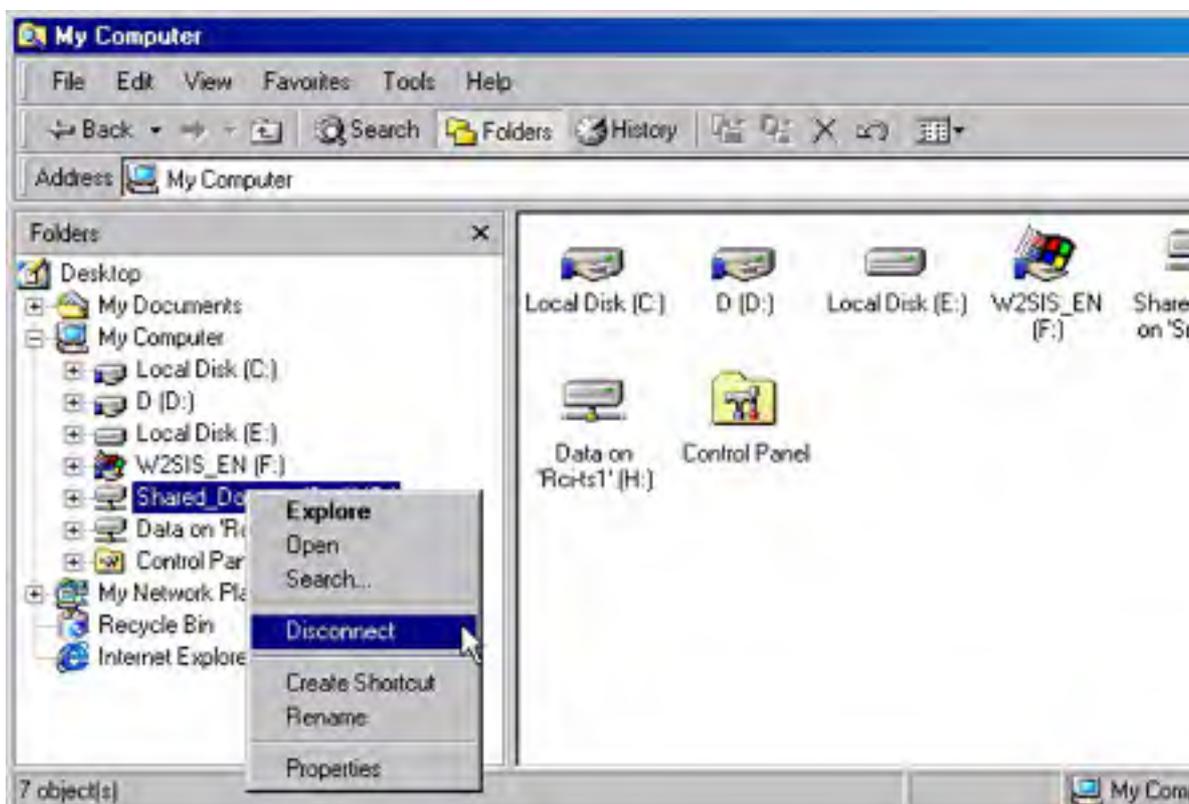

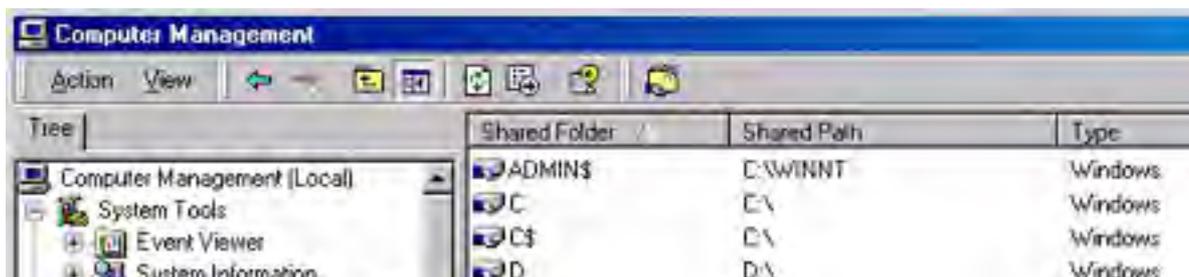

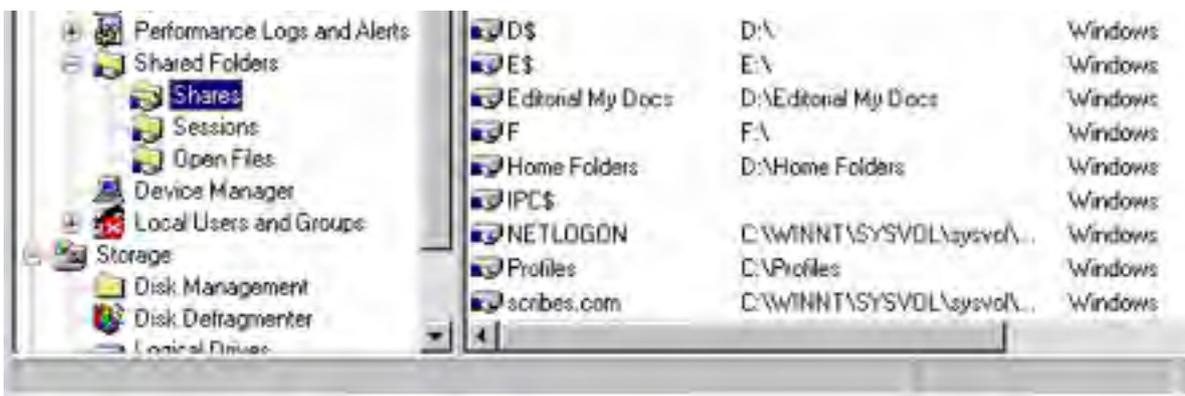

Figure 9-30. Disconnecting a mapped resource.

## Working with Shared Folders

You can see a list of shares, current sessions, and open files by opening Computer Management from the Administrative Tools folder and then expanding Shared Folders (Figure 9-31).

**Figure 9-31.** Viewing shared folders.

Expand Shares to see a list of the shared folders plus the following information about each folder:

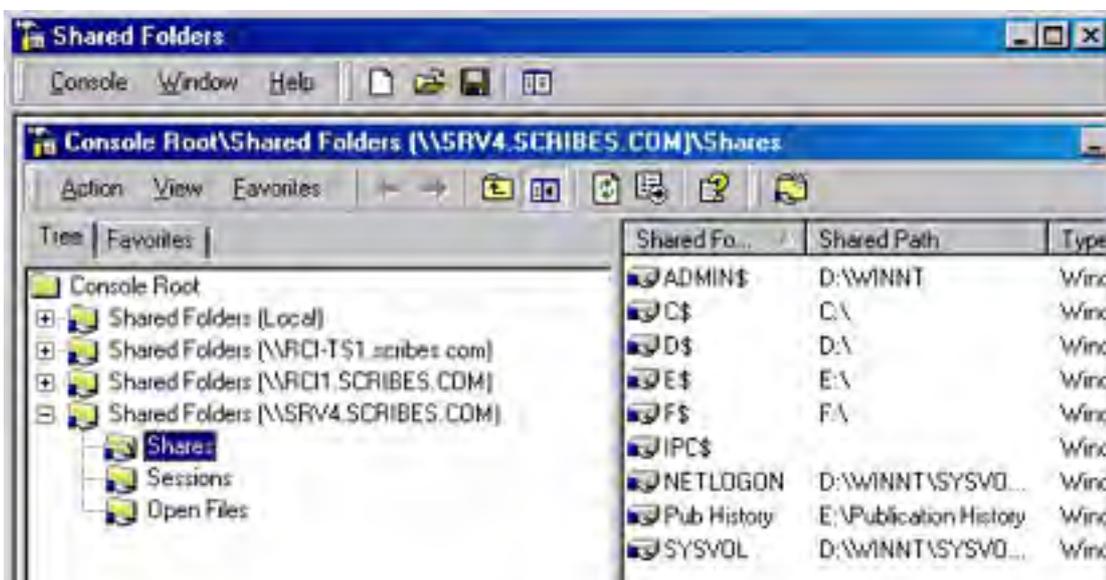

- The path to the shared resource
- The type of connection (Windows, Macintosh, NetWare)
- The number of users connected to the share
- A description of the share

Expand Sessions in the console tree to see the following information about the users who are currently connected:

- The user name and the name of the user's computer
- The type of connection (Windows, Macintosh, NetWare)
- The number of files opened by the user on this share
- The time elapsed since the connection was established
- The time since the user last initiated an action
- Whether the user is connected as a guest

Expand Open Files in the console tree for a list of the files currently open. In the details pane, you can see the name of the file, who opened it, the type of connection, the number of locks on the file (if any), and the share permissions that were granted when the file was opened.

For regular viewing of shares, it might be more efficient to make an MMC that contains the Shared Folders snap-in. You can add a Shared Folders snap-in for several servers and switch among them easily (Figure 9-32).

**Figure 9-32.** *Viewing shared folders on multiple servers.*

## Maintaining Folder and File Permissions

On an NTFS volume, you can set permissions down to the file level. This means for any file you can give individual users different types of access. Although you can set such detailed permissions, this way lies madness for all but the most meticulous of control freaks (who are, arguably, already mad).

Always try to operate with the simplest possible permissions. Set as few restrictions as possible. Assign permissions to groups, not individuals. Don't set file-by-file permissions unless it is unavoidable. Managing the minutiae of permissions can easily and quickly soak up all your time and much of your life's blood as well—unless you guard against it.

## Considering Inheritance

Just to complicate matters a bit more, there are two types of permissions, explicit and inherited permissions. *Explicit permissions* are the ones you set on folders that you create. *Inherited permissions* are those that flow from a parent object to a child object. By default, when you create a subfolder, it inherits the permissions of the parent folder.

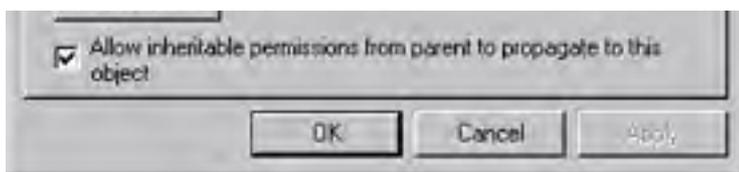

If you don't want the child objects to inherit the permissions of the parent, you can block inheritance at the parent level or at the child level. Where you block inheritance is important. Block at the parent level and no subfolders will inherit permissions. Block selectively at the child level and some folders will inherit permissions and others will not.

To block inheritance at the parent level, choose This Folder Only when assigning special permissions. To block only a certain file or folder from inheriting permissions, right-click the folder, select Properties, and then click the Security tab. Clear the check box for Allow Inheritable Permissions From Parent To Propagate To This Object.

If the check boxes for permissions appear shaded (Figure 9-33), it means the permissions are inherited from a parent object. There are three ways to change this situation:

- Clear the check box for Allow Inheritable Permissions From Parent To Propagate To This Object. Once the check box is cleared, you can make changes to the permissions or change the users or groups in the list.
- Change the permissions of the parent folder.
- Select the opposite permission—Allow or Deny—to override the inherited permission.

**Figure 9-33.** Viewing a folder with inherited permissions.

If neither Allow nor Deny is checked, the users or groups might have acquired the permission through a group membership. Otherwise, failure to explicitly configure Allow or Deny effectively denies the permission.

## What the Permissions Mean

Windows 2000 Server has a set of standard permissions that are combinations of specific kinds of access. The individual permissions are Full Control, Modify, Read & Execute, List Folder Contents, Read, and Write. Table 9-9 shows the special permissions and the standard permissions to which they apply.

**Table 9-9.** Special permissions for folders

Special Permission	Full Control	Modify	Read & Execute	List Folder Contents	Read	Write
Traverse Folder/Execute File	Yes	Yes	Yes	Yes	Yes	No
List Folder/Read Data	Yes	Yes	Yes	Yes	Yes	No
Read Attributes	Yes	Yes	Yes	Yes	Yes	No
Read Extended Attributes	Yes	Yes	Yes	Yes	Yes	No
Create Files/Write Data	Yes	Yes	No	No	No	Yes
Create Folders/Append Data	Yes	Yes	No	No	No	Yes
Write Attributes	Yes	Yes	No	No	No	Yes
Write Extended Attributes	Yes	Yes	No	No	No	Yes
Delete Subfolders and Files	Yes	No	No	No	No	No
Delete	Yes	Yes	No	No	No	No
Read Permissions	Yes	Yes	Yes	Yes	Yes	Yes
Change Permissions	Yes	No	No	No	No	No
Take Ownership	Yes	No	No	No	No	No

File permissions include Full Control, Modify, Read & Execute, Read, and Write. As with folders, each of these permissions controls a group of special permissions. Table 9-10 shows the special permissions associated with each standard permission.

**Table 9-10.** Special permissions associated with standard permissions

Special Permission	Full Control	Modify	Read & Execute	Read	Write
Traverse Folder/Execute File	Yes	Yes	Yes	No	No
List Folder/Read Data	Yes	Yes	Yes	Yes	No
Read Attributes	Yes	Yes	Yes	Yes	No

Read Extended Attributes	Yes	Yes	Yes	Yes	No
Create Files/Write Data	Yes	Yes	No	No	Yes
Create Folders/Append Data	Yes	Yes	No	No	Yes
Write Attributes	Yes	Yes	No	No	Yes
Write Extended Attributes	Yes	Yes	No	No	Yes
Delete Subfolders and Files	Yes	No	No	No	No
Delete	Yes	Yes	No	No	No
Read Permissions	Yes	Yes	Yes	Yes	Yes
Change Permissions	Yes	No	No	No	No
Take Ownership	Yes	No	No	No	No

Any user or group assigned Full Control on a folder can delete files and subfolders no matter what the permissions are on the individual files or subfolders.

## How Permissions Work

If you take no action at all, the files and folders inside a shared folder have the same permissions as the share. Permissions for both directories and files can be assigned to

- Domain local groups, global groups, universal groups, and individual users.
- Global groups, universal groups, and individual users from domains that this domain trusts.
- Special identities such as Everyone and Authenticated Users.

The important rules for permissions can be summarized as follows:

- By default, a folder inherits permissions from its parent folder. Files inherit their permissions from the folder in which they reside.
- Users can access a folder or file only if they've been granted permission to do so or they belong to a group that has been granted permission.
- Permissions are cumulative, but the Deny permission trumps all others. For example, if the Technical Writers group has Read access to a folder and the Project group has Modify permission for the same folder, and Alex is a member of both groups, Alex will have the higher level of permission, which is Modify. However, if the Technical Writers group permission is changed to explicitly Deny, Alex will be unable to use the folder, despite his membership—and ostensibly higher level of access—in the Project group.
- The user who creates a file or folder owns the object and can set permissions to control access.
- An administrator can take ownership of any file or folder but cannot pass ownership along to anyone else.

## Configuring Folder Permissions

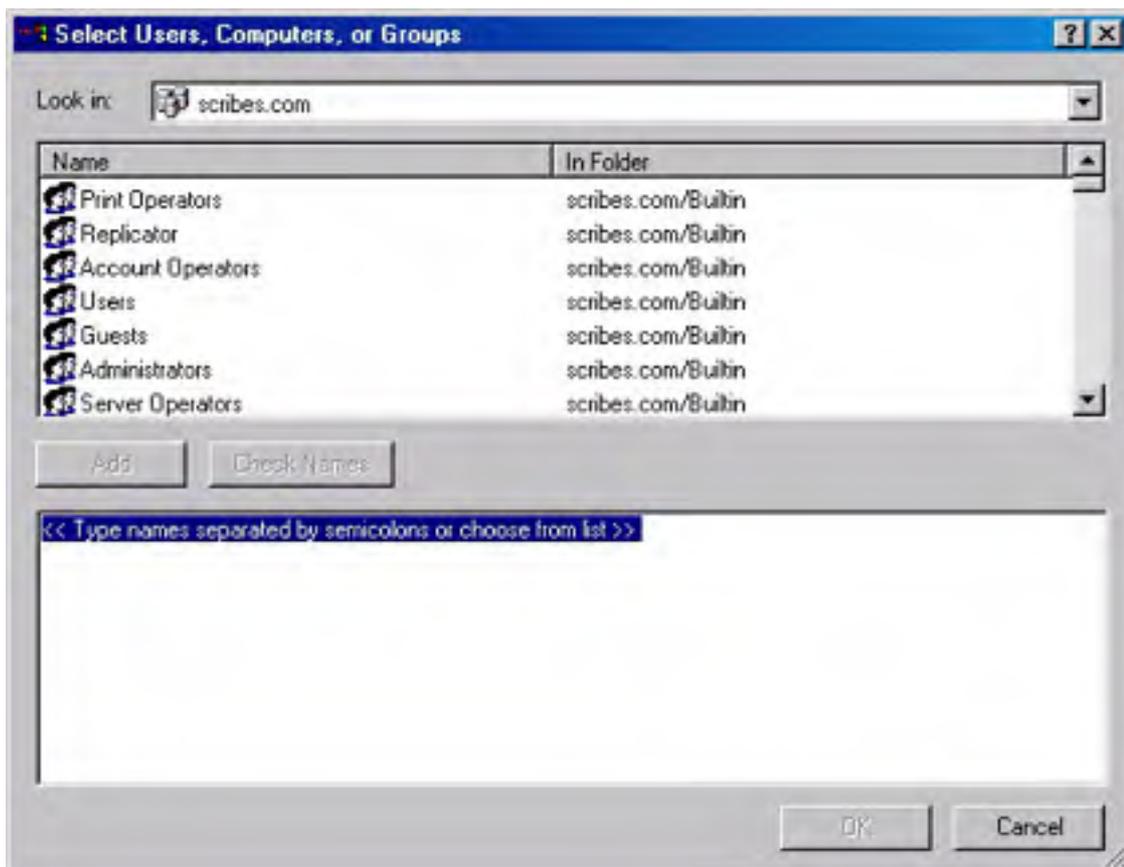

Before sharing a folder on an NTFS volume, set all the permissions on the folder. When you set folder permissions, you're also setting permissions on all the files and subfolders in the folder.

To assign permissions to a folder, right-click the folder in Explorer and choose Properties from the shortcut menu. Then click the Security tab and select Permissions.

To remove an individual or group from the list, just select the name and click Remove.

To add to the list of those with permissions, click Add. This opens the Select Users, Computers, Or Groups dialog box (Figure 9-34).

Click OK when you're done and the Folder Permissions box opens with the new names.

**Figure 9-34.** *Selecting users and groups.*

## Assigning Permissions to Files

Permissions for individual files are assigned in the same way as folders. There are, however, some special considerations:

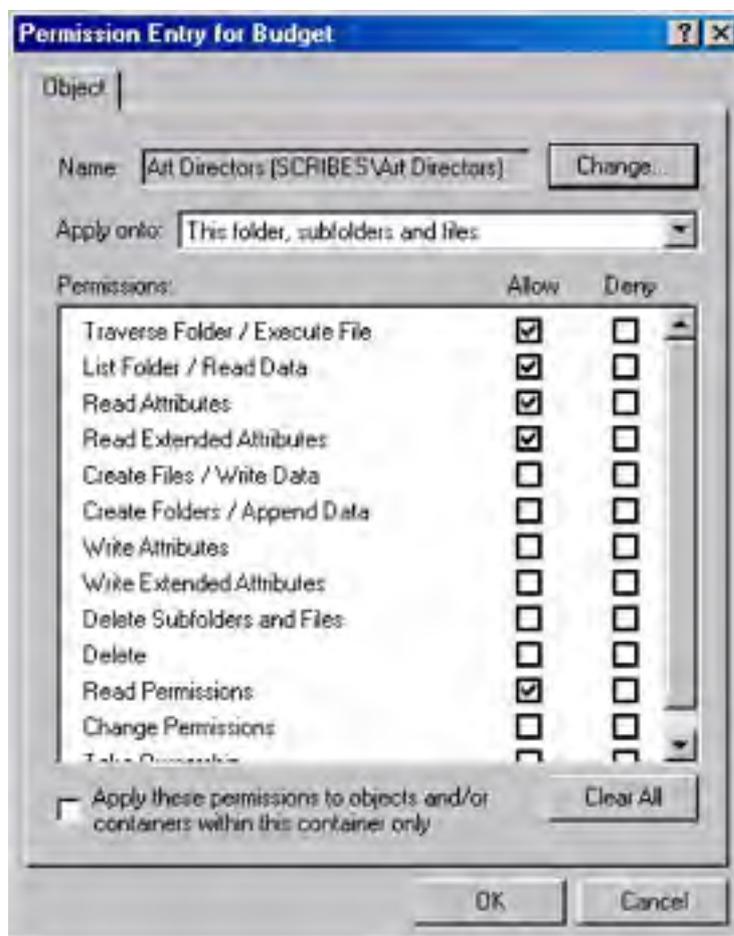

- Remember to grant permissions to groups, rather than individuals.
- Create groups and assign file permissions to them rather than assign permissions directly to local groups.

## Configuring Special Permissions

In some circumstances, you might find it necessary to set, change, or remove special permissions on either a file or folder. (Special permissions on a folder affect only the folder). To access special permissions, follow these steps:

1. In Explorer, right-click the file or folder and choose Properties from the shortcut menu.
2. Click the Security tab, and then click Advanced.
  - To add a user or group, click Add. Double-click the user or group name to open the Permission Entry dialog box.
  - To view or modify existing special permissions, select the name of the user or group and click View/Edit.
  - To remove special permissions, select the name of the user or group and click Remove. If the Remove button is dimmed, clear the check box for Allow Inheritable Permissions From Parent To Propagate To This Object, and skip to step 6.

3. In the Permission Entry dialog box (Figure 9-35), select where you want the permissions applied in the Apply Onto box. (See Table 9-11 and Table 9-12 for explanations of the choices in this drop-down box.) Apply Onto is available for folders only.
4. In Permissions, click Allow or Deny for each permission.
5. To prevent subfolders and files from inheriting these permissions, select Apply These Permissions To Objects And/Or Containers Within This Container Only.
6. Click OK to close the dialog boxes.

**Figure 9-35.** Setting special permissions for a folder.

In the Permission Entry dialog box for folders, you can choose how and where the special permissions are applied. Tables 9-11 and 9-12 demonstrate the application of the special permissions depending on whether Apply These Permissions To Objects And/Or Containers Within This Container Only is selected.

**Table 9-11.** Application of special permissions when Apply These Permissions To Objects And/Or Containers Within This Container Only is selected

Selected in Apply Onto	Applies to Current Folder?	Applies to Subfolders in Current Folder?	Applies to Files in Current Folder?	Applies to Subsequent Subfolders?	Applies to Files in Subsequent Subfolders?
This folder only	Yes	No	No	No	No
This folder, subfolders, and files	Yes	Yes	Yes	No	No
This folder and subfolders	Yes	Yes	No	No	No

This folder and files	Yes	No	Yes	No	No
Subfolders and files only	No	Yes	Yes	No	No
Subfolders only	No	Yes	No	No	No
Files only	No	No	Yes	No	No

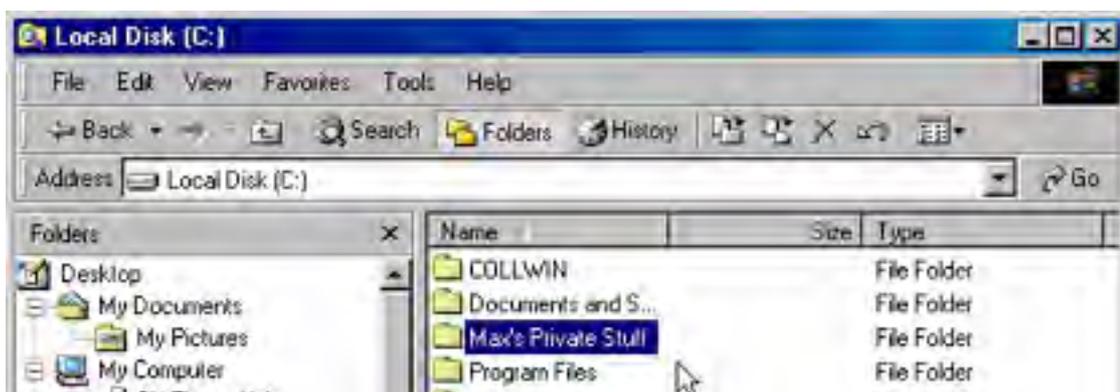

**Table 9-12.** Application of special permissions when Apply These Permissions To Objects And/OR Containers Within This Container Only is not selected

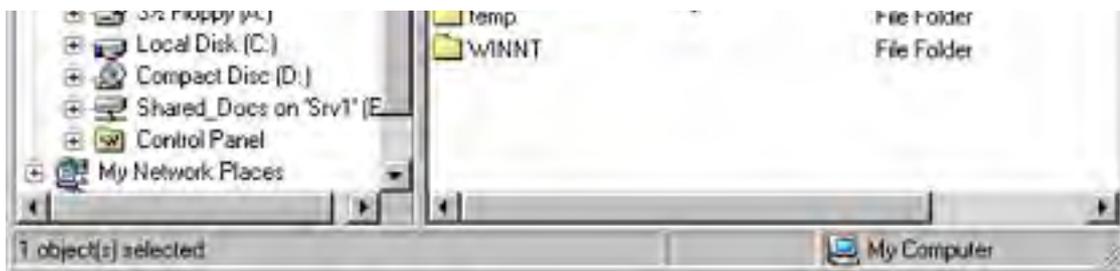

Selected in Apply Onto	Applies to Current Folder?	Applies to Subfolders in Current Folder?	Applies to Files in Current Folder?	Applies to Subsequent Subfolders?	Applies to Files in Subsequent Subfolders?
This folder only	Yes	No	No	No	No
This folder, subfolders, and files	Yes	Yes	Yes	Yes	Yes
This folder and subfolders	Yes	Yes	No	Yes	No
This folder and files	Yes	No	Yes	No	Yes
Subfolders and files only	No	Yes	Yes	Yes	Yes
Subfolders only	No	Yes	No	Yes	No
Files only	No	No	Yes	No	Yes

## Ownership and How It Works

As you've seen, Administrators and members of a few other select groups are the only ones who can grant and change permissions. The exception is when a user is the owner of the folder or file in question. Every object on an NTFS partition has an owner and the owner is the person who created the file or folder. The owner controls access to the file or folder and can keep out anyone he or she chooses.

Figure 9-36 shows an example of a folder called Max's Private Stuff made by the user Maxwell.

**Figure 9-36.** A user's new folder.

To see who has permission to access his new folder, Maxwell right-clicks the folder and chooses Properties and then clicks Security. When he clicks Permissions, the dialog box shown in Figure 9-37 opens.

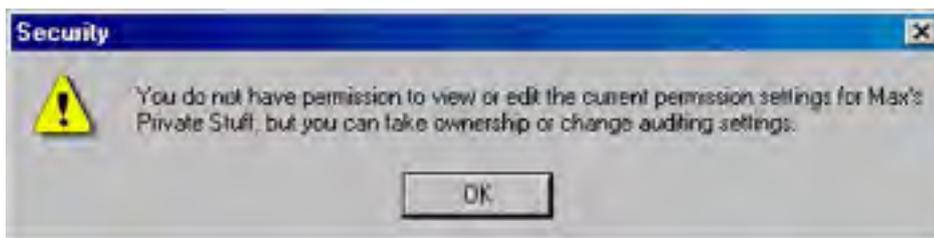

**Figure 9-37.** Viewing the permissions for a new folder.

Much to his surprise, it appears that everyone on the network has access to his "private" stuff. But because Maxwell is the owner of the folder, he can change the permissions so that he has the folder all to himself. To do so, he explicitly adds his name to the permissions list and clears the Allow Inheritable Permissions option.

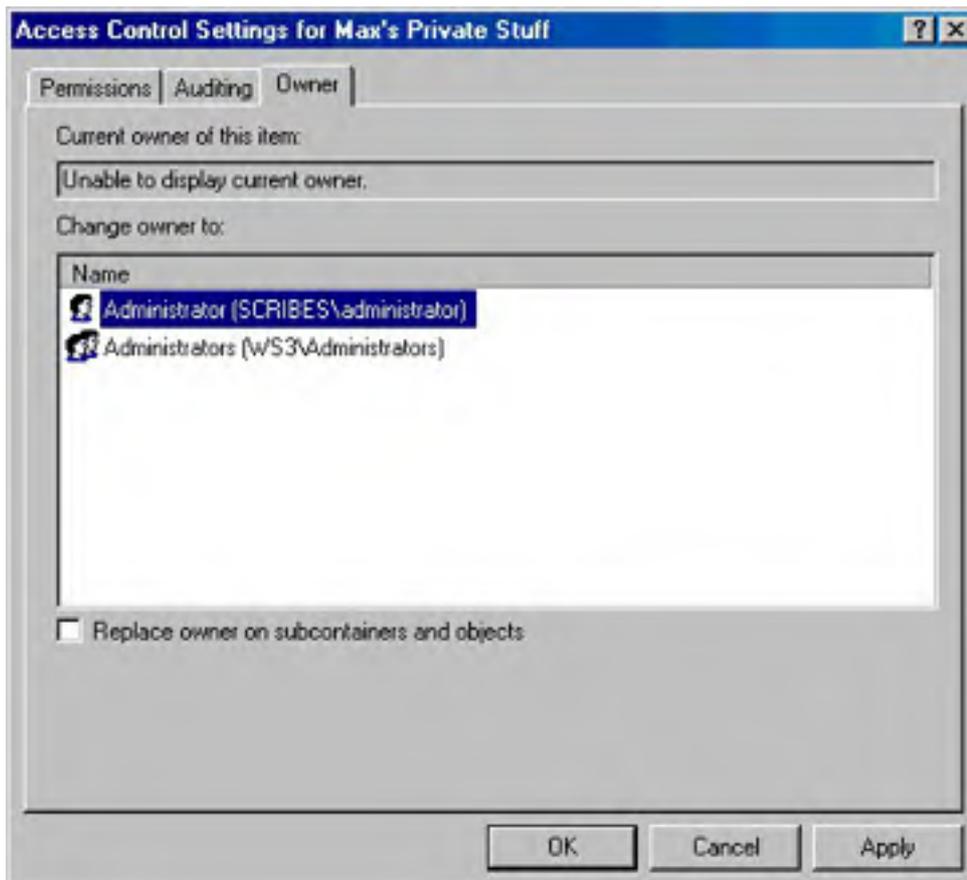

After this is done, even the administrator sees an Access Denied message when trying to open the folder.

Of course, nothing on the network can be completely beyond the reach of administrators, so the administrator can right-click the folder and choose Properties from the shortcut menu. When he or she clicks the Security tab, the information box shown in Figure 9-38 opens.

**Figure 9-38.** The administrator tries to view permissions for a folder owned by a user.

In the Security Properties dialog box, no changes can be made. However, if the administrator clicks Advanced and then the Owner tab (Figure 9-39), he or she can change the owner of the folder to an administrator.

**Figure 9-39.** Changing the ownership of a folder.

No matter what the status of the folder, the administrator can take ownership. When Maxwell logs on the next time, he'll still have access to Max's Private Stuff, but if he clicks Advanced and then Owner, he'll see that he's no longer the owner of the folder. Thus, even though administrators can go into all areas without an invitation, they can't do so without leaving evidence of their presence.

The owner of a file or folder can also grant the Take Ownership special permission to others, allowing those users to take ownership at any time.

## Understanding Group Policies

For many small to medium-sized networks, the groups built into Windows 2000 Server can, with perhaps a little tweaking, provide perfectly adequate security. In larger networks and those with special needs, however, the security settings may be too strict for some groups and too lax for others. For these situations, group policies can give administrators a degree of control that is as granular as one could wish for. In addition, group policies can reduce the amount of lost productivity when users accidentally delete system configuration files, "lose" vital folders, or introduce a virus to the network.

Group Policy is the successor to the System Policy Editor in Windows NT. There is, however, one important difference: you can make group policies without having a Ph.D. in computer mysteries. They can be complex and extremely detailed, but they do work. Group policies can control all aspects of the environment, both large and small, and they are usually set at the site and domain level. With the Group Policy snap-in, you can specify settings for registry-based policy settings, security settings, software installation, scripts, and folder redirection.

Third parties can extend Group Policy to host other policy settings. All of the data generated by Group Policy is stored in a Group Policy object (GPO), which is replicated in all domain controllers within a single domain.

### Real World

#### Windows NT 4 Policies and Windows 2000

System policies set in Windows NT 4 do not migrate to Windows 2000. A Windows NT client upgraded to Windows 2000 will have only Active Directory-based group policies; no Windows NT 4 policies will survive the upgrade. The primary difference between Windows NT system policies and Windows 2000 group policies lies in where the policies are written. Windows 2000 uses only the following four trees of the registry:

HKEY\_LOCAL\_MACHINE\Software\Policies

HKEY\_CURRENT\_USER\Software\Policies

HKEY\_LOCAL\_MACHINE\Software\Microsoft\Windows\CurrentVersion\Policies

HKEY\_CURRENT\_USER\Software\Microsoft\Windows\CurrentVersion\Policies

The first two are preferred. When a group policy changes, these trees are essentially deleted and their contents rewritten. Although none of the templates that come with Windows 2000 include values that write to other places in the registry, it is possible to do so. (Windows NT 4 policies can write to any part of the registry.) However, it is inadvisable to employ Windows NT-style policies that write to other parts of the registry for the following reasons:

- Only the four trees just listed are secure. Applications, the operating system, or users can modify other parts of the registry.
- Once a policy is set in another part of the registry, it persists until the registry is edited or the policy is specifically reversed.
- Sticking with the Active Directory Group Policy gives you considerably more control over when and how policies change.

Windows NT 4 Workstation and Server clients do not have Active Directory, so you will have to continue to use System Policy Editor (Poedit.exe) to set policy for those clients. Group policies will not apply to them. Similarly, run Poedit.exe on Windows Microsoft 95 and Windows 98 clients and copy the resulting Config.pol file to the SYSVOL folder of the Windows 2000 domain controller.

## Components of Group Policy

Group Policy consists of several configurable components. The first is administrative templates, which set registry-based policy. Five administrative templates are included with Windows 2000. Two of these are installed by default:

- **System.adm** System policies for Windows 2000 clients
- **Inetres.adm** Internet Explorer policies for Windows 2000 clients

These templates use the four areas in the registry reserved for Group Policy settings. Three additional administrative templates (Common.adm, Windows.adm, and Winnt.adm) are for setting policy for Windows NT, Windows 95, and Windows 98 clients. They are used with the System Policy Editor (Poedit.exe) on the clients themselves and should not be loaded into Group Policy.

The other components of Group Policy are as follows:

- **Security Settings** Configures security for users, computers, and domains
- **Scripts** Specifies scripts for computer startup and shutdown as well as for user logon and logoff
- **Folder Redirection** Places special folders such as My Documents or specified application folders on the network
- **Software** Assigns applications to users (See [Chapter 25](#) for more on publishing software on the network.)

All components of Group Policy can be edited using the Group Policy Editor.

## Group Policy Objects

Group Policy settings are stored in a Group Policy object (GPO). One or more GPOs can apply to an SDOU (site, domain, or OU), just as multiple SDOUs can be associated with a single GPO. GPOs store information in two locations: in a folder structure called a Group Policy template (GPT) and in a Group Policy container (GPC) in Active Directory.

The GPT is in the SYSVOL folder of all domain controllers. It contains information about software policy, file and application deployments, scripts, and security settings. A GPC contains GPO properties, including the Active Directory class information related to application deployment. The information stored in a GPC changes infrequently.

A GPO that applies locally will be stored in the local computer's %SystemRoot%\System32\Grouppolicy folder. A computer can have only one local group policy.

**Group Policy Templates** When you create a GPO, the corresponding GPT folder structure is created automatically. The actual name of the folder for the GPT will be the globally unique identifier (GUID) for the GPO—a number that is useful to the computer but otherwise incomprehensible. However, to see the policy folder, look in %SystemRoot%\SYSVOL\sysvo\domain\_name\policies.

**Group Policy Containers** Nonlocal Group Policy objects also have an Active Directory component called a GPC that includes subcontainers with version information, status information, and a list of which Group Policy extensions are employed in the GPO. GPCs have no direct relevance to administration.

## Access to Group Policy

Group policies are created and modified in a number of different ways, depending on the type of group policy you want to implement. Table 9-13 describes how to apply Group Policy in various ways.

**Table 9-13.** *Applying Group Policy*

To Apply Group Policy to	Follow These Steps
--------------------------	--------------------

The local computer	For security policy only, select Local Security Policy from the Administrative Tools folder. On a Windows 2000 Professional machine, open Control Panel, click Administrative Tools, and select Local Security Policy.
Another computer	Open MMC <sup>1</sup> and add the Group Policy snap-in. In the Select Group Policy Object dialog box, browse to find the Group Policy object you want.
A domain	Open Active Directory Users and Computers. In the console tree, right-click the domain and choose Properties from the shortcut menu. Click the Group Policy tab.
An organizational unit	Open Active Directory Users and Computers. In the console tree, right-click the OU and choose Properties from the shortcut menu. Click the Group Policy tab.
A site	Open Active Directory Sites and Services. In the console tree, right-click the site and choose Group Policy from the shortcut menu. Click the Group Policy tab.

## Managing Group Policies

Group policies are inherited and cumulative. When you associate a GPO with an Active Directory container, the group policy is applied to all computer and user accounts in the container.

The Users and Computers folders in Active Directory Users and Computers are not organizational units and therefore cannot have group policies applied to them. The Domain Controllers folder is, however, an OU and can have a specific GPO.

### Order of Inheritance

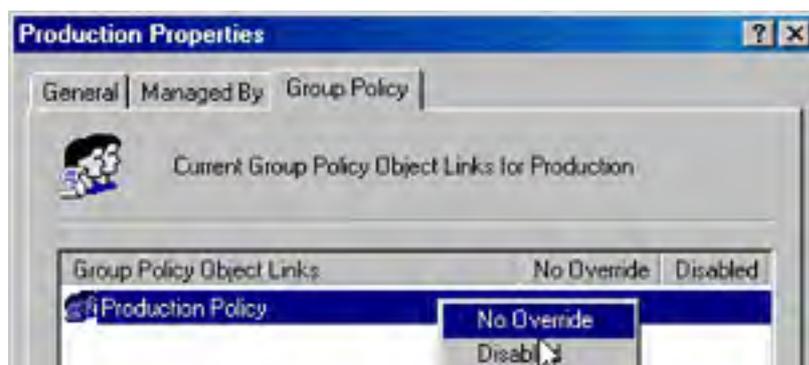

As a rule, Group Policy settings are passed from parent containers down to child containers. This practice means that a policy that is applied to a parent container applies to all of the containers—including users and computers—that are below the parent container in the Active Directory tree hierarchy. However, if you specifically assign a group policy for a child container that contradicts the parent container policy, the child container's policy overrides the parent group policy.

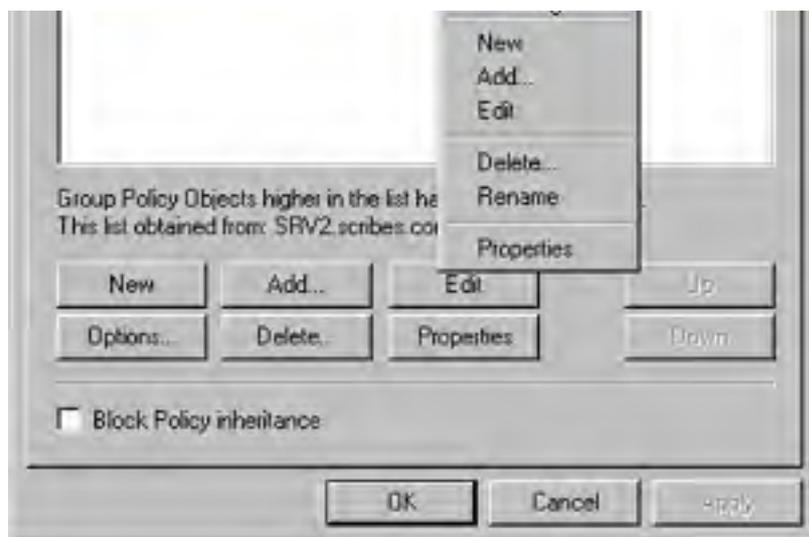

If policies are not contradictory, both can be implemented. For example, if a parent container policy calls for an application shortcut to be on a user's desktop, and the child container policy calls for another application shortcut, both appear. Policy settings that are disabled are inherited as disabled. Policy settings that are not configured in the parent container are not inherited.

### Overriding Inheritance

Two options are available in Windows 2000 for changing how inheritance is processed. One option is No Override. When this option is set, child containers cannot override any GPO set in a higher level. This option is not set by default and must be turned on in each GPO where it's desired. To set the No Override option, follow these steps:

1. Open the GPO you want to administer. (Refer back to Table 9-13.)
2. Right-click the GPO and choose No Override from the shortcut menu (Figure 9-40). A check mark appears next to the GPO under No Override.
3. Click OK.

**Figure 9-40.** Preventing an override to the GPO's inheritance policy.

A second option is Block Policy Inheritance. This option is available in a check box in the GPO's Properties dialog box. (The check box can be seen in Figure 940.) When you select this option, the child container does not inherit any policies from parent containers. If there is a conflict between these two options, the No Override option always takes precedence.

## Order of Implementation

Group policies are processed in the following order:

- Windows NT 4 system policy (if any)
- Local group policy
- Site
- Domain
- Organizational unit
- Child OU

As you can see, local policy is processed first, and the OU of which the user or computer is a member is processed last. There are two exceptions to this. The Block Policy Inheritance option can be set for an SDOU, meaning that policy from above will not be applied. However, an SDOU group policy set to No Override is *always* applied, with the highest policy in the tree taking precedence.

## Implementation and Effective Policy

Because policy can be set at several levels, when you click on a policy object, you'll see both local policy and the policy in effect on the system. These might not be the same if the computer is inheriting settings from domain-level policies. If you make a policy setting and it isn't reflected in effective policy, it's likely that a policy from the domain is overriding your setting.

It's also possible that the policy change hasn't been refreshed since you made it. To force a policy refresh for the local computer, open a command window and type:

```
secedit /refreshpolicy machine_policy
```

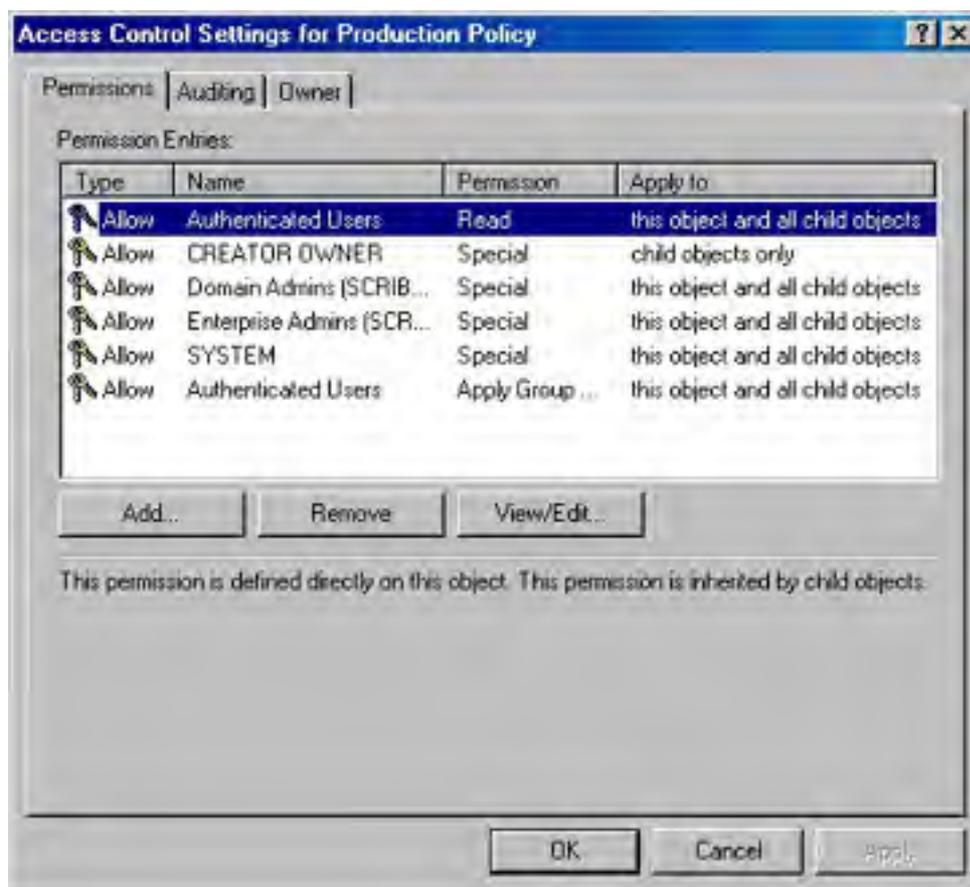

To change the interval between automatic updates, see the section entitled [Refreshing Group Policy](#), later in this chapter.

## Setting the Scope of the GPO

A Group Policy object applies to all of the users and computers in the SDOU with which the GPO is associated. Inevitably, there will be users and computers in the SDOU that should not have a particular GPO applied. In addition, policies for a particular GPO apply only to users who have Read permission for that GPO. To filter the application of a GPO, you can create security groups and assign Read permission only to the groups to which the GPO applies.

Filtering the scope of a GPO involves using the Access Control List (ACL) Editor to allow or deny access to the GPO for particular groups. To set access, follow these steps:

1. Open the GPO you want to administer. (Refer back to Table 9-13.)
2. In the Group Policy tab, select the GPO and click Properties.
3. Click the Security tab. At the bottom of the Security tab, click Advanced to open the ACL Editor (Figure 9-41).
4. Add or remove groups, or edit the settings. Click OK several times when you're done to close all of the open windows.

**Figure 9-41.** Setting the scope of a GPO.

Table 9-14 shows the settings to use to have a GPO apply or not apply to a security group. The location of the security group doesn't matter when making the settings. What matters is the location of the users or computers who are members of the security group. If a user or computer is not a member of the SDOU that the GPO is associated with (either directly, through a link, or by inheritance), no combination of permissions or membership in a security group can force the GPO to apply to that user or computer.

**Table 9-14.** Setting policies for security groups

Intended Result	Permissions Needed	Outcome
This group policy will be applied to the members of this group.	Apply Group Policy: Allow Read: Allow	Group policy will be applied to all members except members who belong to another group with Apply Group Policy or Read set to Deny.

This group policy will not be applied to members of this group.	Apply Group Policy: Deny Read: Deny	Group policy will not be applied to any members of this group, no matter what other groups they belong to.
Membership in this group should not be a relevant factor in whether this group policy is applied.	Apply Group Policy: No setting Read: No setting	Application of this group policy to members of this group will depend on whether members belong to other security groups with Allow or Deny settings.

Bear in mind that just because something can be done doesn't mean that it should be done. Proceed carefully when it comes to setting permissions. Users who are in favor of security in the abstract become annoyed when they receive unnecessary "access denied" messages. Apply restrictions cautiously and only after you're sure you understand the implications of a particular policy, especially in the area of inheritability.

## Creating a Group Policy Object

When you create an Active Directory domain, a default domain policy is also created. You can see it by right-clicking the domain in Active Directory Users and Computers, choosing Properties, and clicking the Group Policy tab. With some judicious adjustments to meet the needs of your own situation, you might never need anything else. Nevertheless, the time might come when you need to set up a GPO of your own. To do so, follow these steps:

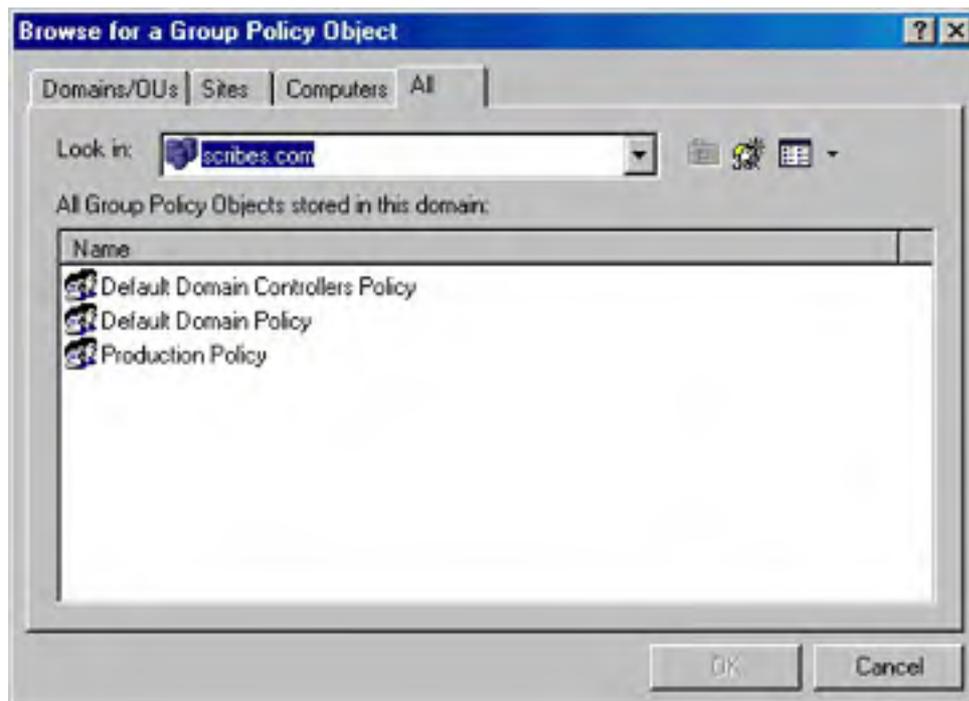

1. Launch Active Directory Users and Computers (for domain or OU GPOs) or Active Directory Sites and Services (for site GPOs).
2. Right-click the object for which you want to create a GPO, and choose Properties from the shortcut menu.
3. Click the Group Policy tab, and then click New.
4. Type a name for the new GPO, and choose one of the following buttons:
  - **Add** To add a link to the new policy.
  - **Edit** To open the new GPO in the Group Policy Editor.
  - **Options** To set No Override or to disable the GPO.
  - **Delete** To remove the GPO permanently or remove it from the list. If you choose Remove The Link From The List, the GPO remains in Active Directory but is no longer applied to the particular SDOU.
  - **Properties** To set filtering for the GPO through security groups.
5. Click OK when you're finished.

## Using the Group Policy Editor

You can edit Group Policy settings by accessing a GPO through the methods described in Table 9-13. For frequently accessed GPOs, create a Microsoft Management Console (MMC) that includes the Group Policy snap-in, and then save the console in a convenient location so that you can open it quickly when you need it. For example, to make an MMC that is focused on the default domain policy, follow these steps:

1. Click Start and choose Run.
2. Type *mmc* and click OK.
3. From the Console menu, choose Add/Remove Snap-in.
4. Click Add and select Group Policy from the list of available snap-ins.
5. Click Add. This opens the Select Group Policy Object dialog box. Click Browse.
6. In the Browse For A Group Policy Object dialog box (Figure 9-42), select Default Domain Policy, and click OK.

7. Click Finish in the Select Group Policy Object dialog box. Close the open dialog boxes.

**Figure 9-42.** Finding an existing Group Policy object.

### Inside the Group Policy Editor

If you click Default Domain Policy in the Group Policy console tree, you'll see that the Group Policy Editor displays two nodes: Computer Configuration and User Configuration. When you click these nodes, you'll find that each displays extensions for Software Settings, Windows Settings, and Administrative Templates.

Use the Computer Configuration folders to customize policies for computers on the network. These policies go into effect when the computer is turned on and the operating system starts. Settings in these folders apply to any user who logs on to the computer. For example, if you have machines in a training room for which you want to enforce a strict environment, the Computer Configuration node is where you'd make those settings.

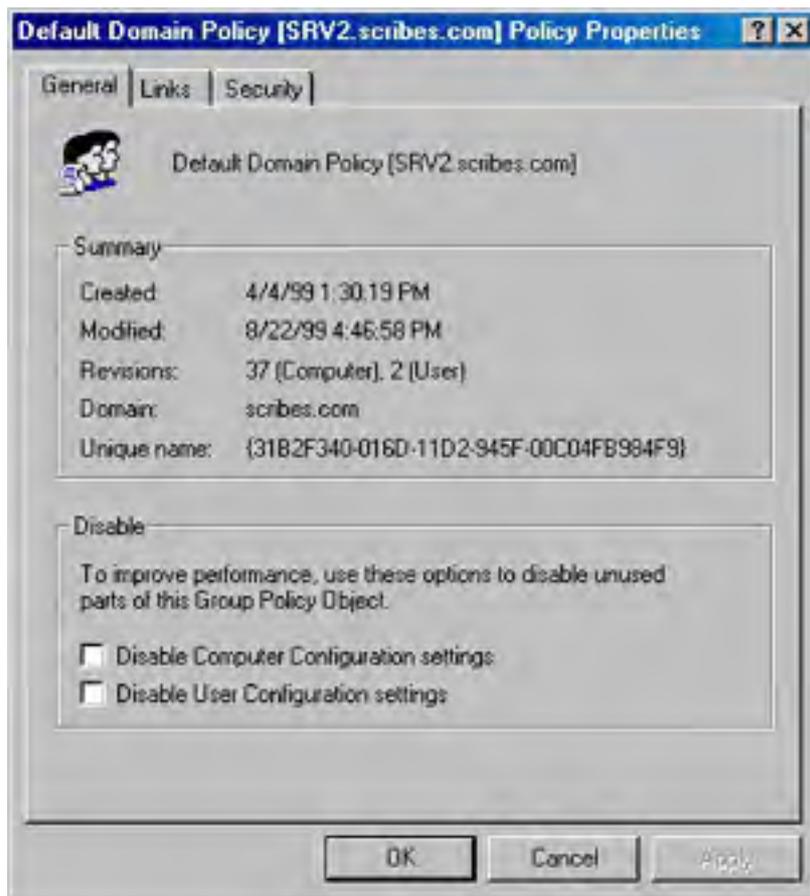

The User Configuration node contains settings for customizing environments or setting policies for users on the network. User Configuration policies come into play when a specific user logs on to the network.

### Disabling a Branch of a GPO

If a GPO has an entire node under User Configuration or Computer Configuration that is not configured, disable the node to avoid processing those settings. This speeds startup and logon for all users subject to that GPO. To disable a node, follow these steps:

1. Right-click Group Policy Object, either in a console or in the Group Policy Properties dialog box.
2. Choose Properties from the shortcut menu.
3. In the General tab, select the option to disable the User Configuration or Computer Configuration settings for this GPO (Figure 9-43).

4. Click OK when you're finished. The disabled settings will no longer affect any SDOU linked to this GPO.

**Figure 9-43.** Disabling unused parts of a GPO.

### Finding Group Policy Links

With numerous GPOs on a network, it's important to keep track of links between GPOs and SDOUs. To find out what SDOU uses a particular GPO, right-click Group Policy Object, either in a console or in the Group Policy Properties dialog box. Choose Properties and then click the Links tab. Click Find Now, and a list of SDOUs that use the Group Policy object is returned.

### Refreshing Group Policy

Policy changes are immediate, but they are not propagated to clients automatically. Client computers request policy when

- The computer starts
- A user logs on
- An application requests a refresh
- A user requests a refresh
- A Group Policy refresh interval is enabled and the interval has elapsed

To set a Group Policy refresh interval, follow these steps:

1. Open the GPO.
2. In the console tree, select Computer Configuration, then Administrative Templates, System, and finally Group Policy.
3. In the details pane, double-click Group Policy Refresh Interval For Computers.
4. Enable the refresh interval. Click OK.

Don't make the interval very short because of the large amount of network traffic generated by each refresh. The refresh interval for domain controllers is set separately.

## Using Group Policy for Folder Redirection

Folder Redirection is an extension to Group Policy that allows you to place designated folders on the network. In particular, you might want to redirect users' My Documents folders or other folders that can become quite large over time. With redirected folders the following conditions apply:

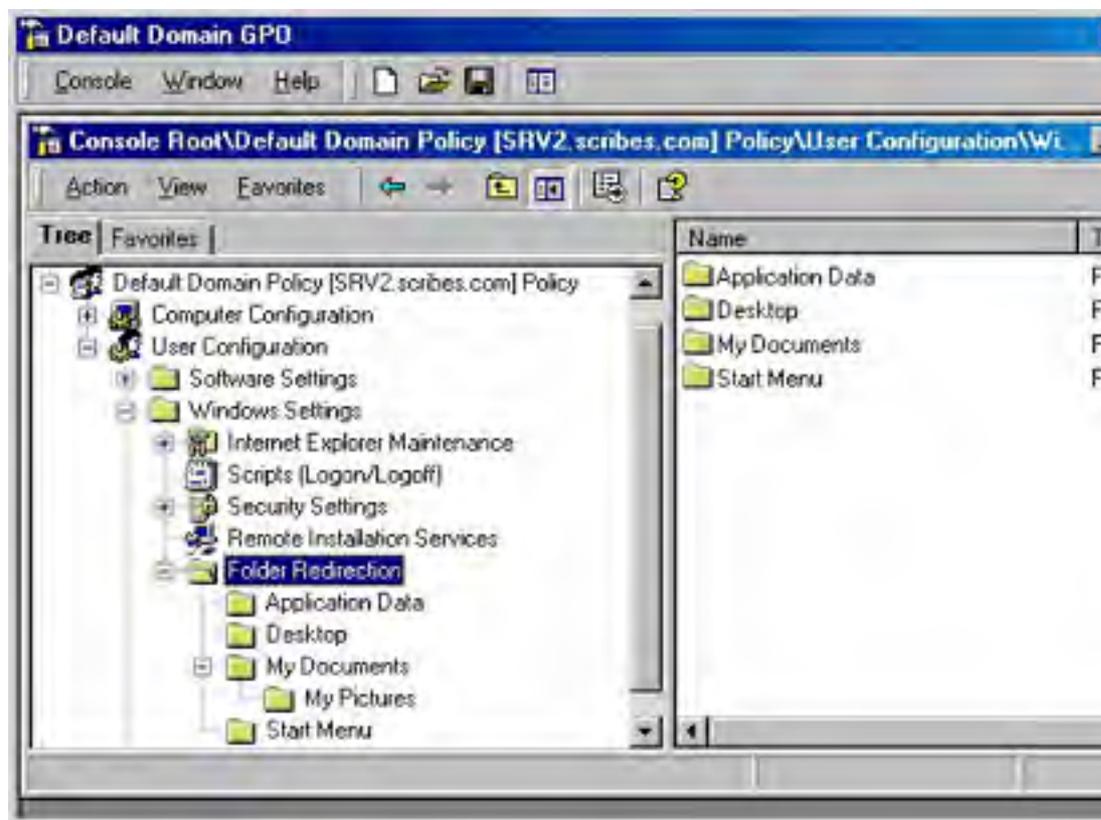

- A user can log on to different computers and still have the folders available.
- When employing roaming profiles, only the network path to the redirected folders is part of the profile, not the folders themselves. This makes logging on and off much faster.
- Folders on a network server can be backed up as part of routine maintenance with no action on the part of the user.

Folders can be redirected to one location for everyone in the SDOU affected by the Group Policy object. They can also be redirected to different locations according to security group membership.

### Redirecting to One Location

By far the most common form of redirection is to send everyone's My Documents folder to a single location on a network server. The following steps show how to do this. You can substitute other Windows special folders in the steps to redirect them as well.

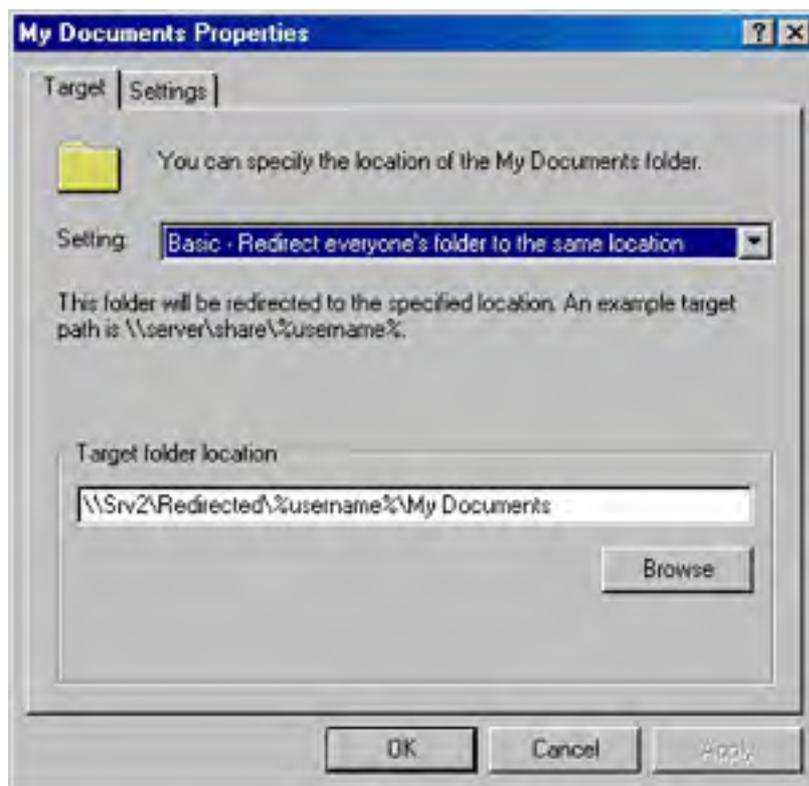

1. Create a shared folder on the server.
2. Open the Group Policy object linked to the SDOU containing the users whose folders are to be redirected.
3. In the console tree, click User Configuration, then Windows Settings, and finally Folder Redirection (Figure 9-44).

**Figure 9-44.** Locating the Folder Redirection node in the GPO.

4. Right-click My Documents and choose Properties from the shortcut menu.

- In the drop-down list, select Basic - Redirect Everyone's Folder To The Same Location. Enter the path for the shared folder on the server. Use a UNC path with the %username% variable, as shown in Figure 9-45.

**Figure 9-45.** Setting a path for the redirection of My Documents folders.

- Click the Settings tab. The following settings are enabled by default:
  - Grant The User Exclusive Rights To My Documents** The user and the local system have exclusive rights to the folder. No administrative rights are enabled. If this setting is disabled, the permissions that exist on the folder in its present position will remain.
  - Move The Contents Of My Documents To The New Location**
  - Policy Removal** The default is to leave the folder in the new location when the policy is removed. If you choose to redirect the folder back to the local user, see the section entitled [Removing Redirection](#), later in this chapter.
  - My Pictures Preference** My Pictures will follow My Documents as a subfolder.
- Click OK when you're finished.

## Redirecting by Group Membership

Special folders can also be redirected to various locations based on the user's membership in security groups. To do so, follow these steps:

- Create the shared folders at the locations to which the folders will be redirected.
- Open the Group Policy object linked to the SDOU containing the users whose folders are to be redirected.
- In the console tree, click User Configuration, then Windows Settings, and finally Folder Redirection.
- Right-click the special folder (in this case My Documents), and choose Properties from the shortcut menu.
- In the drop-down list, select Advanced - Specific Locations For Various User Groups, and then click Add.

6. In the Specify Group And Location box, enter the security group and the location for the redirected folders (Figure 9-46). Always use a UNC path, even if the folders are to be on the local computer, so that roaming users will be able to see their folders.

**Figure 9-46.** Setting folder redirection for an entire group.

7. Click OK. Add more groups and locations as needed.
8. Click the Settings tab. The following settings are enabled by default:
  - **Grant The User Exclusive Rights To My Documents** The user and the local system have exclusive rights to the folder. No administrative rights are enabled. If this setting is disabled, the permissions that exist on the folder in its present position remain.
  - **Move The Contents Of My Documents To The New Location** The contents of the user's current My Documents folder will be sent to the new location. If this option is disabled, the user will have a new, but empty, My Documents folder at the new location.
  - **Policy Removal** The default is to leave the folder in the new location when the policy is removed. If you choose to redirect the folder back to the local user, see the next section, "Removing Redirection."
  - **My Pictures Preference** My Pictures will follow My Documents as a subfolder.
9. Click OK when you're finished.

## Removing Redirection

When folders have been redirected and later the policy changes, the effect on the folders depends on the combination of choices made in the Settings tab in the special folder's Properties dialog box. Table 9-15 shows the various combinations of settings and the outcome when the policy is changed. (Software policy settings are covered in [Chapter 25](#).)

**Table 9-15.** Settings and their outcome when redirection is removed

Policy Removal Option	Move Contents of Folder to New Location	Outcome When Policy Is Removed
Redirect the folder	Enabled	The folder returns to its user profile location; the

back to the local user profile location when policy is removed.		contents of the folder are copied back to the original location; the contents are not deleted from the redirected location.
Redirect the folder back to the local user profile location when policy is removed.	Disabled	The folder returns to its user profile location; the contents of the folder are not moved or copied back to the original location. Warning: this means that the user cannot see the folder contents.
Leave the folder in the new location when policy is removed.	Enabled or Disabled	The folder and its contents remain at the redirected location; the user has access to the contents at the redirected location.

## **Summary**

The success of a network operation is measured by both the availability of some information and resources and the restriction and protection of others. Windows 2000 offers the network administrator the tools and functionality to meet the information needs of users, while protecting sensitive information stored on or passed through the network. This chapter has explored the options available to administrators for configuring groups, users, group scope, permissions, and group policy through Windows 2000. Proper management of built-in and customized groups provides accessibility and security for any network—from the simplest to the most complex. The next chapter covers day-to-day administrative tasks, including using the secondary logon and Microsoft Management Console.

## **Managing Day-to-Day Operations**

If it's true that, as Mies van der Rohe said, "God is in the details," then a network is a very holy place indeed. A network administrator's job consists of masses of details, and if you're to cope, you must find ways of handling and tracking them. Microsoft Windows 2000 supplies plenty of tools for this, including ones that allow you to delegate tasks to other users or groups, use scripts to automate tasks, and schedule tasks to run periodically. Nevertheless, administering a network is still largely a process of planning and organization, and in that area there's no substitute for brainpower. This chapter discusses some of the tools that can help in the daily business of network management.

## Using the Secondary Logon

Recommended administrative practice dictates that an administrator be logged on to a privileged account (one with administrative rights) only while doing chores that require privileges. For ordinary work, the administrator is supposed to log off from the privileged account and then log on again to an ordinary account. Of course, it's not unusual that ten minutes later a situation arises requiring use of the privileged account. So then it's necessary to log off from the ordinary account and log back on to the administrator account, with the process reversed again a few minutes later.

After a few days of this, even the most security-conscious person begins to toy with the idea of logging on to the administrator account and staying there. And in time, most administrators succumb to the temptation and stay in the privileged account most of the time.

This practice makes Microsoft Windows NT systems highly susceptible to Trojan horse attacks. Just running Microsoft Internet Explorer and accessing a non-trusted Web site can be very risky if done from an administrator account. A Web page with Trojan code can be downloaded to the system and executed. The execution, done in the context of administrative privileges, will be able to do considerable mischief, including such things as reformatting a hard disk, deleting all files, or creating a new user with administrative access. When you think about it, it's like handing the keys to your network to a complete (and malicious) stranger.

This problem is finally addressed in Windows 2000 with the Run As feature (enabled by the RunAs service, which is on by default). This feature allows you to work in a normal, nonprivileged account and launch applications or tools using the credentials of a different account (most likely your administrator account) without logging off and then logging back on again.

To use the Run As feature, create an ordinary user account for your own use (if you don't have one already). Make sure that the user account has the right to log on locally at the machine you want to use.

Windows 2000 views all domain controllers as special cases. On a domain controller, for example, all management of users and groups must be done through the Active Directory Users and Computers snap-in. Also, by default, users can't log on locally to a domain controller. [Chapter 9](#) has more on creating user accounts and granting rights.

## Opening Programs Using Another Account

To open a program or system tool using a different user account (most likely an account with Administrator privileges), use the following steps:

1. Hold down the Shift key and right-click the desired program, Control Panel tool, or Administrative Tools icon.
2. Choose Run As from the shortcut menu.
3. Enter the desired user name and password, as well as the domain name that stores the user account.
4. Click OK to open the program or tool using the specified account's credentials.

## Starting a Command-Line Window for Administration

You might want to open a command shell for performing administrative tasks. To do so, use the following steps:

1. After logging on as a regular user, open a command window and type the command `runas /user:<domain \username> cmd`. In this case, `username` is the account with administrative privileges. If you are logged on as a local user, the command is `runas /user:<machinename \username> cmd`.
2. A command-line window opens, and you're prompted for the password for the administrative account.

3. After you enter the password, a second window opens. As shown in Figure 10-1, the title bar of the window clearly indicates that it is running as the account selected.

**Figure 10-1.** A command-line window for an administrator account.

You can perform any command-line tasks you want from this window. Of course, there are some administrative tasks that can't be done from the command line or that can be done only with great difficulty. So some applications, such as the Printers folder and Control Panel, are launched from the shell at the time of logon, so if you're logged on as an ordinary user, the Control Panel functions stay in that context (although you can open individual tools with a different account using the procedure covered earlier in this chapter).

To stop the shell and start it again as an administrator so that you can use functions like the Printers folder, follow these steps:

1. Right-click the taskbar and choose Task Manager from the shortcut menu.
2. Click the Processes tab. Select Explorer.exe, and click End Process. A warning message appears. Click Yes. The entire desktop, except for Windows Task Manager and any active applications, disappears.
3. Select the Applications tab in Windows Task Manager, and then click New Task.
4. In the Create New Task box, enter `runas /user:<domain\username> explorer.exe`. As before, *username* is the account with administrative privileges. If you're logged on locally, use the command `runas /user:<machinename\username> explorer.exe`.
5. Enter the password for the user name. The desktop, along with the taskbar, returns. This desktop is in the security context of the user name you specified in the command.

To return to the ordinary user's desktop, use Task Manager again to shut down Explorer.exe. Then start a new instance by typing `explorer.exe` (without `runas`, so that Internet Explorer is restarted in the original security context) in the Create New Task dialog box.

Don't close Task Manager while you're working in the desktop's administrative context—just minimize it to the taskbar. Closing Task Manager can produce unpredictable results and is likely to cost you more time than you can possibly save by using RunAs.

## Administration Tools

Most of the tools you'll need for managing a Windows 2000 network come as part of the Windows 2000 Server and Windows 2000 Advanced Server packages, but only a few of them are automatically installed along with the operating system. Table 10-1 gives the complete list of Administration Tools.

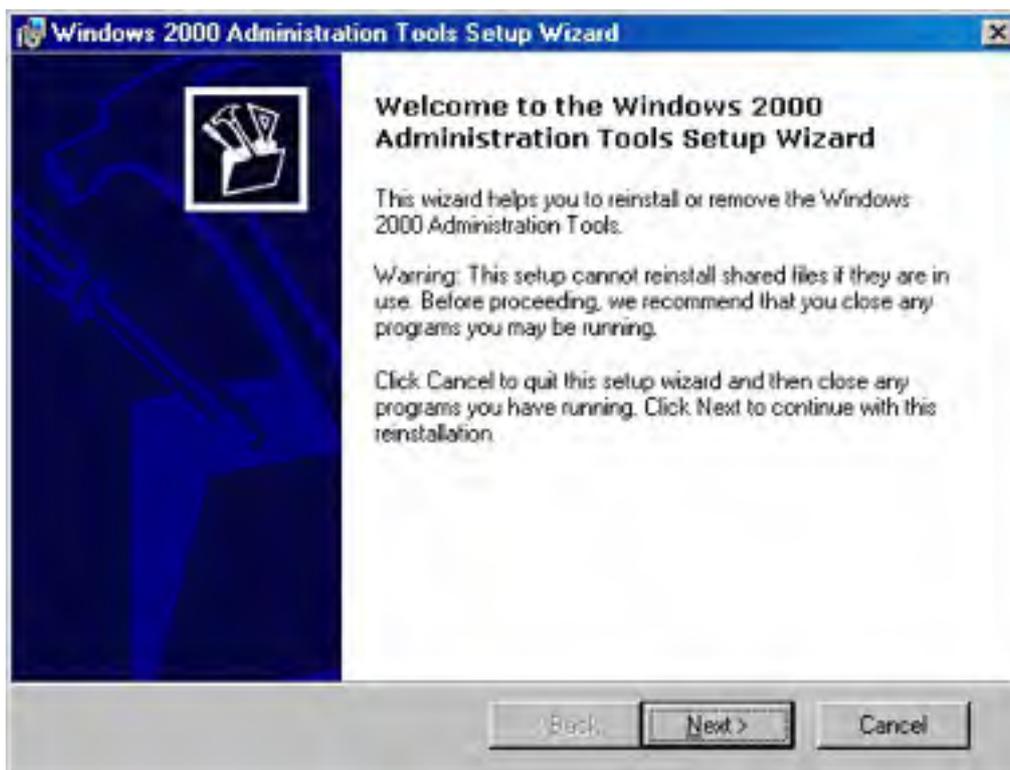

**Table 10-1.** Administration Tools for Windows 2000

Tool Name	Description
Active Directory Domains and Trusts	Administers domain trusts, changes the domain mode, adds and changes user principal name suffixes
Active Directory Sites and Services	Establishes and administers sites, replication, and security services
Active Directory Users and Computers	Manages users, computers, and groups within a domain
Certification Authority	Manages Certificate Services, which issues certificates for public key security
Cluster Administrator (Advanced Server only)	Handles the configuration of clusters and nodes
Component Services	Configures and administers Component Object Model (COM) components and applications
Computer Management	Administers disks, shares, users, groups, and services on the local computer
Configure Your Server	Sets up and configures Windows services
Connection Manager Administration Kit	Manages and customizes local and remote connections
Data Sources	Adds, removes, and configures Open Database Connectivity(ODBC) databases and drivers
DHCP	Manages Dynamic Host Configuration Protocol (DHCP) services
Distributed file system	Manages Distributed file system (Dfs) installation, topology, and replication
DNS	Manages DNS services
Event Viewer	Displays application, security, and system notification logs
Internet Authentication Service	Configures security and authentication for dial-in users
Internet Services Manager	Manages Internet Information Services (IIS)
Licensing	Manages client licenses
Local Security Policy	Views and configures user rights, audit policy, and other security settings for the local computer
Network Monitor	Captures frames of network data for detection and analysis of network problems
Performance	Views system performance graphs; configures performance logs and alerts
QoS (Quality of Service) Admission Control	Assigns network bandwidth by subnet
Remote Storage	Manages the storage of infrequently accessed files

Routing and Remote Access	Administers dial-up, virtual private networking, and internetwork connections
Server Extensions Administrator	Manages FrontPage server extensions
Services	Starts, stops, and configures services
Telephony	Manages telephony clients and servers
Telnet Server Administration	Starts, stops, and returns information about Telnet Server
Terminal Services Client Creator	Makes floppy disks for installing Terminal Services client software
Terminal Services Configuration	Configures new connections for Terminal Services; modifies and deletes existing connections
Terminal Services Manager	Displays terminal servers in trusted domains
WINS	Administers WINS

## Installing Administration Tools Locally

To install the full set of Administration Tools locally, double-click the Adminpak.msi file in your Winnt\System32 folder (it's also in the \i386 folder on the latest Windows 2000 Server or Windows 2000 Advanced Server Service Pack CD-ROM). This starts the Administration Tools Setup Wizard (Figure 10-2), which installs the tools (and later removes them and reinstalls them, if you wish). Click Next and the installation proceeds.

**Figure 10-2.** The first screen of the Administration Tools Setup Wizard.

## Making Administration Tools Available Remotely

To make the Administration Tools available to others on your network, you can assign the tools to other computers or publish them in Active Directory. [Chapter 25](#) covers the process of assigning and publishing software to other users.

## Support Tools

The Windows 2000 Support Tools are immensely valuable because they provide functionality not otherwise available in the operating system. You'll probably never use some of the tools, but a few will prove to be worth their weight in Microsoft stock options. This section discusses a few of these utilities. You can see a complete list by choosing Tools Help from the Windows 2000 Support Tools menu.

If you don't see the Support Tools on your Programs menu, you'll need to install them. To install the Windows 2000 Support Tools, insert the latest Windows 2000 Service Pack CDROM. (The tools have been updated since the release of Windows 2000.) Open the Support folder and then the Tools folder. Double-click Setup.

The tools provided on the Windows 2000 CD-ROM are a subset of the tools you can get by purchasing the full *Microsoft Windows 2000 Server Resource Kit*. The *Resource Kit* is a separate product with its own companion CD, available from Microsoft Press.

## Network Connectivity Tester

Network connections can fail in a spectacular number of ways—at any number of servers and in a variety of client configurations. Determining the source of a problem can be a daunting process. Netdiag.exe can report on an equally spectacular number of functions, running tests on the DNS server, the WINS server, Kerberos, the bindings, the WAN, trust relationships, the IP configuration, the routing table, IPX, NetWare, DHCP, the default gateway, and more. Netdiag.exe can be run on Windows NT and Microsoft Windows 95/98, as well as Windows 2000, so you can use this excellent troubleshooting tool on servers and clients alike.

## Windows 2000 Domain Manager

With Netdom.exe, most forms of domain management can be handled from the command line. Machine accounts can be added, removed, renamed, or moved to another domain. Netdom.exe also retrieves information about trusts and lets you establish trusts, synchronize the time, and verify secure channel passwords. The syntax for Netdom.exe is simple, but the range of possible parameters is extensive.

### More Info

Command syntax and examples are available in the Support Tools Help files. To find the syntax for a specific tool, open a command window and enter *tool\_name /?*.

## Active Directory Replication Monitor

Rather than merely monitoring low-level replication among servers, the Active Directory Replication Monitor (Replmon.exe) reports on a wide range of Active Directory functions. It displays the site topology while reporting on the server's properties, indicating whether it is a Global Catalog server, and listing its replication partners, its replication history, and the attributes replicated.

The units of replication among domain controllers are directory partitions that must contain the most current information about objects in the domain. If a server is down or the network is disrupted, the information might not be completely up-to-date. The Replication Monitor can synchronize a monitored server with a specific replication partner to get everything back in order. It also generates status reports for servers throughout a forest for troubleshooting replication errors.

## Disk Probe

Disk Probe (Dskprobe.exe) is indispensable when a critical hard disk goes bad. It is a sector editor that you can use to repair damaged partition tables, replace the master boot record, and repair or replace partition boot sectors. Even better, Disk Probe saves master boot records and partition boot sectors as files that can be used to restore the sectors if they become damaged in the future. This can be a great benefit because these data structures aren't part of the file system and are not backed up by any backup program. Table 10-2 briefly describes some of the Windows 2000 Support Tools. For a complete list, see [Appendix E](#).

**Table 10-2.** *Additional Windows 2000 Support Tools*

<b>Tool</b>	<b>Filename</b>	<b>Format</b>	<b>Description</b>
ADSI Edit	Adsiedit.msc	GUI	Low-level editor for Active Directory; enables adding, moving, and deleting objects within Active Directory.
DependencyWalker	Depends.exe	GUI	Scans any Win32 module and reports all dependent modules. Used to find the minimum set of files needed to load an application and to find what functions a module uses or exports.
Distributed file system Utility	Dfsutil.exe	Cmd	Queries and troubleshoots Dfs.
DNS Trouble shooting Tool -	Dnscmd.exe	Cmd	Allows you to view and modify DNS servers, zones, and resources.
Global Flags Editor	Gflags.exe	GUI	Edits global registry settings or flags in use by the kernel.
Memory Profiling Tool	Memsnap.exe	Cmd	Takes a snapshot of all of the memory resources being used by all processes and reports the information to a log file.
Registry Console Tool	Reg.exe	Cmd	Modifies the registry database from the command line. Used to query, add, delete, copy, save, and restore entries.
Remote Command	Remote.exe	Cmd	Runs command-line programs on Lineremote computers using named pipes only.
Security Administration Tools	Sidwalk.exe, Showacccs.exe, Sidwalk.msc	Cmd/Cmd/GUI	Manage access control lists.
SNMP Query Utility	Snmputilg.exe	GUI	Graphical version of Snmputil.exe used to troubleshoot Simple Network Management Protocol (SNMP).

## Microsoft Management Console Basics

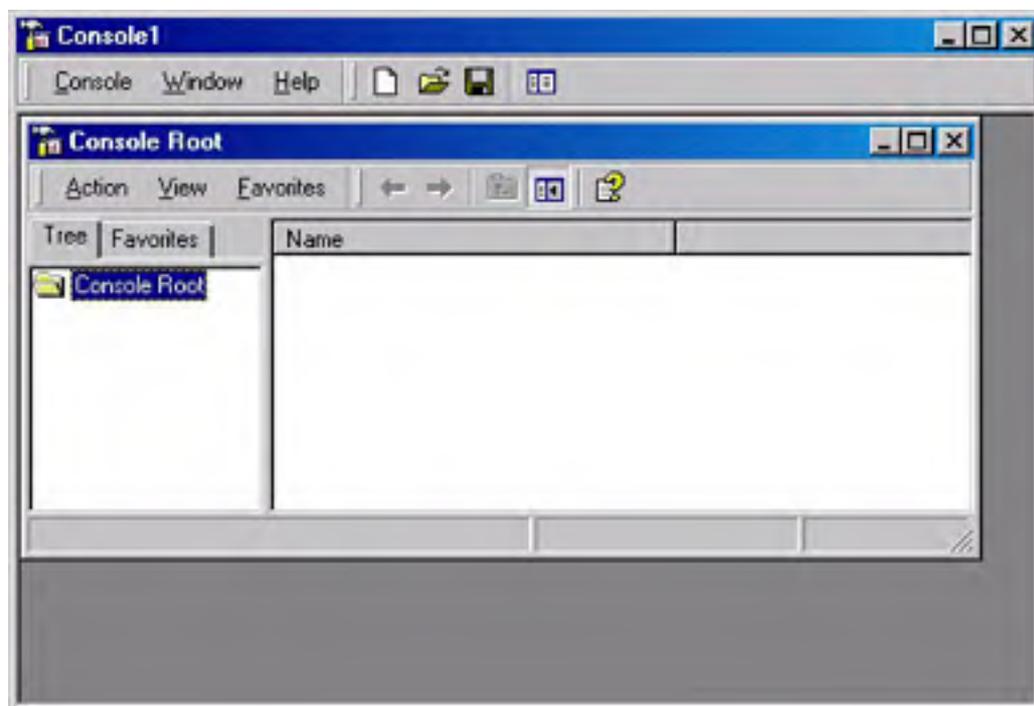

The Microsoft Management Console (MMC) is a powerful addition to the system administrator's arsenal. The MMC works as a packager of system tools, enabling the system administrator to create specialized tools that can then be used to delegate specific administrative tasks to users or groups. Saved as MMC (.MSC) files, these custom tools can be sent by e-mail, shared in a network folder, or posted on the Web. With system policy settings, they can also be assigned to users, groups, or computers. The tools are flexible enough to be modified, scaled up or down, and generally shaped for any use to which you might want to put them.

To build a custom tool, you can either start with an existing console and modify it or start from scratch. In a mature network, you'll most likely use the former method, taking predefined consoles and adding or subtracting snap-ins.

### Creating an MMC-Based Console with Snap-ins

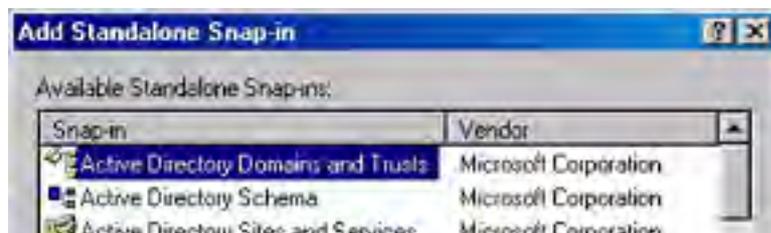

Building your own tools with the MMC's standard user interface is a straightforward process. The next few sections walk you through the creation of a new console and describe how to arrange its administrative components into separate windows.

1. Click Start and select Run. In the Open text box, type `mmc` and then click OK. An empty MMC window opens, as shown in Figure 10-3, ready for you to add snap-ins.

**Figure 10-3.** An empty MMC window.

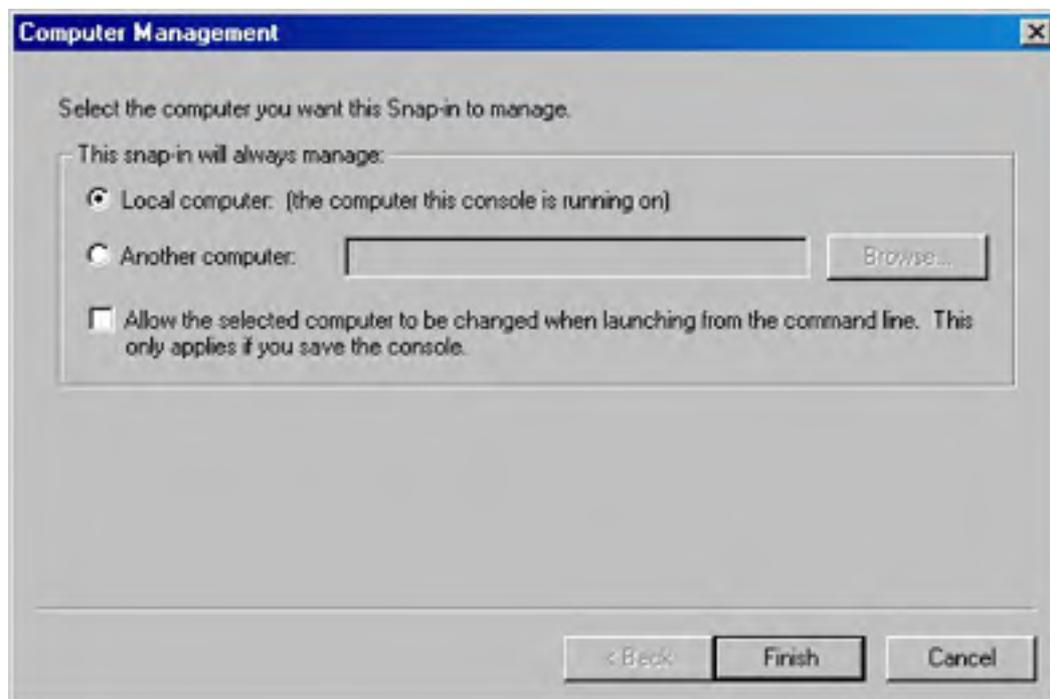

2. From the Console menu, select Add/Remove Snap-In. (The menu commands on the menu bar at the top of the MMC window apply to the entire console.) The Add/Remove Snap-In dialog box opens. Here you can choose which snap-ins are in the console file as well as enable extensions. In the Snap-Ins Added To box, accept the default, Console Root.
3. Click Add. This opens a dialog box listing the snap-ins installed on your computer (Figure 10-4).

**Figure 10-4.** The Add Standalone Snap-In dialog box.

4. Select a snap-in to see a description of its function. Double-click a snap-in to add it to the console. For this example, we'll add Computer Management. The Computer Management dialog box asks you to select the computer to manage (Figure 10-5).

**Figure 10-5.** The Computer Management dialog box.

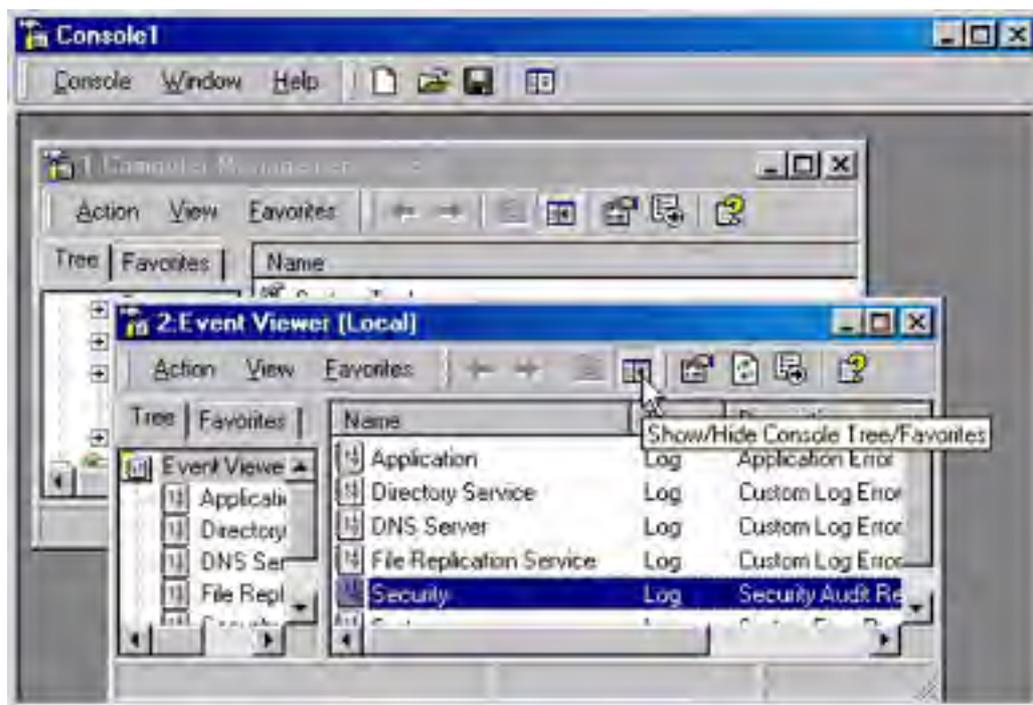

5. Select the Local Computer option, and select the Allow The Selected Computer To Be Changed When Launching From The Command Line check box. These options are common to many of the snap-ins. Click Finish.
6. From the Add Standalone Snap-In dialog box, select Event Viewer and click Add. As before, select the Local Computer option and select the check box. Click Finish, and then close the list of available snap-ins. The Add/Remove Snap-In dialog box lists two snap-ins: Computer Management (Local) and Event Viewer (Local).
7. Click the Extensions tab. By default, the box labeled Add All Extensions is checked, which means that when this console is opened on a particular machine, all extensions that are locally installed on that machine will be used. If this box isn't checked, only extensions that are selected on the list of available extensions will be loaded.
8. Click OK to close the Add/Remove Snap-In dialog box. The Console Root window now has two snap-ins, rooted at the Console Root folder.

Save the console by choosing Save from the Console menu. You are prompted for a name—be as descriptive as possible. The file is saved in the Administrative Tools folder by default. This folder is part of your profile, so an added benefit is that if you use roaming profiles, any tools you create go with you. See [Chapter 9](#) for information on creating roaming profiles.

## Customizing the Layout of a Console

After you've added the snap-ins, you can provide different administrative views in the console by adding windows. To create one window for each of the snap-ins, follow these steps:

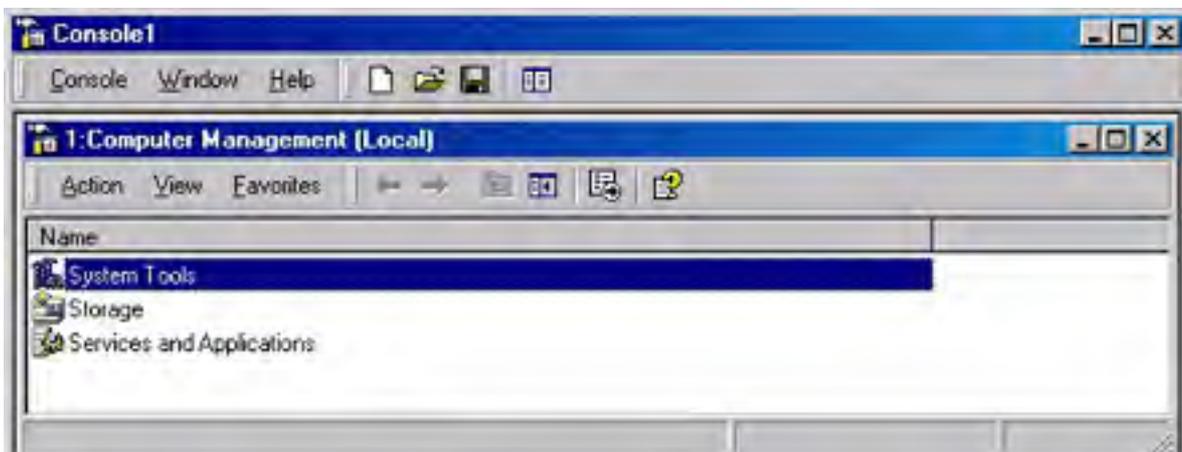

1. In the left pane of the console window, right-click the Computer Management folder and select New Window From Here from the shortcut menu. This opens a new Computer Management window rooted at the Computer Management snap-in.
2. In the Console Root window, right-click the Event Viewer folder and choose New Window From Here. Click the Show/Hide Console Tree toolbar button in each window to hide the console tree (Figure 10-6).

**Figure 10-6.** The Show/Hide Console Tree Favorites button.

3. Close the original Console Root window. From the Window menu, choose Tile Horizontally. The console window should now look like Figure 10-7.

Note that the buttons and menus in each window apply only to that window. Remember to save your console file after completing the changes.

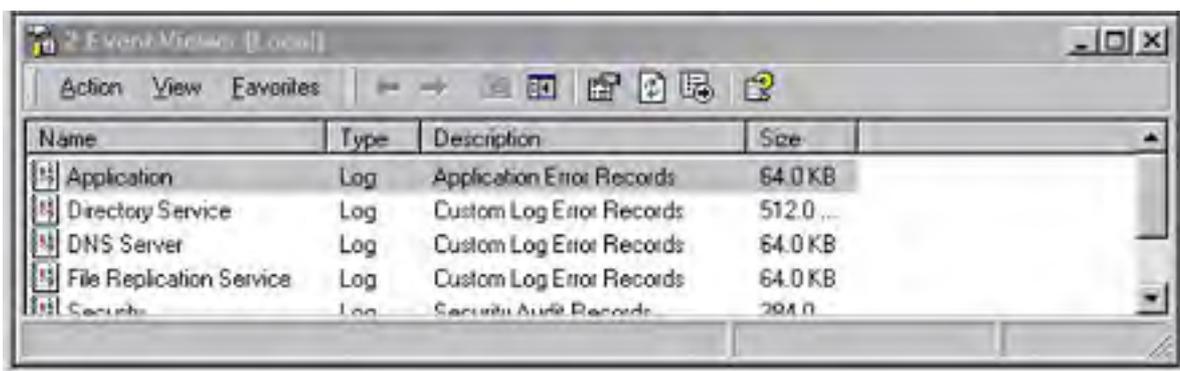

Figure 10-7. The console with tiled windows.

## Setting Options for a Console File

When creating consoles for workgroup managers or other users, you might want to restrict how the console is used. Console options can be set so that users can access only the tools that the administrator allows. To set console file options, follow these steps:

1. With the console file open, click the Console menu and choose Options. This opens the Options dialog box.
2. Click the Console tab. Choose the console mode:
  - **Author Mode** No restrictions. The user can access all parts of the console tree as well as change this console file at will.
  - **User Mode—Full Access** The user can access all parts of the console tree but cannot make changes that affect functionality. Cosmetic changes, such as the arrangement of windows, are saved automatically.
  - **User Mode—Limited Access, Multiple Window** The user can access only the parts of the console that were visible at the time the console file was saved.
  - **User Mode—Limited Access, Single Window** The same as the previous mode, except that only one window is visible.
3. In all but Author mode, you can also select the Do Not Save Changes To This Console option, so that the console always opens in the same view.
4. Click OK and save the console file.

## Modifying Console Files

After you've saved a console file in any mode other than author mode, the Console menu is no longer visible, even to administrators. This prevents the user from changing the options. To modify a console file, open a command-prompt window and type `mmc /a`. The `/a` switch sets author mode, overriding any user mode setting, and opens the console window, from which you can open any console file and make changes.

The system administrator can set user profiles to disallow the use of the `/a` switch, and should do so to ensure that inappropriate modifications can't be made.

## Distributing and Using Consoles

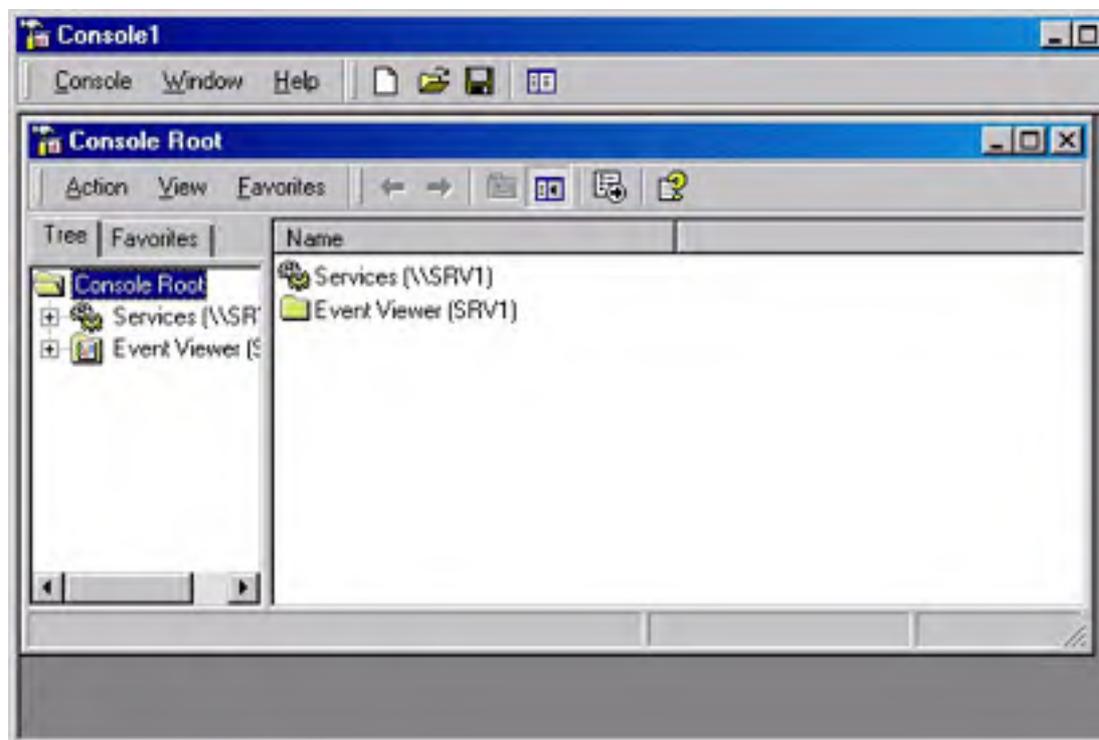

As mentioned earlier, the default location for saved console files is the Administrative Tools folder. Console files can be distributed in a variety of ways. You can copy a console file to a shared folder on the network, or you can mail it to another person by right-clicking the file, pointing to Send To, and selecting Mail Recipient. When you assign a console to be used by a particular person, be sure that the person's user profile includes permission to access the tools and services in the console. The user also has to have any administrative permissions necessary to use the system components administered by the console.

If you know the location of a console, you can open it from Windows Explorer by clicking it as you would any other file. You can also open it from the command line. For example, to open the Fax Service console (which resides in a system folder) from the command line, type `mmc %systemroot%\system32\faxserv.msc`.

## Using MMC for Remote Administration

MMC-based tools are admirably suited for remote administration. You can easily construct a console to administer a number of computers or a single machine. This section describes how to create a console that can be used to remotely administer a domain controller. The console will include the Services snap-in, which manages system services, and the Event Viewer snap-in, which allows access to the various event logs. To make this remote administration console, follow these steps:

1. Click Start, and then select Run. In the Open text box, type `mmc` and then click OK. An empty MMC window opens.
2. From the Console menu, select Add/Remove Snap-In. The Add/Remove Snap-In dialog box opens.
3. Click Add to open the Add Standalone Snap-In dialog box.
4. Select Services, and then click Add.
5. In the This Snap-In Will Always Manage area, select Another Computer and then click Browse. This opens another Select Computer dialog box.
6. Highlight the computer you want this snap-in to manage, and then click OK. Click Finish.
7. Repeat steps 4 through 6, except choose the Event Viewer snap-in. Close the Add Standalone Snap-In dialog box. Click OK in the Add/Remove Snap-In dialog box.
8. At this point, the console will look like the one in Figure 10-8. Save it under a descriptive name. You can use this console to view events on the remote machine and to start and stop services.

**Figure 10-8.** A console for remote administration.

As you can see, consoles can be configured in dozens, if not hundreds, of different ways and then distributed. Snap-ins for every imaginable function will increasingly be available from Microsoft as well as third-party suppliers.

Because consoles are excellent tools for organizing and delegating administrative chores, examples of their use can be found in many other chapters of this book.

## Automating Chores with Scripts

Of necessity, most network administrators quickly acquire scripting skills. There aren't enough hours in the day to do everything manually, even if that were desirable. In addition, good scripts are like any program: once the information is entered correctly, there's no need to worry about it until something external changes.

Through ActiveX, Windows 2000 enables scripting options using Visual Basic, Scripting Edition (VBScript); JScript; or Perl. Previously, the only native scripting language supported by Windows was the MS-DOS command language, and many administrators will undoubtedly continue to use MS-DOS scripts because they're very small and very fast. Why use anything else if an MS-DOS script will do the job? The answer is that you shouldn't. However, in a large enterprise or for more complicated scripts, a more sophisticated scripting language is in order.

The Windows Scripting Host (WSH) is built into Windows 2000 and Windows 98. In addition, Windows 95 and Windows NT can run WSH, so scripts are portable across the Windows spectrum. Scripts run under WSH using Wscript.exe and Cscript.exe. Wscript.exe runs in the background, and Cscript.exe runs at the command prompt. To run a script from the command line, the syntax is

```
Cscript <scriptname.extension> [options] [arguments]
```

To view the entire list of host options, enter *Cscript //?* at a command prompt. The most important options are listed here:

- **//B** Specifies batch mode; script errors and prompts are not displayed
- **//D** Enables active debugging
- **//T:nn** Indicates the maximum time in seconds that the script is permitted to run

### Real World

#### Uses for WSH

WSH is useful for logon and logoff scripts that can be assigned to users—individually or as a group—or to computers. The other important use for WSH is the creation of user accounts, a tedious process at best and, in a large enterprise, quite impossible without scripts. [Chapter 9](#) covers Group Policy objects and the creation of user accounts.

## Auditing Events

Auditing certain computers, users, and operating system events is a necessary part of network administration. You choose what's to be audited and then, by reviewing the event logs, track usage patterns, security problems, and network traffic trends. Beware of the impulse to audit everything, however. The more events you audit, the bigger the logs. Reviewing huge event logs is a painful chore, and eventually no one looks at them anymore. Therefore, it's critical to decide on an auditing policy that protects your network without creating a large administrative burden. Also bear in mind that every audited event results in a small increase in performance overhead.

By default, all auditing categories are turned off when Windows 2000 is installed. Table 10-3 lists the categories of events that can be audited.

**Table 10-3.** Auditing categories

Event Category	Activated When
Account logon events	A domain controller receives a logon request
Account management	A user account or group is created or changed
Directory service access	An Active Directory object is accessed
Logon events	A user logs on or logs off
Object access	An object is accessed
Policy change	A policy affecting security, user rights, or auditing is modified
Privilege use	A user right is used to perform an action
Process tracking	An application executes an action that is being tracked
System events	A computer is rebooted or shut down or another event occurs that affects security

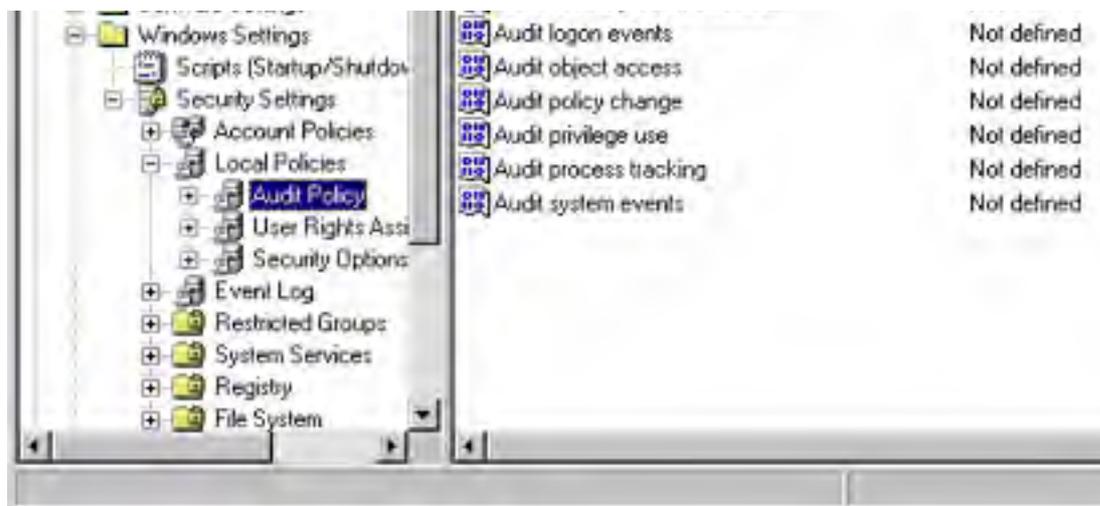

Every audited event tells you something, but it's not always something you need to know. For example, auditing successful logons and logoffs might reveal the use of a stolen password, or it may just produce endless pages showing that your duly authorized users are logging on and off as expected. Auditing logon failures, however, will definitely be rewarding if someone is trying a random password hack.

Before you can audit access to Active Directory objects (described in the next section), you must turn on the Audit Policy setting, using Group Policy. To do so, as well as to enable auditing of any of the other categories in Table 10-3, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the domain name in the console tree, and choose Properties from the shortcut menu.
3. Click the Group Policy tab and then click Edit.
4. In the left pane of the Group Policy console, click your way through Computer Configuration, Windows Settings, Security Settings, and Local Policies to reach Audit Policy (Figure 10-9).

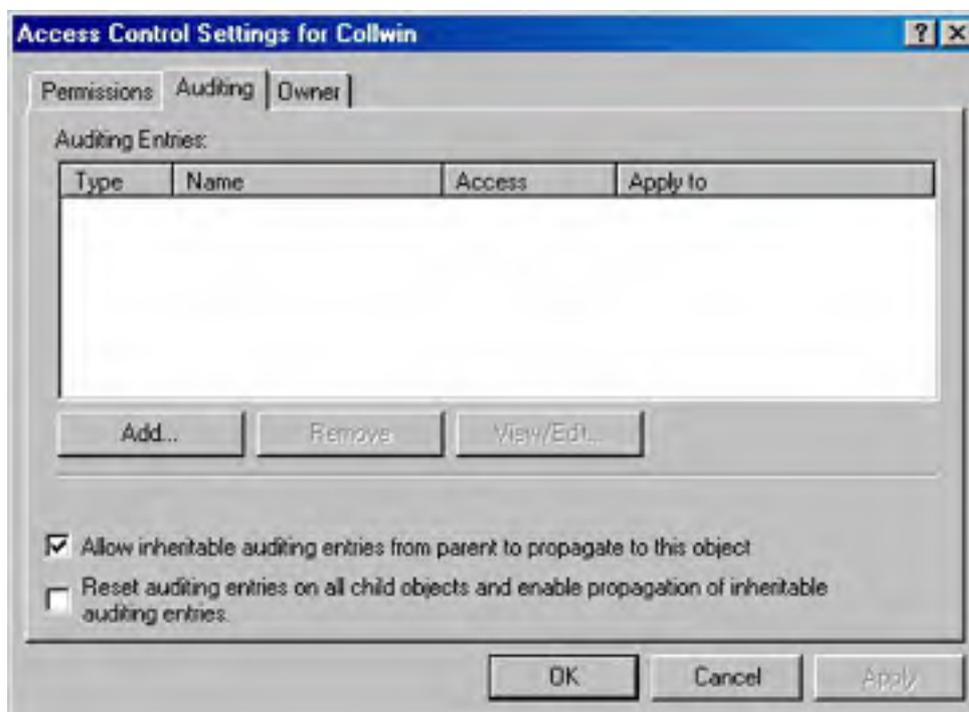

**Figure 10-9.** Choosing categories of events to audit.

5. Right-click the event category you want to audit, and choose Security from the shortcut menu.
6. In the dialog box that opens, select the check box to define the setting and select the option to audit successful and/or failed attempts.

## Audit Settings for Objects

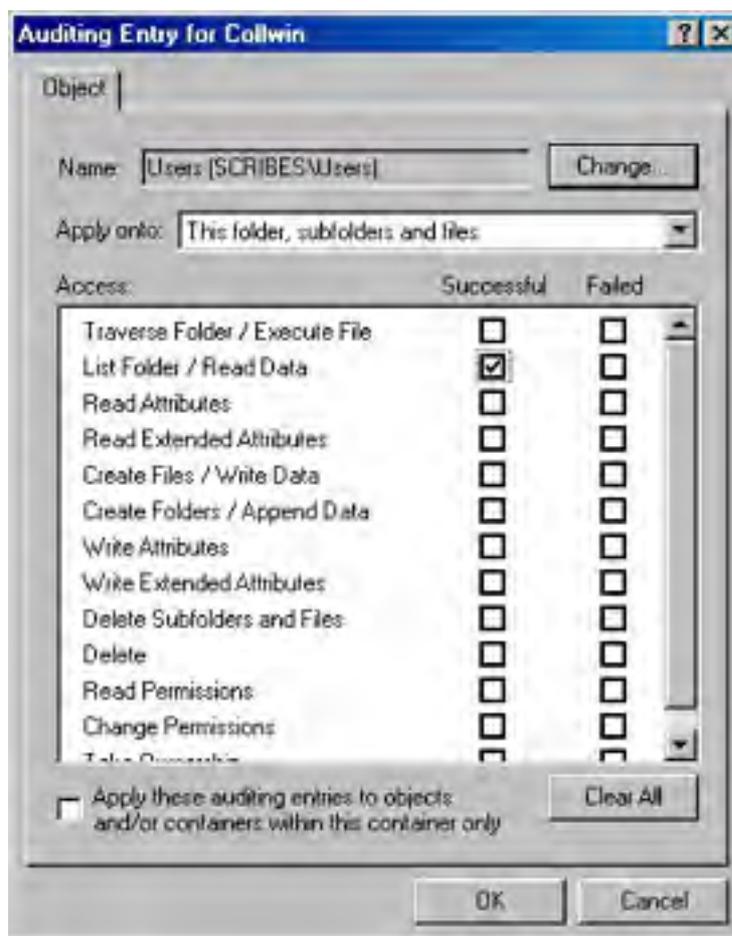

Assuming that you've turned on a policy setting for auditing an Active Directory object, you create audit settings by following these steps:

1. Right-click the object you want to audit, and choose Properties from the shortcut menu. Click the Security tab.
2. Click Advanced, and then click the Auditing tab (Figure 10-10).
3. Click Add to set up auditing for a new group or user. Make your selection and click OK.

**Figure 10-10.** Selecting a group or user or computer to be audited in connection with an object.

- In the Auditing Entry For Collwin dialog box (Figure 10-11), select the objects you want to audit from the Apply Onto drop-down list. Then, in the Access window, select each type of access that you want audited. (Table 10-4 describes each event.) Click OK when you're finished.

**Figure 10-11.** Selecting the specific events you want audited.

By default, audit settings are inherited by child objects. In the Auditing tab of the Access Control Settings dialog box (shown in Figure 10-10) is a check box for allowing inheritable auditing entries. Clear this box and the audit settings for the object remain constant, even if the parent object's audit settings are changed. In addition, clearing the box removes any audit settings that have already been inherited. The second check box in this tab resets existing auditing and allows audit entries to be inherited from the parent object once again.

**Table 10-4.** File system events that can be audited

Event	Activated When
Traverse Folder/Execute File	A folder is traversed (that is, someone passes through the folder on the way to a parent folder or a child folder) or an application is run
List Folder/Read Data	A folder is opened or data is viewed in files
Read Attributes	The attributes of a file or folder are viewed
Read Extended Attributes	Extended attributes (defined and created by programs) of a file or folder are viewed
Create Files/Write Data	A file is created inside a folder or a file is changed, overwriting existing information in the file

Create Folders/Append Data	A folder is created inside the folder being audited or information is added to an existing file
Write Attributes	A file or folder attribute is changed
Write Extended Attributes	Extended attributes (defined and created by programs) of a file or folder are changed
Delete Subfolders and Files	A file or subfolder is deleted
Delete	A specific file is deleted
Read Permissions	Permissions for a file or folder are viewed
Change Permissions	Permissions for a file or folder are modified
Take Ownership	Ownership of a file or folder changes

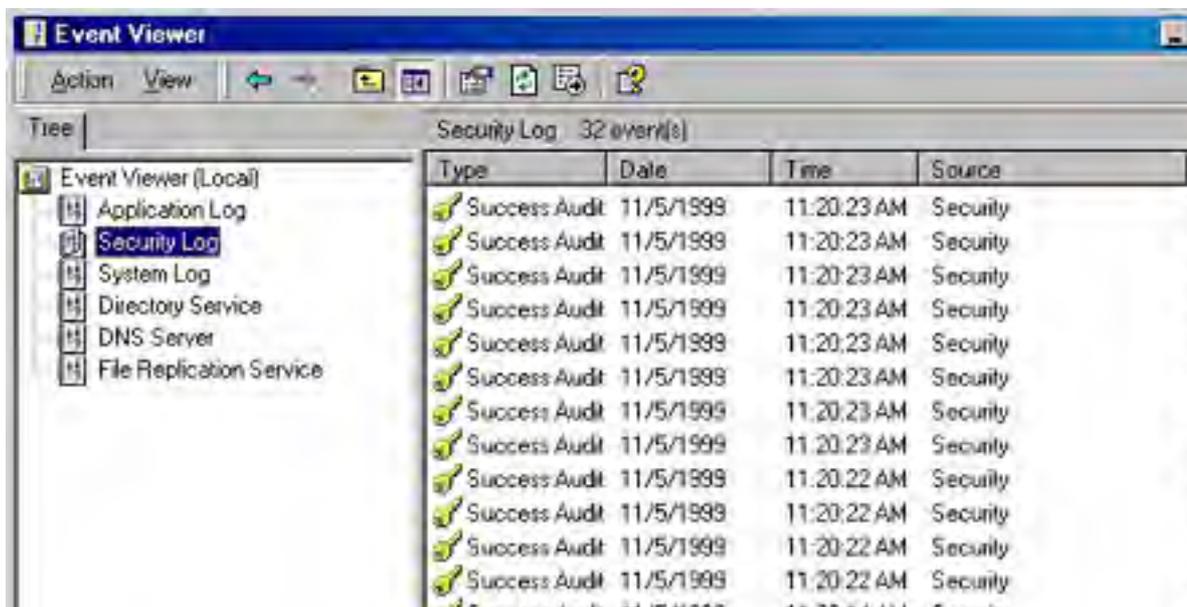

### Real World

#### Auditing Cautions

Windows 2000 allows such granularity that it's possible—no, *easy*—to create a real morass when selecting audit settings. So many items can show up in the event log that really important issues might be lost in the crowd. Be very careful when deciding what events need to be audited. Audit as few as is reasonable. You can always add events later as circumstances dictate.

## Viewing Event Logs

Event logs must be viewed with regularity for auditing to have any effect. To view the security log, open Event Viewer from the Administrative Tools folder and then click Security Log. Double-click any entry to see more information about it. The security entries in Figure 10-12 are the result of *one* event. The folder was set to audit successful List Folder/Read Data events. One user opening the folder one time generated all the entries you see. Of course, you'll generally learn more from auditing failed events than from auditing successful ones, but this does demonstrate the need to choose one's auditing battles carefully.

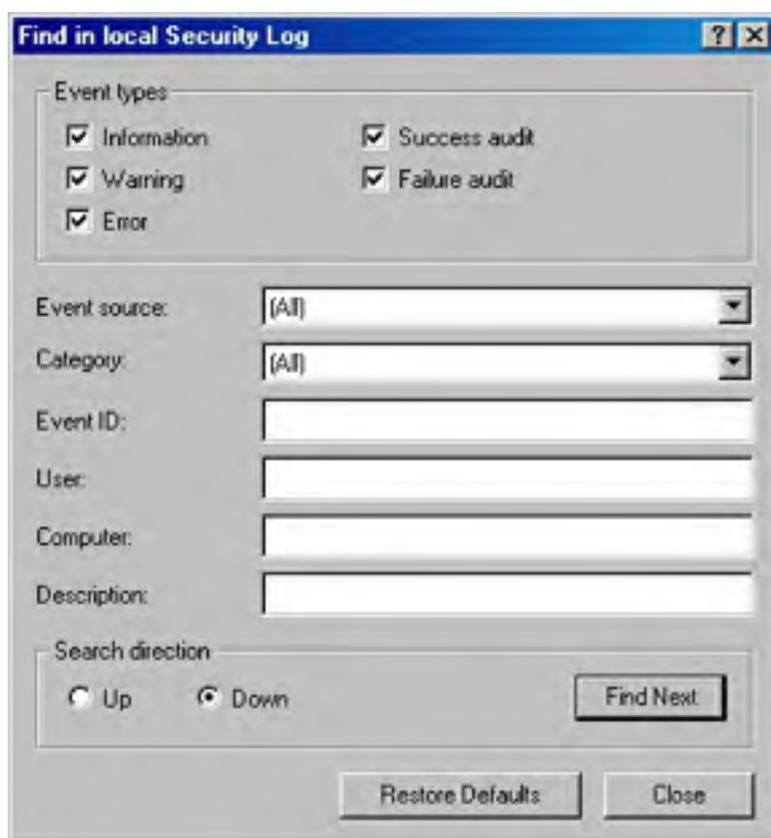

**Figure 10-12.** Viewing the security log.

## Searching Event Logs

No matter how selective you are, the event logs will mix all sorts of information together, making searches for specific information difficult. To search for a specific type of event, select the log in Event Viewer, and choose Find from the View menu. In the Find dialog box (Figure 10-13), select the type or types of events you want returned. Table 10-5 describes the other options in the Find dialog box.

**Figure 10-13.** Searching for specific events in a log.

## Filtering Event Logs

If you don't have enough specific information to locate what you need, you can filter an event log for certain types of information. To use event log filtering, follow these steps:

1. Launch Event Viewer from the Administrative Tools folder.
2. Right-click the log you want to search, and choose Properties from the shortcut menu.
3. Click the Filter tab. Table 10-5 describes the fields in this tab. Click OK when you're ready to start the filtering.
4. The log appears, filtered as you requested. To view the full, unfiltered log again, return to the Filter tab and click Clear.

**Table 10-5.** Options for filtering event logs

Option	Use to Search or Filter for
Information	Notification that some major operation has been performed successfully.
Warning	Notification of some problem or potential problem. Warnings might or might not be significant. For example, replication performed after repeated tries will generate a warning.
Error	Notification of an important event. Errors signify a loss of data or a loss of function. For example, failure of a service to start during bootup will generate an error.
Success Audit	Events audited for success.
Failure Audit	Events audited for failure.
Event Source	A source for an event, such as a system component or a program.
Category	Events by category, such as logon/logoff, policy change, or process tracking.
Event ID	The specific ID number assigned to each logged event.
User	A specific user.
Computer	A specific computer.
From	Events after a specific date. The default is the first date in the log. You can click the drop-down box to select events on a specific date.
To	Events before a specific date. The default is the last date in the file.

## Setting the Size of Event Logs

When an event log is full, a dialog box pops up to notify you. If this happens often, you might want to reduce the number of items being reported or increase the size of the log. To set event log options, follow these steps:

1. Launch Event Viewer from the Administrative Tools folder.
2. Right-click the log you want to configure and choose Properties.
3. In the General tab, set the options you want. Under When Maximum Log Size Is Reached, there are three options:
  - If you don't archive this log, choose Overwrite Events As Needed.
  - If you archive this log at regular intervals, you can select the Overwrite Events Older Than option. Fill in the appropriate number of days.
  - Do Not Overwrite Events, the last option, means that the log must be cleared manually. When the maximum log size is reached, new events will simply not be recorded.
4. Click OK when you're finished.

### Real World

#### Calling a Halt When the Log Is Full

Maybe you are so security-conscious that none of the event log options are acceptable. If you absolutely, positively mustn't lose a single security event, you can set the computer to halt when the security log is full. A registry change is necessary to make this happen. First, set Event Log Wrapping to either Do Not Overwrite Events or Overwrite Events Older Than *n* Days. Then start Regedit.exe and proceed to

HKEY\_LOCAL\_MACHINE\SYSTEM\CurentControlSet\Control\Lsa\CrashOnAuditFail, and change the value to *1*.

This setting will take effect after a reboot; then, when the log is full, the system will simply stop. After restarting, only administrators will be able to log on until the security log is cleared. This is a drastic measure, but it is necessary in some cases.

## Archiving Event Logs

If you will be using event logs to track system usage trends, you must save them. To archive an event log, launch Event Viewer from the Administrative Tools folder, and click the log you want to archive. Then, from the Action menu, choose Save Log As. If you save the file in the event log format (.EVT), it can be reopened in Event Viewer, and all the binary data for each event will be retained. You can also save logs as .TXT files or in comma-delimited format (.CSV), but in those cases the binary data isn't saved. [Chapter 33](#) has details on using Event Viewer and the logs that are generated to learn more about the network and tune its performance.

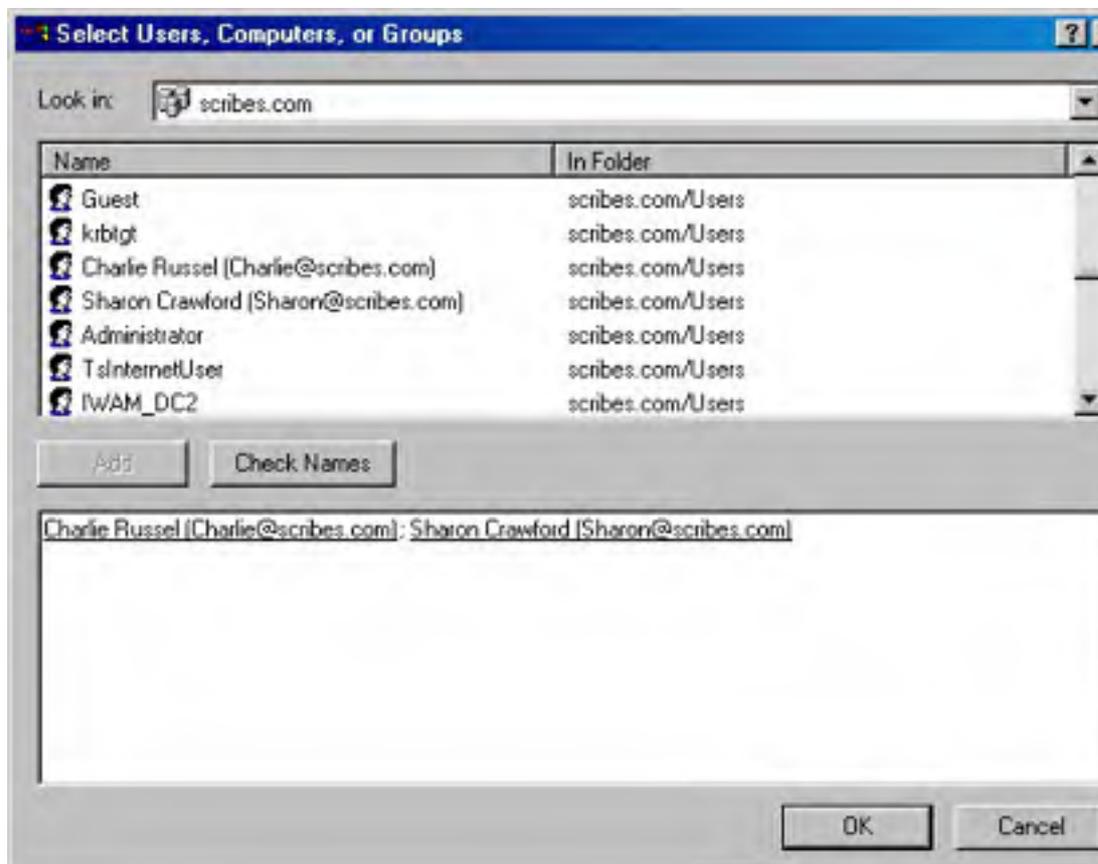

## Delegating Control

Obviously, one of the simplest ways to minimize your administrative chores is to delegate them. In a Windows NT network, the usual way to grant broad administrative rights is to make users members of the Domain Admins group. Or you can parcel out administrative rights through some combination of other groups such as Print Operators or Server Operators.

These groups are still available, but Windows 2000 makes delegation even simpler: it allows you to assign responsibility for management of some portion of the namespace to another user or group. The recipient of the delegated authority can have complete administrative control within the area chosen but not the sweeping administrative rights inherent in being a member of the Domain Admins group.

Assign control by organizational unit (OU) whenever possible, because assigning permissions at the object level quickly becomes too complicated to be worthwhile. Records of security assignments are critical, so keep track of all delegations. To delegate control, use the Delegation of Control Wizard, which always assigns permissions at the OU level. (Detailed descriptions of permissions are provided in [Chapter 9](#). For more on the planning and deployment of security policies, see Chapters 18 and 19.) To use the wizard, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Double-click the domain node, and then right-click the container whose control you want to delegate and choose Delegate Control from the shortcut menu. This starts the Delegation of Control Wizard. Click Next.
3. Click Add to select the user or group to be granted control. Make your selection from the Select Users, Computers, Or Groups screen (Figure 10-14).
4. In the Tasks To Delegate screen, select the tasks that you want to delegate. Select predefined tasks or click Create A Custom Task. Click Next.
5. If you selected a predefined task, you're essentially finished. Review the summary and click Finished.

**Figure 10-14.** Selecting the recipients of delegated control.

If you selected Create A Custom Task, you're presented with more specific choices about what objects you're delegating control on and the specific permissions to be granted. When those choices are made, you'll see a summary of the delegation. Click Finished.

## Using Task Scheduler

It's true that you could—and still can—schedule tasks using the AT command, as described later in this chapter, but Task Scheduler provides a graphical interface and is much easier to use. Tasks can be scheduled during off-hours and to run repeatedly. The Task Scheduler service is started at bootup and runs in the background. To use Task Scheduler, open Control Panel, double-click the Scheduled Tasks folder, and then follow these steps:

1. In the Scheduled Tasks window, double-click the Add Scheduled Task entry. This starts the Scheduled Task Wizard. Click Next.
2. Select a program from the screen (Figure 10-15), or click Browse to locate another program. Click Next.
3. Supply a name for the task, and then indicate how often you want it performed. Click Next.

**Figure 10-15.** Selecting the program to be scheduled.

4. Select the time of day you want the task performed. Depending on the timing you've selected, you'll also need to specify one of the following:
  - **Daily Task** Every day, every *n* days, or weekdays only.
  - **Weekly Task** Every *n* weeks; supply the day of the week.
  - **Monthly Task** Select the day of the month, and select which months.
5. Supply the user name and password for the user who will be scheduling tasks. Click Next. Note that the account you specify must have the privileges necessary to run the task. For example, if you're scheduling a backup program, the user must have backup rights.
6. If you need to specify parameters for the task being scheduled, select the check box next to Open Advanced Properties and then click Next.
7. Make the necessary changes and click OK.

For tasks to run as expected, it's important that the computer's date and time be set correctly.

Many programs will start to run in Task Scheduler and then pause, waiting for input that never comes—or that comes much later, when someone looks at the machine to see what's going on. To make sure you have all of the parameters for a task to be able to run successfully, open a command prompt and type **program\_name** /?. Then right-click the task in the Scheduled Tasks window and choose Properties from the shortcut menu. Enter the necessary parameters in the Run text box and click OK.

You might want to schedule a task to run right away so you can test its performance. If a task is scheduled by a user and that user isn't logged on at the scheduled time, the task still runs but is in the background and not visible.

Unfortunately the Windows 2000 disk defragmenter utility doesn't support scheduled operation (unlike the defrag program in Microsoft Windows XP and the Microsoft Windows .NET Server family). To schedule a defrag operation, you can either purchase a commercial defrag program that supports scheduling, such as Executive Software's Diskkeeper, or you can write or download a script that enables the Windows disk defragmenter to be scheduled. (To find such a script, perform a Web search on "Windows 2000 disk defragmenter".)

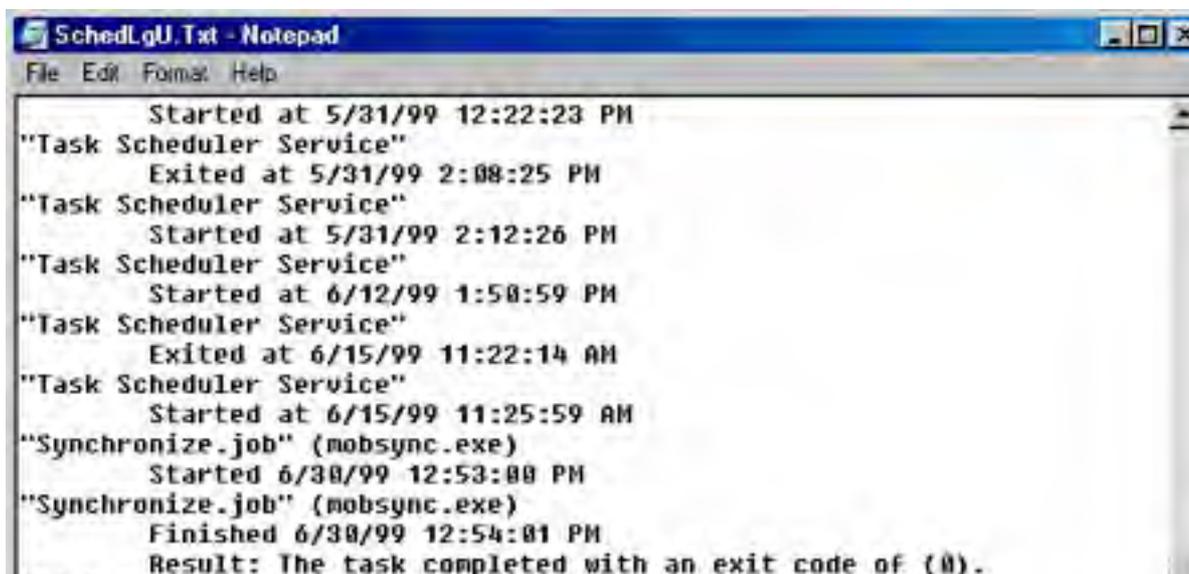

## Changing a Schedule

Even the best schedule can run up against reality now and again, so you need to be able to adjust your planned events.

- To run a task immediately, right-click the task's icon in the Scheduled Tasks window and choose Run from the shortcut menu.
- To stop a task that's running, right-click the task's icon in the Scheduled Tasks window and choose End Task. If the scheduled task has been set up to start another task, the End Task command halts only the original scheduled task.
- To temporarily halt all Task Scheduler actions, open the Advanced menu in the Scheduled Tasks window and choose Pause Task Scheduler. Any tasks that do not start because Task Scheduler is paused will run again only at their next scheduled time. To start Task Scheduler up again, click the same menu and choose Continue Task Scheduler.
- To stop using Task Scheduler, open the Advanced menu in the Scheduled Tasks window and choose Stop Using Task Scheduler. No scheduled tasks will run, and the Task Scheduler service will no longer start automatically when the system is rebooted.

## Tracking Task Scheduler

The system maintains a detailed log of Task Scheduler's activities. To view the log, double-click Scheduled Tasks in Control Panel. From the Advanced menu, choose View Log. This opens a log like the one shown in Figure 10-16, with the most recent entry at the bottom of the window. The Details view in the Scheduled Tasks window displays information about each task (Figure 10-17).

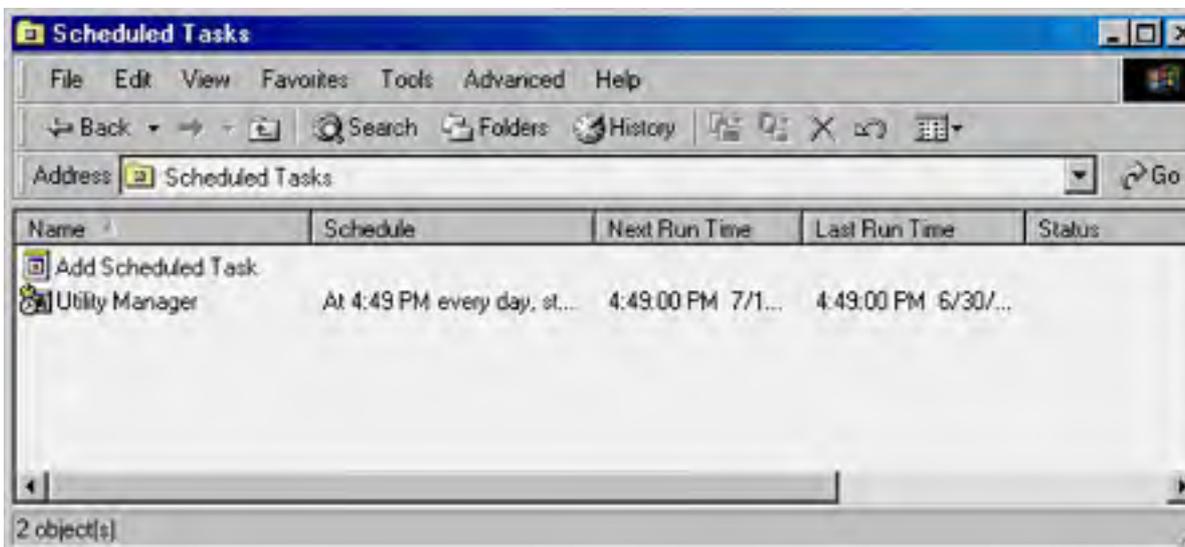

Figure 10-17. The Details view for scheduled tasks.

If a scheduled task doesn't execute as expected, right-click the task in the Task Scheduler window and choose Properties from the shortcut menu. Verify that the task is in fact enabled. (The Enabled check box in the Task Properties window should be selected.)

## Viewing Tasks on a Remote Computer

If you are an administrator of a remote computer running Windows NT or Windows 2000, you can view and edit the Task Scheduler settings on that computer. Find the computer in the My Network Places window (in Windows 2000) or in the Network Neighborhood window (in Windows NT), and then double-click the Scheduled Tasks folder.

To view and edit scheduled tasks on computers running Windows 95 or later, the remote computer must

- Have remote administration enabled
- Specify your user account as having remote administrative access
- Share the hard disk on which the Scheduled Tasks folder resides

## Using the AT Command

You can also use the AT command to schedule tasks. By default, the AT command is run using the LocalSystem account, which requires administrative privileges. To specify another account as the user of the AT command, follow these steps:

1. Open Control Panel and double-click Scheduled Tasks.
2. In the Scheduled Tasks window, open the Advanced menu and then choose AT Service Account.
3. Click This Account and specify a particular user and password. Click OK.

The command structure for the AT command is as follows:

```
AT [\\computername] [id] [[/delete]||/delete [/yes]]
AT [\\computername] time [/interactive] [/every:date[,...] |
/next:date[,...]] command
```

The following parameters can be used with the AT command. Used without parameters, the AT command returns a list of scheduled commands.

- **\\computername** Specifies a remote computer. Without this parameter, the local computer is assumed.
- **id** Indicates the identification number, if one is assigned.
- **/delete** Cancels a scheduled command. If no identification number is specified, all scheduled commands on the computer will be canceled.
- **/yes** Forces a yes answer to all system queries when canceling all commands.
- **time** Specifies when the command is to run, expressed as *hours:minutes* in 24-hour notation.
- **/interactive** Allows the task to interact with the desktop of the user logged on at the time the job is run.
- **/every:date[,...]** Runs the command on the date specified. The date can be specified as one or more days of the week (M, T, W, Th, F, S, Su) or as one or more days of the month (numbers 1 through 31). Separate multiple dates with commas. If this parameter is omitted, the current day of the month is assumed.
- **/next:date[,...]** Runs the command on the next occurrence of the specified day. If this parameter is omitted, the current day of the month is assumed.
- **command** Indicates the program, batch file, or command to be run. If a path is required, use the Uniform Naming Convention (UNC) path.

Here are some important facts to keep in mind about the AT command:

- The AT command doesn't automatically load Cmd, the command interpreter, so if the command parameter doesn't point to an executable file, you must explicitly specify Cmd, followed by the /c switch, at the beginning of the command.
- Commands scheduled using AT run as background processes, so there is no displayed output. To redirect output to a file, use the redirection symbol (>). The redirection symbol must be preceded by the escape symbol (^), so a sample command would be *at retrieve.bat ^>c:\daylog.txt*.
- If you have to use a drive letter to connect to a shared directory, include an AT command to disconnect the drive when the task is completed. Otherwise, the assigned drive letter will be neither available nor seen at the command prompt.

You can switch back and forth between the AT command and Task Scheduler, although there are some limitations. For example, if you schedule a task using AT and later modify that same task using Task Scheduler, the task is then "owned" by Task Scheduler and you can no longer access it using AT.

## Real World

### Autocompletion on the Command Line

The command line may be moribund, but it's far from dead. Windows 2000 includes a number of improvements in command-line functions, such as file and folder autocompletion. To turn this feature on, open a command-line window and type *cmd /f:on*. Now you can avoid typing long file or folder names at the command line. For example, to navigate into the Program Files folder from the root of the system drive (typically C), you'd type *c:\cd p* and then press Ctrl+D. The command expands immediately to *c:\cd "Program Files"*. Press Enter to invoke that path.

For the true command-line junkie, you can change Ctrl+D to the Tab key (far easier to remember than Ctrl+D) by changing the CompletionChar (REG\_DWORD) to a value of 9 in HKEY\_CURRENT\_USER\Software\Microsoft\Command Processor. When toggling through several possible choices, the Tab key is easier to use.

Autocompletion also works with files. Let's say you're in C:\Program Files\Windows Media Player and you would like to execute Mplayer.exe. At the command line, type *mp* and then press Ctrl+F. The path expands to include Mplayer.exe. Press Enter to actually execute the file.

Another command-line feature re-creates the functions of DOSKEY. Press the up and down arrows on the keyboard to navigate through recently used commands. Press F7 for a GUI-based display of recently used commands from which you can choose, also using the up and down arrows. Press Enter when you've arrived at the command you want to reuse.

For complete documentation on the command prompt, open a command window and type *help cmd*.

## **Summary**

Windows 2000 supplies plenty of tools to help in the management of daily operations, including ones that handle delegation, scripts, and task scheduling. However, it's still up to the humans to do the planning and decide which tools are appropriate for which chores. Every network has its own quirks and needs, and only experience can show you the optimal path. The next chapter covers the basics of installing and using Active Directory.

# Chapter 11

## Installing and Configuring Active Directory

Managing Microsoft Active Directory service is an important part of the Microsoft Windows 2000 administration process, and familiarity with the various tools provided for this purpose is essential. Nearly all the tools use Microsoft Management Console (MMC) snap-ins to provide the user interface. The Administrative Tools program group on the Start menu includes some snap-ins, but you must add others manually by using the MMC's Add Snap-In function.

You'll find that some of the Active Directory management tools are programs that you run every day, whereas others are needed only during Active Directory installation or occasionally thereafter. The MMC snap-ins that provide Active Directory management functions are as follows:

- **Active Directory Installation Wizard** Creates domain controllers, new domains, trees, and forests.
- **Active Directory Domains and Trusts** Changes the domain mode, manages domain trust relationships, and configures user principal name (UPN) suffixes.
- **Active Directory Users and Computers** Creates, manages, and configures Active Directory objects.
- **Active Directory Sites and Services** Creates and configures domain sites and manages the domain controller replication process.
- **Active Directory Schema** Modifies the schema that defines Active Directory objects and properties.

In addition to the MMC snap-ins, Microsoft Windows 2000 Server includes separate utilities for importing data to and exporting it from Active Directory. This chapter examines the tasks that Active Directory administrators typically perform using the Active Directory Installation Wizard, the Active Directory Domains and Trusts snap-in, and the Active Directory Users and Computers snap-in. The next chapter examines the Active Directory Sites and Services snap-in and the Active Directory Schema Administrator snap-in.

## Using the Active Directory Installation Wizard

Unlike Microsoft Windows NT Server version 4 and earlier, Windows 2000 Server doesn't allow you to designate a system as a domain controller during the operating system installation. Every Windows 2000 server installs as a stand-alone system or a member of a domain. After the installation is complete, you can promote the server to domain controller status using the Windows 2000 Active Directory Installation Wizard. This tool provides a great deal of additional flexibility to Active Directory administrators because servers can be promoted or demoted at any time, while Windows NT 4 servers are irrevocably designated as domain controllers during the installation process.

Also gone is the distinction between primary and backup domain controllers. Windows 2000 domain controllers are all peers in a *multiple-master replication system*. This means that administrators can modify the contents of the Active Directory tree on any server functioning as a domain controller, and the system will replicate the changes to all the other controllers on the domain. This is a major advance from the Windows NT 4 *single-master replication system*, in which an administrator can change only the primary domain controller (PDC), after which the changes are replicated to all the backup domain controllers (BDCs).

Another advantage of Windows 2000 is that you can use the Active Directory Installation Wizard to demote a domain controller back to a stand-alone or member server. In Windows NT 4, once you install a server as a domain controller, you can demote it from a PDC to a BDC, but you can't remove its domain controller status completely, except by reinstalling the operating system.

The basic function of the Active Directory Installation Wizard is to configure a server to function as a domain controller, but depending on the current state of Active Directory on your network, this task can take several forms. If you're installing the first Windows 2000 server on your network, then promoting the system to a domain controller creates an entirely new Active Directory with that computer hosting the first domain in the first tree in the first forest.

Be sure to read [Chapter 3](#) before launching into Active Directory. Unless you have an independent test network where you can make mistakes without serious consequences, it's essential that you know where you're going before you get on the train.

## Preparing for Installation

To promote a Windows 2000 server to a domain controller, you first complete the entire operating system installation process. After the final reboot, you then log on to the machine using an administrator account (you can log on either locally or across the network using the Terminal Server Administration mode).

### NTFS 5

To host Active Directory, the server must have an NTFS 5 partition. NTFS 5 is an updated version of the file system introduced in the first release of Windows NT. When you create new NTFS partitions during a Windows 2000 installation or upgrade existing NTFS partitions created with prior Windows NT versions, the system uses NTFS 5. If you choose to install Windows 2000 on a system with only FAT partitions, you must convert at least one partition to NTFS before you can use the Active Directory Installation Wizard. For the reasons described in the [Planning Partitions](#) section of [Chapter 5](#), you should convert all partitions to NTFS when possible. You can do this by using the Convert.exe utility from the command prompt or the Disk Management screen in the Computer Management snap-in for the MMC.

Converting the Windows 2000 boot partition (the partition on which Windows 2000 is installed) requires a reboot of the system. Because the conversion can't actually occur while the Windows 2000 GUI is loaded, a registry flag is used to schedule the conversion to take place the next time the machine restarts. You can then reload the Active Directory Installation Wizard and begin the installation sequence again.

## DNS Server

The last requirement for installing Active Directory is that the server must have access to a DNS server. Active Directory uses DNS to store information about the domain controllers on the network. Client systems locate a domain controller for authentication by sending a query to the DNS server identified in their TCP/IP client configurations. The DNS server that Active Directory uses need not be running on the computer being converted to a domain controller, nor does it have to run the Microsoft DNS service. However, the DNS server you use must support the Service Location resource record defined in the RFC 2052 document and the Dynamic Update protocol defined in RFC 2136.

### More Info

RFCs (requests for comments) are the TCP/IP specification documents published by the Internet Engineering Task Force (IETF). All the documents are in the public domain and available for viewing at <http://www.rfc-editor.org>.

A DNS server is essentially a database composed of individual elements called *resource records* that contain information about the computers on a TCP/IP network. Various types of resource records are defined in the DNS specifications, and Active Directory requires a new type of resource record—the SRV (the DNS resource record for specifying the location of services)—to store information about Active Directory domain controllers. In addition, a DNS server used by Active Directory requires the ability to dynamically update its records, based on the availability of the domain controllers on the network. More information on DNS and dynamic DNS can be found in [Chapter 13](#).

Until recently, network administrators have configured DNS servers by manually creating the resource records that identify the computers on the network. Each time a system was added or taken out of service, the administrator had to add, remove, or modify the resource record associated with it. A Windows 2000 network running Active Directory uses multiple domain controllers to provide fault tolerance and load balancing. If a domain controller should fail or become unavailable to clients for any reason, another domain controller takes over its duties automatically.

Unfortunately, traditional DNS servers have no such automatic self-configuration capabilities. A network administrator has to manually modify the appropriate SRV resource record every time a domain controller goes offline and another takes its place. The Dynamic Update protocol defined in RFC 2136, on the other hand, enables DNS servers to receive messages from domain controllers containing their availability status. The server modifies its own resource records based on the contents of these messages, thus ensuring that all the domain controllers identified in the resource records are available and that all the available domain controllers are listed in the DNS server.

The Microsoft DNS Server version included with the Windows 2000 Server products supports both new specifications, as does the UNIX-based DNS Server BIND version 8.1.2. If you already have a DNS server supporting these features on your network, you should specify its IP address in the new server's TCP/IP configuration before you begin the Active Directory installation process. You need not install a DNS server on your new domain controller in this case because the Active Directory Installation Wizard will locate the specified server and create the appropriate SRV resource records in it.

However, if a DNS server supporting the new features isn't available on the network, the wizard offers to install and configure Microsoft DNS Server on the system automatically. You can refuse the offer and install a DNS server on another system, but your new server must be able to access that DNS server to install Active Directory and promote the system to a domain controller.

### Real World

#### The Case for On-Site DNS Servers

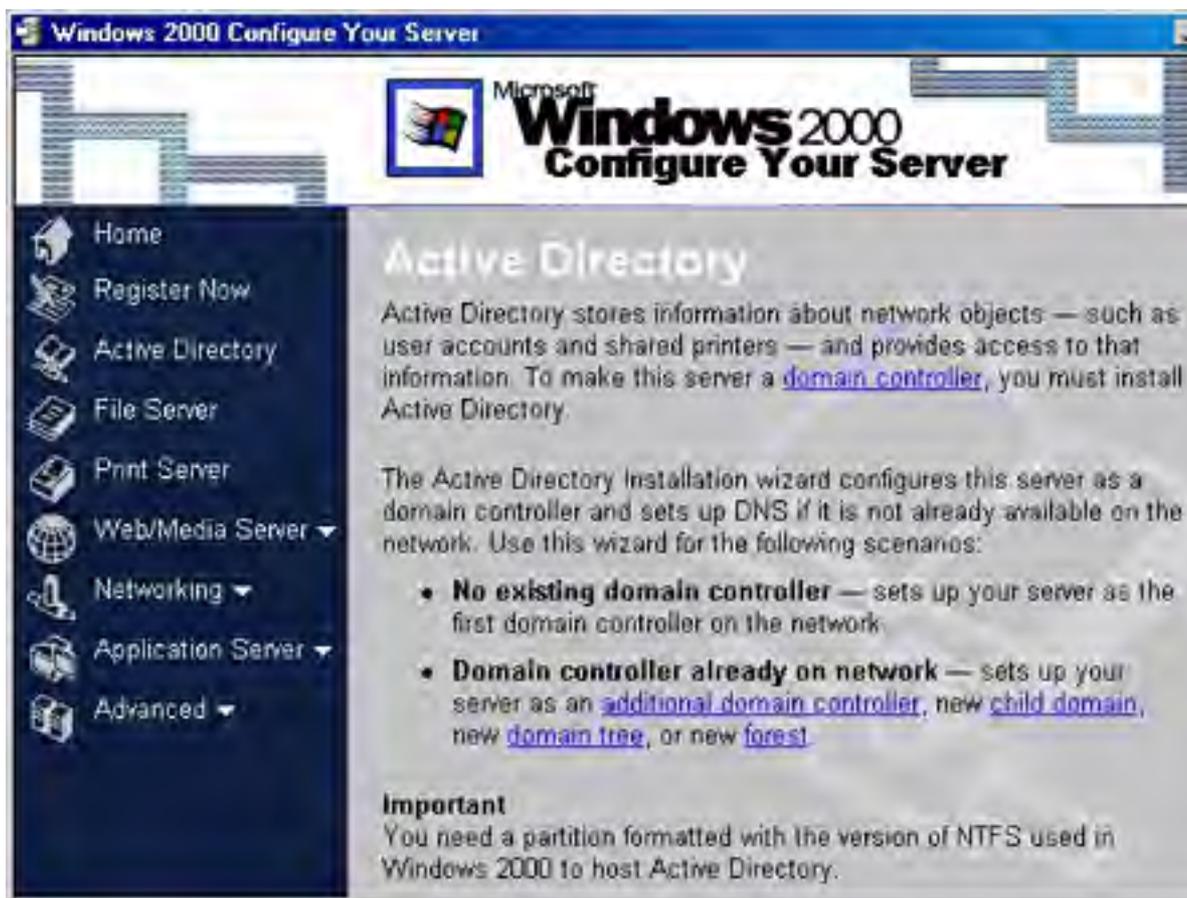

If your network currently uses off-site DNS servers for name resolution, such as those provided by your Internet service provider (ISP), you should install at least one new DNS server on your local network to support Active Directory. Although your ISP's DNS servers might support the Service Location resource record and the Dynamic Update protocol, it's unlikely that your Windows 2000 servers will be authorized to dynamically update the ISP's DNS server records. Even if that were permitted, it is neither practical nor secure for your client systems to traverse a WAN link just to request information about local resources.

## Promoting Your First Server to a Domain Controller

Assuming you've already designed the Active Directory hierarchy that you're going to use on your network (as discussed in [Chapter 3](#)), the process of actually installing Active Directory and promoting a server to a domain controller is quite simple. The following sections examine the process of installing Active Directory on the first server of a Windows 2000 network. In the [Choosing Installation Options](#) section later in this chapter, we'll cover the various Active Directory installation options you can use when installing subsequent servers.

### Launching the Active Directory Installation Wizard

Following the standard wizard pattern, installing Active Directory on a server is a matter of responding to prompts in a sequence of screens. Windows 2000 incorporates links to the wizard onto the Active Directory page of the Windows 2000 Configure Your Server home page. This page is displayed automatically after the OS installation, as shown in Figure 11-1. This screen is designed to walk you through all the processes needed to configure a new server by asking questions in wizard fashion and linking to the appropriate tools for each task.

**Figure 11-1.** The Windows 2000 Configure Your Server tool.

For users new to Windows 2000, this page functions as a combination mini-tutorial and checklist of server configuration procedures. More advanced users can bypass the configuration page and launch the wizard directly by running the executable file `Dcpromo.exe` from the Run dialog box. Or users can run the file from the command prompt after logging on using an administrator account. `Dcpromo.exe` is located in the `\%SystemRoot%\System32` folder, making it possible to execute it from any folder without specifying a path.

When you upgrade a Windows NT 4 primary domain controller to Windows 2000 Server, the system launches the Active Directory Installation Wizard automatically after the operating system installation finishes.

After a welcome screen, the Installation Wizard prompts you for the action you want to perform, based on the system's current Active Directory status. If the server is already a domain controller, the wizard provides the option to only demote the system back to a stand-alone or member server. (Domain controllers are covered in [Chapter 7](#).) On a computer that isn't yet a domain controller, the wizard displays the Domain Controller Type screen shown in Figure 11-2, which prompts you to select one of the following options:

- **Domain Controller For A New Domain** Installs Active Directory on the server and designates it as the first domain controller in a new domain.
- **Additional Domain Controller For An Existing Domain** Installs Active Directory on the server and replicates the directory information from an existing domain. (Creating replicas is covered later in this chapter.)

**Figure 11-2.** The Domain Controller Type screen of the Active Directory Installation Wizard.

## Creating a New Domain

When you install the first Active Directory server on your network, you select the Domain Controller For A New Domain option in the Domain Controller Type screen. This instructs the wizard to install the Active Directory support files, create the new domain, and register it in the DNS. The new domain is further configured in one of two ways, as shown in the Create Tree Or Child Domain screen (Figure 11-3).

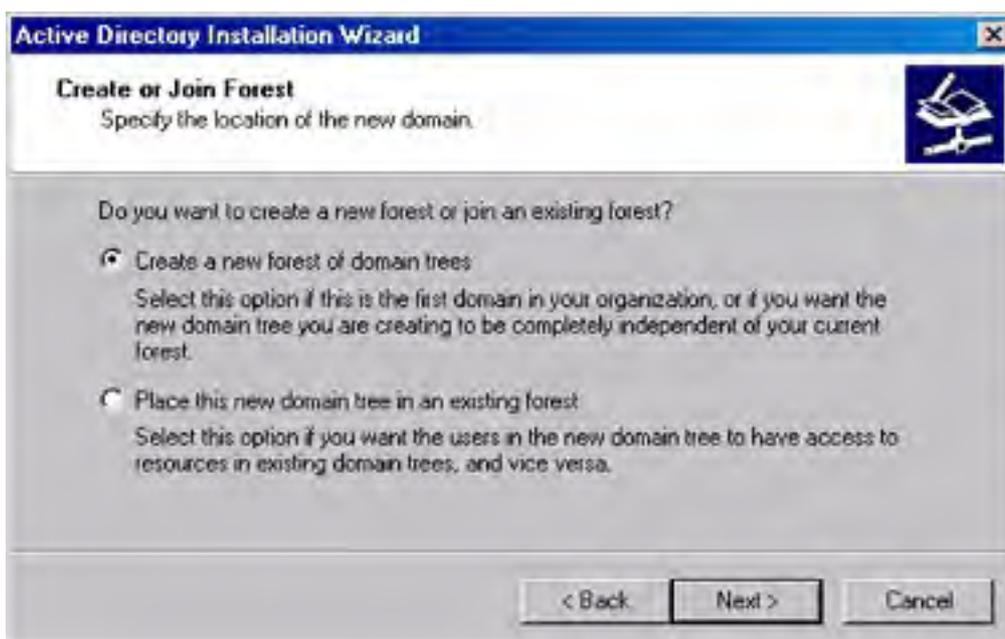

- **Create A New Domain Tree** Configures the new domain controller to host the first domain in a new tree.
- **Create A New Child Domain In An Existing Domain Tree** Configures the new domain controller to host a child of a domain in an already existing tree.

**Figure 11-3.** The Create Tree Or Child Domain screen of the Active Directory Installation Wizard.

Because this is to be the first Active Directory server on the network, you should select Create A New Domain Tree. The wizard then displays the Create Or Join Forest screen, shown in Figure 11-4, which enables you to specify one of the following options:

- **Create A New Forest Of Domain Trees** Configures the domain controller to be the root domain in a new forest of trees.
- **Place This Domain Tree In An Existing Forest** Configures the domain controller to host the first domain of a new tree in a forest already containing one or more trees.

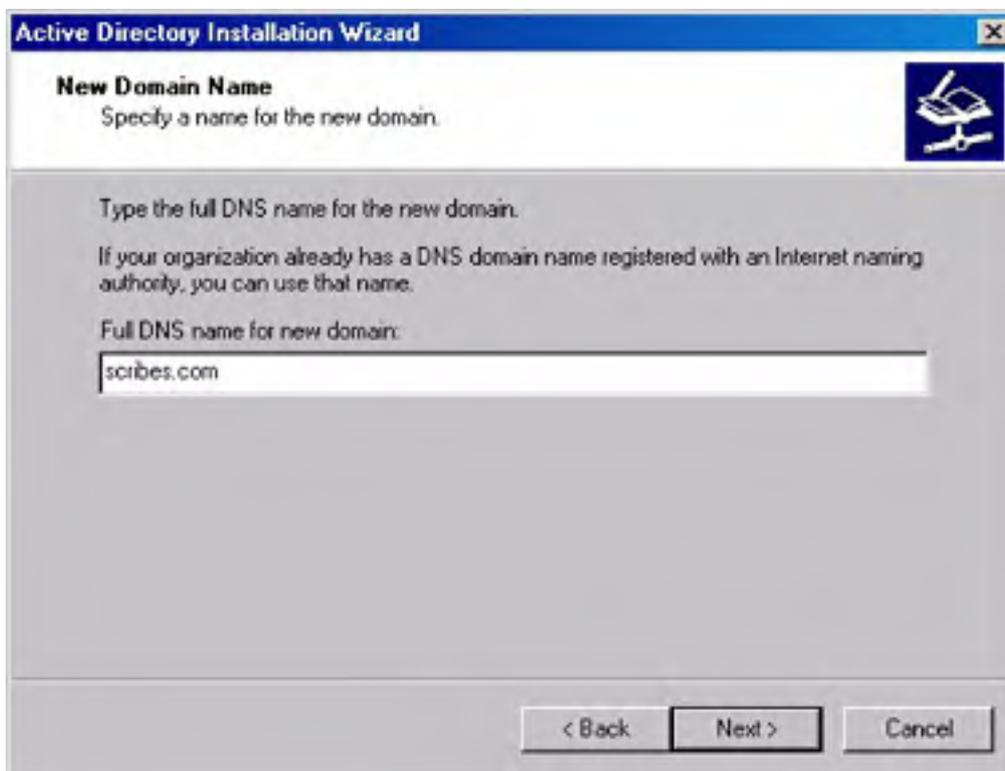

**Figure 11-4.** The Create Or Join Forest screen of the Active Directory Installation Wizard.

Select Create A New Forest Of Domain Trees in this instance, because the first Windows 2000 domain controller on your network will always be a new domain, in a new tree, in a new forest. As you install additional domain controllers, you can use these same options to create other new forests or to populate the existing forest with additional trees and domains.

## Specifying Domain Names

To identify the domain controller on the network, you must specify a valid DNS name in the New Domain Name screen (Figure 11-5) for the domain you're creating.

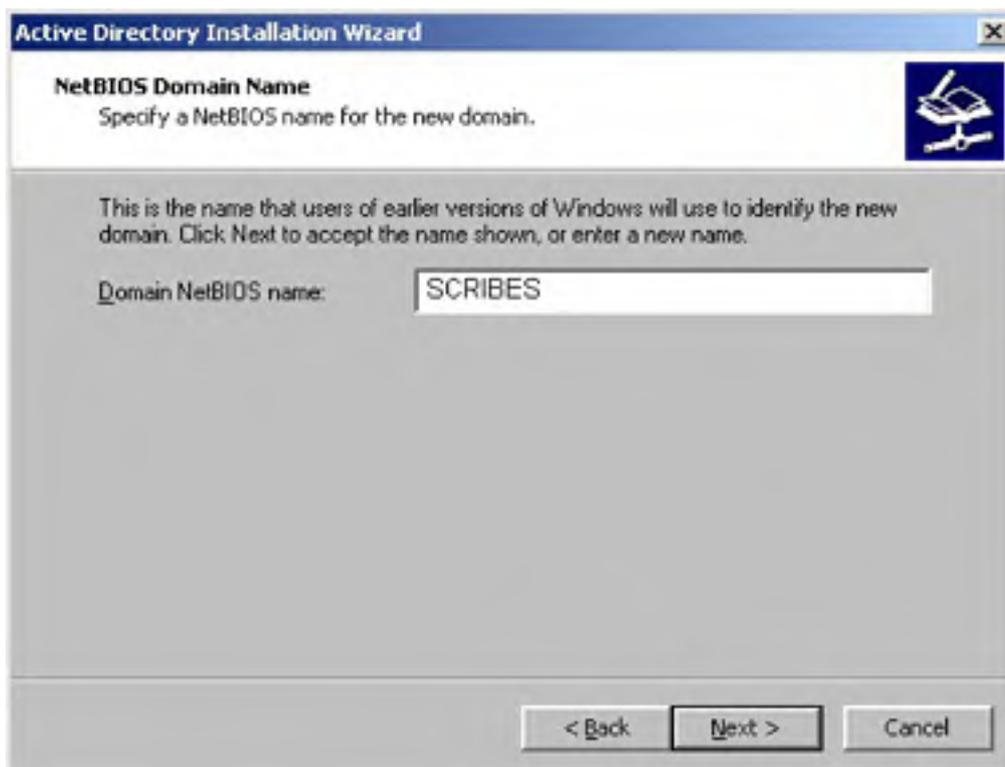

**Figure 11-5.** The New Domain Name screen of the Active Directory Installation Wizard.

This name doesn't have to be the same as the domain your organization uses for its Internet presence (although it can be). Nor does the name have to be one registered with a registrar such as Network Solutions—one of the organizations responsible for maintaining the registry of DNS names in the *com*, *net*, *org*, and *edu* top-level domains. However, using a registered domain name is a good idea if your network users will be accessing Internet resources at the same time as local network resources, or if users outside the organization will be accessing your local network resources using the Internet.

When users access Internet resources at the same time as Windows 2000 network resources, the possibility exists for your unregistered domain name to conflict with a registered Internet domain using the same name. When Internet users are permitted to access resources on your network using standard application-layer protocols like HTTP and FTP, confusion can arise if internal and external users must use different domain names.

After you enter a DNS name for the domain, the system prompts you for a NetBIOS equivalent to the domain name for use by clients that don't support Active Directory. Windows 2000 systems still use the NetBIOS namespace for their computer names, but Active Directory uses DNS naming for domains. Windows NT 4 and Microsoft Windows 95/98 systems use NetBIOS names for all network resources, including domains.

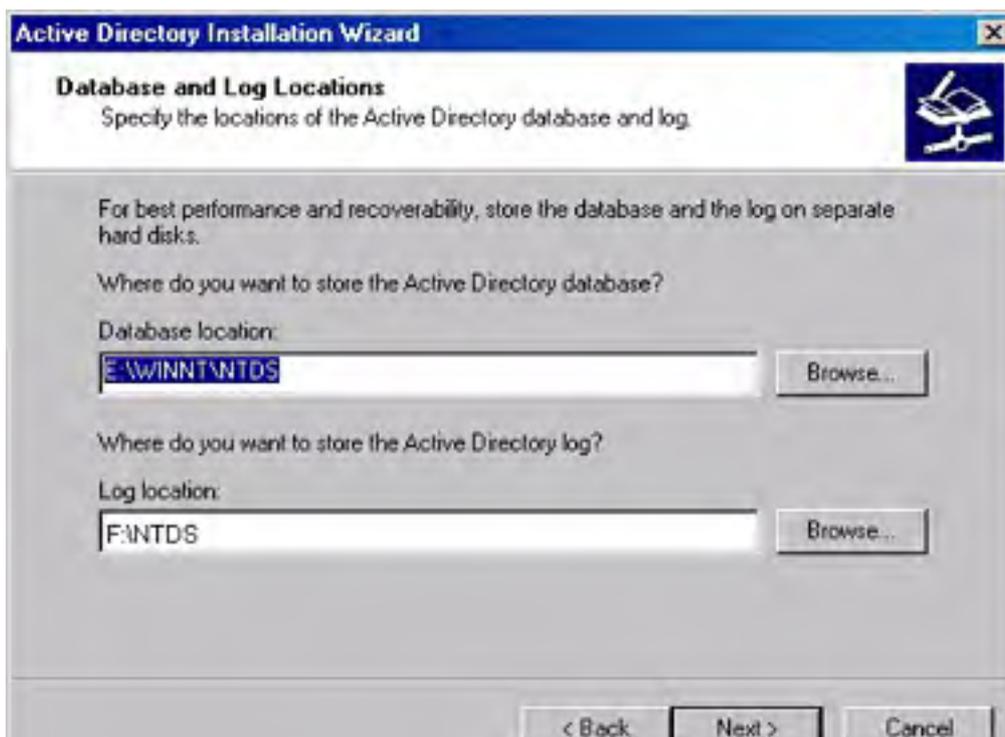

If you have any downlevel clients on your network (that is, Windows NT 4, Windows 95/98, Microsoft Windows for Workgroups, or Microsoft Network Client for MS-DOS systems), they'll only be able to see the new domain using the NetBIOS name. The NetBIOS Domain Name screen (Figure 11-6) will contain a suggested name that you can use, based on the DNS name you specified, or you can replace it with a name of your own selection that is 15 characters or fewer.

**Figure 11-6.** The NetBIOS Domain Name screen of the Active Directory Installation Wizard.

### Locating Active Directory Files

After you specify domain names, the wizard prompts you for the locations of the Active Directory database, log files, and the system volume. The Active Directory database will contain the actual Active Directory objects and their properties, and the log files track the activities of the directory service. You specify the directories for these files in the Database And Log Locations screen, shown in Figure 11.7. The default location for both the database and the logs is the %SystemRoot%\Ntds folder on the system volume, but you can modify these locations as needed—in fact, you probably should, so as not to have all your directory eggs in one basket.

**Figure 11-7.** *The Database And Log Locations screen of the Active Directory Installation Wizard.*

The Shared System Volume screen enables you to specify the location of what will become the Sysvol share on the domain controller. The *system volume* is a share containing domain information that is replicated to all the other domain controllers on the network. By default, the system creates this share in the %SystemRoot%\Sysvol folder on the system drive.

The Active Directory database, logs, and system volume must all be located on volumes using the NTFS 5 file system. If the wizard detects that any of the volumes you've chosen don't use NTFS 5, you must either convert them or select other volumes before you can complete the Active Directory installation process.

### **Real World**

#### **Storing the Active Directory Database and Logs**

Because Active Directory often writes to the database and the logs at the same time, Microsoft recommends not storing them on the same hard disk. This isn't a major issue on a single domain controller or other small network, but on an enterprise network with frequent directory service updates and many domain controllers replicating their databases, the data storage burden can be significant, so using separate disks or disk arrays (RAID) is strongly recommended.

The recommendation for the placement of the database and log files calls for the use of separate hard disks, not separate volumes on the same disk drive. This is because the physical constraints of the disk's head traveling mechanism can be responsible for a reduction in disk performance. The heads on a single disk drive can't be in two positions at the same time, so the device must perform writes to the database and the logs consecutively. When the files are stored on separate disks, the writes can occur simultaneously. It is also preferable to use SCSI drives for this purpose rather than EIDE because SCSI is better suited to executing simultaneous commands on multiple devices.

## **Using Automatic DNS Configuration**

At this point, the Active Directory Installation Wizard has all the configuration information it needs to install Active Directory and promote the server to a domain controller. The system checks to see that the domain names you supplied are not already in use by your DNS server or any other computers on your network. If, for example, the NetBIOS name you selected is already being used by a Windows NT 4 domain on the network, the wizard prompts you to select another name.

The wizard also checks to determine whether the DNS server hosting your domain supports the Dynamic Update protocol. If the system can't contact the DNS server specified in the computer's TCP/IP client configuration, or if the specified DNS server is incapable of supporting a Windows 2000 domain, the wizard offers to install Microsoft DNS Server and configure it to function as the authoritative server for the domain. The Configure DNS screen enables you to specify whether you want to install the DNS server or configure one yourself. If you elect to use another machine for the DNS server, you must install and configure it before you can complete Active Directory installation.

## **Specifying Permissions Compatibility**

After the wizard contacts the DNS server that will provide the locator service for the new domain (or you tell it to install DNS on the server), you are asked whether you want to set up user and group permissions that are compatible with pre-Windows 2000 servers (specifically Windows NT 4 RAS servers). You don't. As mentioned in [Chapter 5](#), you should eliminate these servers before upgrading your network to Windows 2000, and choosing permissions that are compatible with pre-Windows 2000 application servers opens up your network to anonymous users, which is a major security risk. We recommend that you follow Bob Dole's advice: Just don't do it.

Instead, choose the Permissions Compatible Only With Windows 2000 Servers option, and click Next to move on.

## **Finishing Active Directory Installation**

After specifying the permission compatibility level you want, enter the passwords you want to use for the server's local Administrator account. Because you can't log on locally to a domain controller, the only time you'll have occasion to use this password is when booting in the directory services restore mode or using the Recovery Console, so it's important that you remember this password or keep it somewhere safe. The usual password recommendations apply here—at least a seven-character password that consists of uppercase and lowercase letters, numbers, and other characters. Acronyms for phrases that are meaningful only to you are good choices.

Click Next after entering the password, review the summary screen, and then click Next to allow the installation and configuration of Active Directory to proceed without further user input. The wizard logs all the activities that occur during the installation process in two files called Dcpromo.log and Dcpromoui.log, located in the %SystemRoot%\Debug folder. Installation can take several minutes, after which you must reboot the system for the changes to take effect.

The procedure for installing additional domain controllers on your network is similar to that for the installation of the first domain controller. The following sections examine the other options provided by the Active Directory Installation Wizard and how you use them to build a Windows 2000 network with Active Directory.

## Choosing Installation Options

Planning an effective directory service strategy is an essential element of an Active Directory deployment. As stated earlier, before running the Installation Wizard on any Windows 2000 Server, you should have a directory structure in mind that outlines which domains, trees, or forests you intend to create in Active Directory and how they should be configured. As you create additional domain controllers on the network, you can use the Installation Wizard to specify any of the Active Directory installation options.

## Creating a Replica Domain Controller

Replicas provide fault tolerance for an Active Directory domain, and they can reduce internetwork traffic by enabling network clients to authenticate using a domain controller on the local segment. When a domain controller malfunctions or is unavailable for any reason, its replicas automatically assume their functions. Even a small domain needs at least two domain controllers to maintain this fault tolerance.

To create a replica of an existing domain, you run the Active Directory Installation Wizard on a newly installed Windows 2000 server after joining the domain you intend to replicate. For the computer to join the domain, you can either join the domain for the first time and supply the administrative credentials that enable the system to create a computer object in the domain, or create the computer object manually using Active Directory Users and Computers. After joining the domain, log on to the system using the local administrator account and launch the wizard from the Configure Server page or by running Dcpromo.exe from the Run dialog box.

When the Domain Controller Type screen appears in the wizard, select Additional Domain Controller For An Existing Domain and specify the DNS name of the domain to be replicated. You must then supply the user name, password, and domain name of an account with administrative privileges in the domain.

The rest of the process is exactly like the creation of the first domain, as outlined in the section [Promoting Your First Server to a Domain Controller](#), earlier in this chapter. The wizard installs Active Directory on the server; creates the database, logs, and the system volume in the locations you specify; registers the domain controller with your DNS server; and replicates the data from an existing domain controller for that domain.

Once the replica of the domain controller is up and running, it is indistinguishable from the existing domain controller, as far as client functionality is concerned. The replicas function as peers, unlike Windows NT servers, which are designated as primary and backup domain controllers. Administrators can modify Active Directory contents (either objects or schema) from any domain controller, and the changes are replicated to all of the other controllers for that domain.

When creating a replica, the Active Directory Installation Wizard automatically configures the replication process between the domain controllers. You can customize the replication process using Active Directory Sites and Services, included with Windows 2000 Server. (See "Using Active Directory Sites and Services" in [Chapter 12](#).)

## Creating a Child Domain in an Existing Tree

When you create the first Windows 2000 domain on your network, you're also creating the first tree in a forest. You can populate the tree as you create additional domains by making them children of existing domains. A *child domain* is one that uses the same namespace as a parent domain. This namespace is established by the DNS name of the parent domain, to which the child adds a preceding name for the new domain.

For example, if you create a domain called mycorp.com, a child of that domain would be called something like research.mycorp.com. Typically, child domains reflect the geographical, departmental, or political divisions of an organization, but you can use any tree design principle you want, although it's usually desirable to create domains based on administrative boundaries when possible. A parent domain can have any number of children, and the tree structure can extend through any number of generations, which enables you to use a single namespace to create a domain tree that reflects the structure of your entire organization.

To install Active Directory and create a child domain, you must first join your Windows 2000 Server to the parent domain by joining that domain and supplying administrative credentials or by manually creating a computer object in the domain using Active Directory Users and Computers. Then log on to the system using the local administrator account and launch the Active Directory Installation Wizard from the Configure Server page or by running Dcpromo.exe from the Run dialog box.

A child domain is not a replica; it is a completely separate domain located in the same tree. Therefore, when the wizard displays the Domain Controller Type screen, you must select Domain Controller For A New Domain. In the Create Tree Or Child Domain dialog box, you select Create A New Child Domain In An Existing Domain Tree. The wizard then prompts you for the DNS name of the domain that is to be the parent of the child. After supplying this, you specify the short name for the child domain. The short name is the name that will be added to the parent domain's DNS name to form the full name of the child domain. For example, to create a child domain called research.mycorp.com, you specify mycorp.com as the parent domain name and Research as the short name of the child.

As with the creation of the first domain in the tree, you must supply a NetBIOS name for the new domain of no more than 15 characters (Figure 11-6). In the preceding example, the domain would be called RESEARCH. You must also supply credentials for an account that has administrative privileges in the parent domain. The wizard then completes the Active Directory installation and prompts you for a system reboot.

### **Creating a New Tree in an Existing Forest**

In addition to creating child domains in an Active Directory tree, you can also create entirely new trees, thus forming a forest. Each tree in a forest has its own separate namespace, but the trees all share the same schema and configuration. If, for example, you modify the schema to add customized attributes to a particular object in one tree, those attributes will be present in the same object type in all of the other trees in the forest.

Before you create a new tree in an existing forest, your new Windows 2000 Server must join the root domain of that forest. The root domain is the first domain created in the forest, and you join the system to that domain by logging on to it and specifying credentials for an administrative account in the domain or manually creating a computer object in the domain using Active Directory Users and Computers.

Once the computer has an account in the forest's root domain, you can launch the Active Directory Installation Wizard from the Configure Server page or run Dcpromo.exe from the Run dialog box. When the Domain Controller Type dialog box appears, select Domain Controller For A New Domain. Then select Create A New Domain Tree in the Create Tree Or Child Domain dialog box, and select Place This New Domain Tree In An Existing Forest in the Create Or Join Forest dialog box.

To create the new tree, you must first specify the DNS name of the root domain in the forest and then the DNS name that you want to assign to the first domain in the new tree. This second DNS name must not be a part of any existing namespace in the forest. That is, if a tree already uses mycorp.com as the DNS name of its root domain, you can't use the name research.mycorp.com for the root domain in your new tree, even if that exact domain name doesn't exist in the mycorp.com tree.

After supplying the DNS names, you furnish a NetBIOS equivalent in the usual manner, and you provide credentials for an administrative account in the forest's root domain. The wizard then completes the installation process and prompts you to reboot the system.

### **Creating a New Forest**

The fundamental difference between creating a new tree and creating a new forest is that forests each have their own individual schema and configuration, whereas trees do not. The most obvious scenario in which a network would have multiple forests is when two organizations with existing Active Directory installations merge, and sufficient schema and configuration differences exist between the two to make joining them into one forest impractical.

The procedure for creating a new forest is the same as that for creating the first domain on the network, as described in the section entitled [Promoting Your First Server to a Domain Controller](#), earlier in this chapter. Once you complete this or any of the other Active Directory installation processes described in the preceding sections, you can log on to the domain and proceed to perform the activities outlined in the rest of this chapter and in the next chapter.

## Upgrading Windows NT 4 Domain Controllers

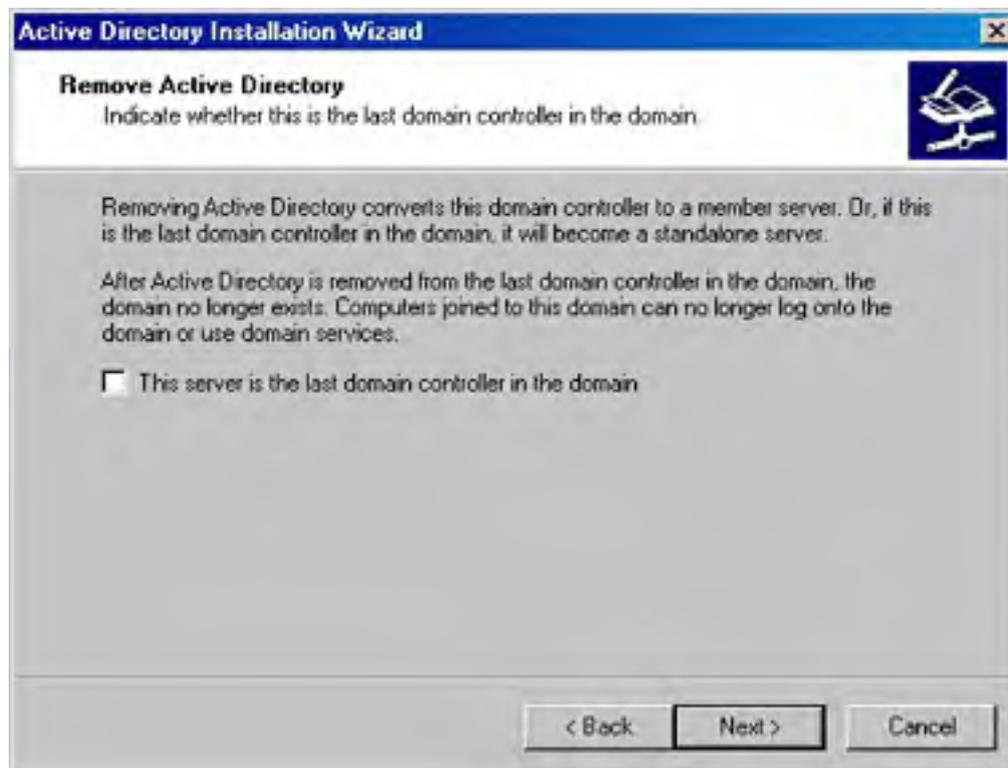

Windows 2000 simplifies the process of converting the domains from a Windows NT 4 network to Windows 2000 Active Directory domains by enabling you to upgrade the servers gradually. Windows NT domain controllers can coexist on the same network as Windows 2000 domain controllers and can even function in the same domain. The only special rule for the upgrade process is that you must upgrade the PDC of a Windows NT 4 network before any of the BDCs.

When you install the Windows 2000 operating system on the PDC, the Active Directory Installation Wizard launches automatically after the final reboot and begins the promotion process. After the server is promoted to a domain controller, the system can host your existing domain, using the NT 4 BDCs as replicas. You can then upgrade the BDCs at your own pace.

When all the domain controllers are running Windows 2000, you can then use the Active Directory Domains and Trusts snap-in to convert the domain from mixed mode to native mode, enabling you to take full advantage of Active Directory's grouping capabilities. See the section entitled [Changing the Domain Mode](#), later in this chapter, for more information on switching the domain operational mode.

## Demoting a Domain Controller

A major difference between Windows 2000 domain controllers and Windows NT domain controllers is that you can demote a Windows 2000 domain controller to a stand-alone or member server. When you launch the Active Directory Installation Wizard, the program ascertains that the system is already functioning as a domain controller and only provides the option to demote the server, as shown in Figure 11-8.

**Figure 11-8.** The Remove Active Directory screen of the Active Directory Installation Wizard.

The Configure Your Server screen also detects the status of the system and provides only a single option (Figure 11-9).

**Figure 11-9.** The Windows 2000 Configure Your Server screen.

Demoting a domain controller erases the Active Directory database from the machine, removes all references to it from the DNS server, and returns the system's security accounts to a state identical to that of a newly installed Windows 2000 server. If the domain to which the system belongs has replica domain controllers on the network, the server remains a member of that domain after the demotion.

If the server is the sole domain controller for a particular domain, the demotion causes that domain to be erased completely from Active Directory, and the system becomes a stand-alone server until you join it to another domain. If the server is the only controller of a forest's root domain, you must destroy all the other domains in the forest before you can proceed with the demotion of the root domain controller. To demote the controller, follow these steps:

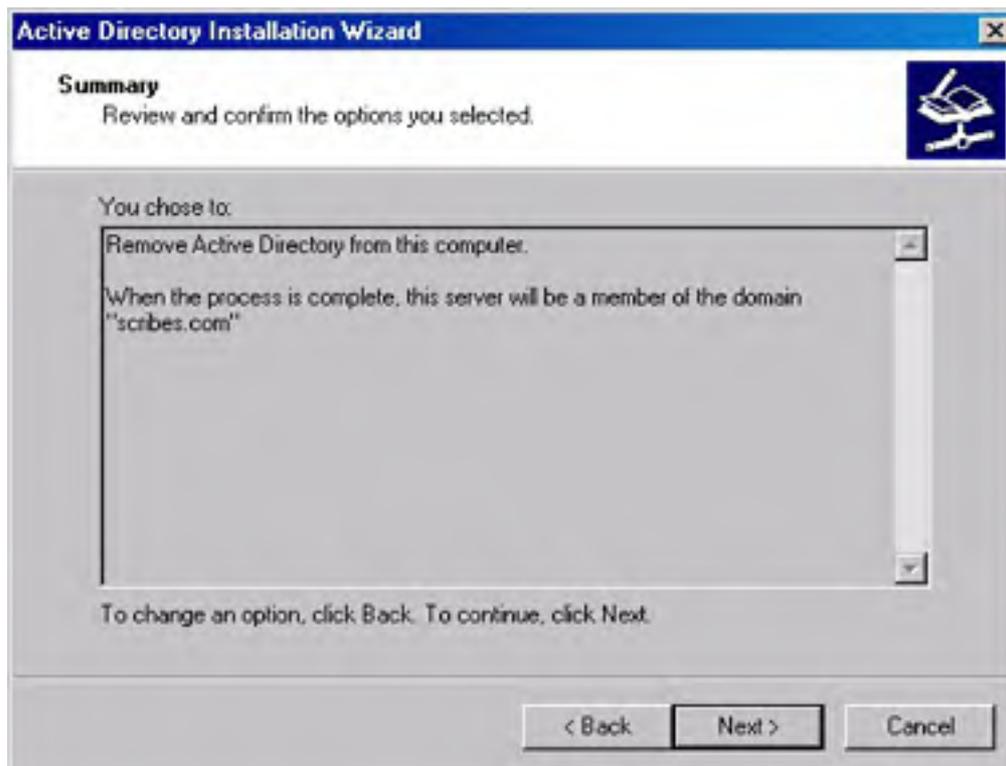

1. Open the Active Directory Installation Wizard by running Dcpromo.exe. If you see a message box like the one in Figure 11-10, don't proceed with the demotion of the server until you're sure at least one other Global Catalog server exists in the domain. (See the section entitled [Setting a Global Catalog Server](#), later in this chapter.)

**Figure 11-10.** A warning message when demoting a Global Catalog server.

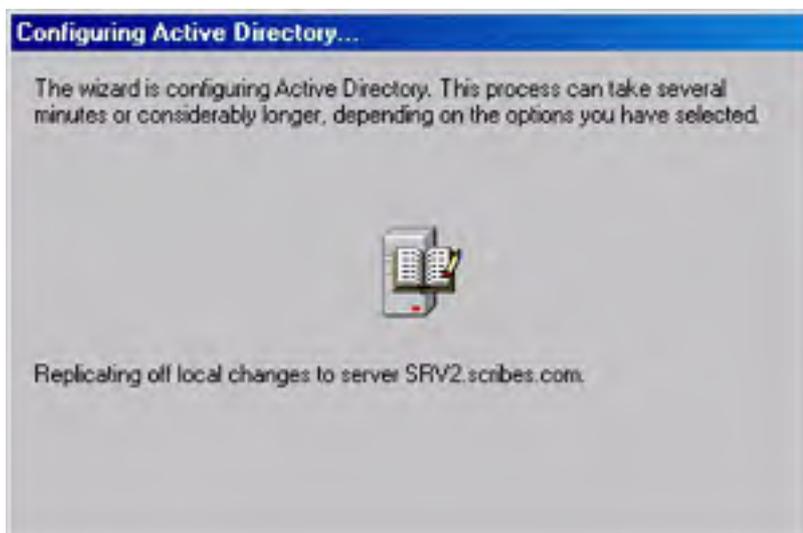

2. You'll see the screen shown in Figure 11-8. Click Next.

3. Provide a password for the server administrator account. You'll then see a summary showing what you've selected and what the result will be if you proceed (Figure 11-11).

**Figure 11-11.** *The Summary screen of the Active Directory Installation Wizard.*

The Configuring Active Directory screen opens and provides a running description of the processes being performed (Figure 11-12). This takes at least a few minutes, and sometimes considerably longer, depending on the machine. When the configuration is complete, the server is no longer a domain controller and you'll be prompted to click Finish and then Restart Now.

**Figure 11-12.** *The Configuring Active Directory screen.*

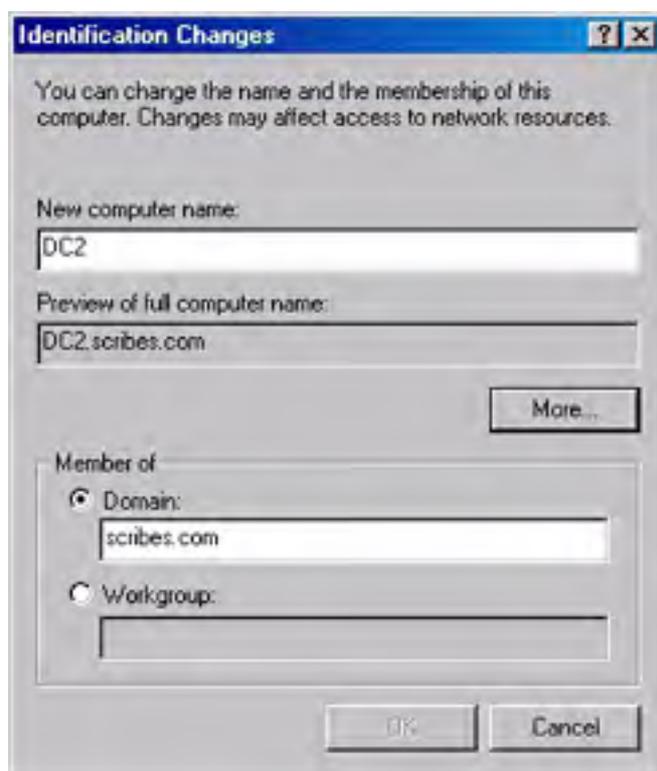

## Changing a Domain Controller Identification

Changing a domain controller's network identity requires demoting the server from its status as a domain controller, changing the identity, and then promoting the machine again.

When changing a domain controller's name, exercise caution, especially in a mixed environment with downlevel clients. References to your server's old domain name can be perpetuated by WINS servers, causing browsing problems as well as preventing the reuse of the computer name, and clearing out WINS databases to correct the problem can be tricky.

First open Run from the Start menu, type *dcpromo*, and click OK. Follow the steps in the previous section, [Demoting a Domain Controller](#). Once the domain controller is demoted, follow these steps to change the computer's network identity:

1. Open the System tool in Control Panel and click the Network Identification tab.
2. Click Advanced to open the Identification Changes dialog box.
3. Enter the new name for your computer (Figure 11-13), or make changes to the domain or workgroup to which the computer belongs.

**Figure 11-13.** The Identification Changes dialog box.

4. Click More to manually specify the DNS domain name for the computer and to preview the NetBIOS name. Click OK when you're finished.

Try to use a computer name that is both DNS- and NetBIOS-compatible so that all types of clients see the same name for your computer. To do this, keep the name shorter than 15 characters in length and don't use asterisks or periods. It's also preferable to avoid using spaces, underscores, and hyphens for the best application compatibility.

Once you've made the change to the computer's network identity, you can promote it once more to a domain controller by following these steps:

1. Open Run from the Start menu and type *dcpromo* to start the Active Directory Installation Wizard.
2. Select the type of domain controller you want—an additional controller for an existing domain or a controller for a new domain.

3. Supply a user name and password, being sure to use an account with sufficient privileges to perform the operation (Figure 11-14).

The screenshot shows a window titled "Active Directory Installation Wizard" with a sub-header "Network Credentials". Below the sub-header is the instruction "Provide a network user name and password." and a small icon of a network card. The main area contains the text "Type the user name, password, and user domain of the network account you wish to use for this operation." followed by three input fields: "User name:" with "Administrator", "Password:" with "\*\*\*\*\*", and "Domain:" with "SCRIBES". At the bottom right are three buttons: "< Back", "Next >", and "Cancel".

**Figure 11-14.** The Network Credentials screen of the Active Directory Installation Wizard.

4. Supply the full DNS name of the domain, the locations for the Active Directory database, the Active Directory log, and the SYSVOL folder.
5. The Summary screen will again show you which options you've selected. Click Back to make any changes; otherwise, click Next.
6. Active Directory will be configured (Figure 11-15). The process takes several minutes, even on a relatively fast system.

**Figure 11-15.** The Configuring Active Directory screen.

At the end of the process, the Active Directory Installation Wizard informs you that Active Directory is installed and to which domain and site. A reboot is required before the installation of Active Directory is complete.

## Setting a Global Catalog Server

The first Windows 2000 domain controller in a forest is automatically a Global Catalog server. The Global Catalog (GC) contains a full replica of all directory objects in its host domain plus a partial replica of all directory objects in every domain in the forest. The point of a GC is to provide authentication for logons. In addition, because a GC contains information about all objects in all the domains in the forest, finding information in the directory doesn't require unnecessary queries across domains. A single query to the GC produces the information about where you can find the object.

As long as your enterprise has any Windows NT domain controllers, each domain must have at least one Global Catalog server.

By default, there will be one GC, but any domain controller can be configured as a Global Catalog server. If you need additional logon and search services, you can have multiple Global Catalog servers in the domain.

To make a domain controller into a Global Catalog server, follow these steps:

1. Launch Active Directory Sites and Services from the Administrative Tools folder.
2. Open Sites and select the applicable site.
3. Open Servers and then select the domain controller you want to make into a Global Catalog server.
4. Select NTDS Settings from the right-hand pane and choose Properties from the Action menu.
5. In the General tab, select the Global Catalog Server check box.

As long as your enterprise is operating in mixed mode (that is, you have domain controllers other than Windows 2000 domain controllers), you must have at least one Global Catalog server per domain. Once you've upgraded every domain controller to Windows 2000, you can switch the domain to native mode, as described in the section entitled [Changing the Domain Mode](#), later in this chapter.

## Using Active Directory Domains and Trusts

Windows 2000 Active Directory Domains and Trusts is an MMC snap-in that you can use to view a tree display containing all the domains in your forest. With this snap-in, you can manage the trust relationships between the domains, change the domain mode, and configure the user principal name (UPN) suffixes for the forest. Active Directory Domains and Trusts also provides access to Active Directory Users and Computers for each domain that you use to view and modify the properties of individual objects.

## Launching Active Directory Domains and Trusts

Windows 2000 Server adds the Active Directory Domains and Trusts Manager snap-in to the Start menu by default, so after logging on using an account with administrative privileges, you can run the utility by selecting Active Directory Domains and Trusts from Administrative Tools in the Start menu's Programs group. The MMC snap-in file is called Domain.msc, so you can also launch the manager from the Run dialog box by executing that filename.

When the Active Directory Domains and Trusts Manager loads, the console tree (on the left) displays all the domains in the forest in expandable tree fashion, stemming from a root labeled Active Directory Domains and Trusts, as shown in Figure 11-16. The result pane (on the right) displays the children of the currently selected domain, or if you select the root, the root domains of all the trees in the forest. The functions provided by Active Directory Domains and Trusts are accessible from the Action menus produced by clicking a domain name or the root object, as well as within the Properties dialog box for a domain.

**Figure 11-16.** The Active Directory Domains and Trusts snap-in.

## Changing the Domain Mode

By default, newly installed domain controllers operate in mixed mode, which means that you can use Windows NT BDCs as domain controllers in a Windows 2000 domain. Thus, you can upgrade an existing Windows NT domain to Windows 2000 gradually by first upgrading the Windows NT PDC to Windows 2000. You can then use Active Directory to store information about your domain and modify the directory using the Active Directory snap-ins included with Windows 2000 Server.

When Windows 2000 Server is operating in mixed mode, the Windows NT BDCs are fully functional domain controllers in the Active Directory domain, capable of multiple-master replication just like Windows 2000 domain controllers. The only drawback to using mixed mode is that you can't take advantage of the Windows 2000 advanced grouping features, such as the ability to nest groups and create groups with members in different domains.

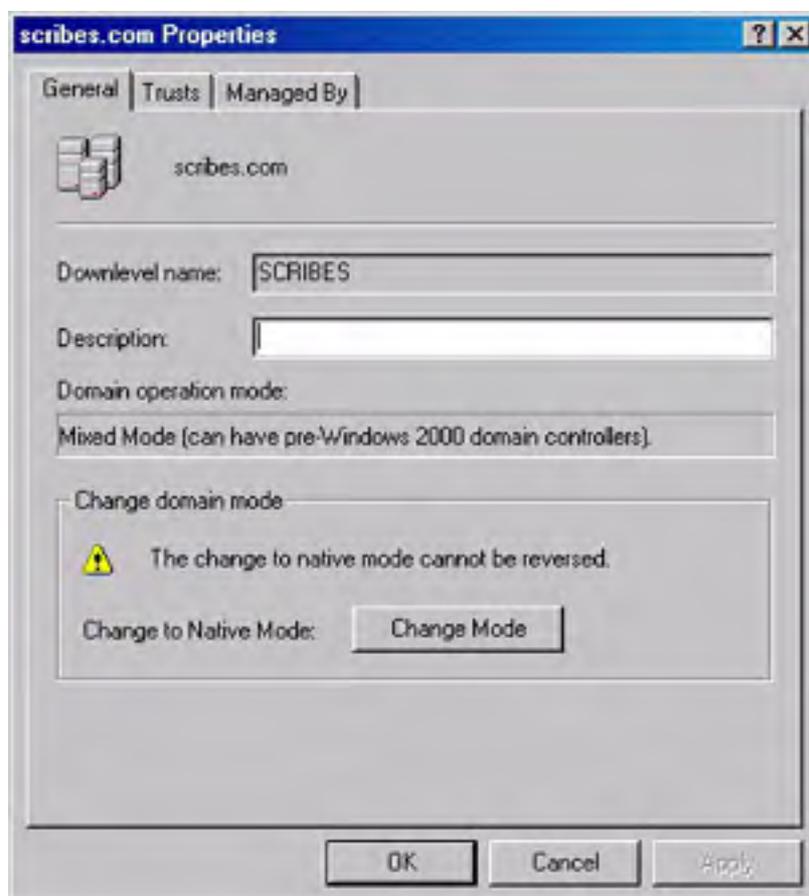

Once you've completed upgrading all the Windows NT BDCs in your domain to Windows 2000, you can switch the computer to native mode, which enables these grouping capabilities. However, once you switch the operational mode for the domain from mixed to native, you can't switch it back without reinstalling Active Directory. Be sure that you'll have no further need for Windows NT domain controllers on your network before making this modification.

To change the domain mode to native Windows 2000 mode, use the following steps:

1. Right-click the domain you want to upgrade in the Active Directory Domains and Trusts console.

2. Choose Properties from the shortcut menu. The General tab (Figure 1117) displays the NetBIOS name by which the domain is known to downlevel clients and enables you to specify a description for that domain. This tab also displays the domain's current operational mode.
3. To change the domain mode, click Change Mode.
4. Click Yes to irreversibly convert the domain to native Windows 2000 mode (there's no going back without an arduous restoration of the Active Directory domain from a backup, so make sure that you're ready for this step).

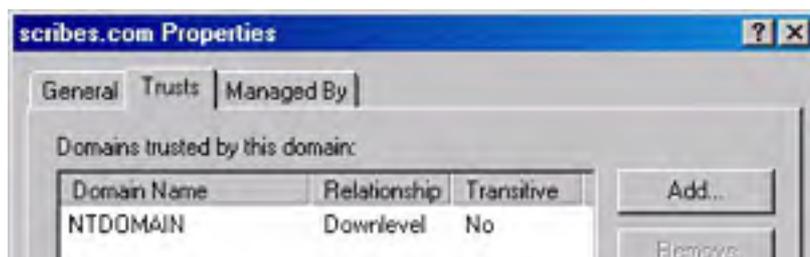

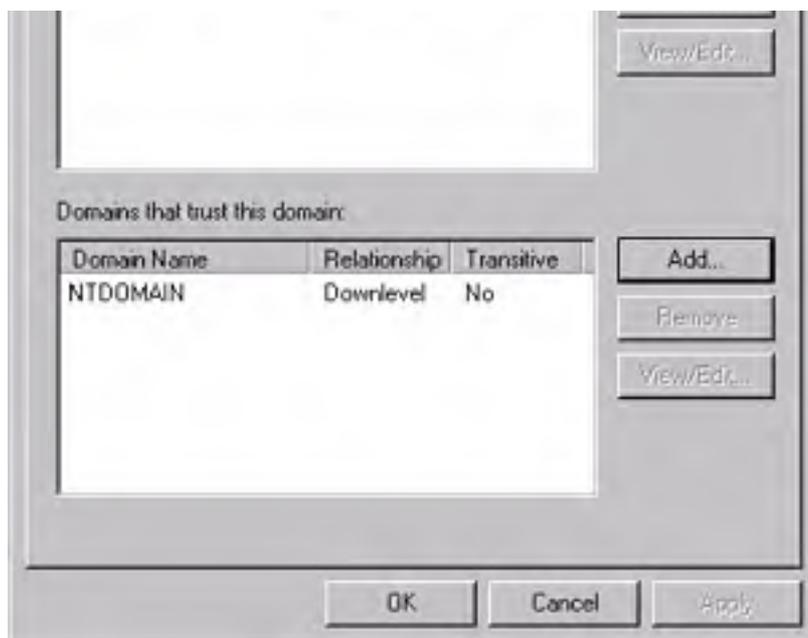

**Figure 11-17.** The General tab of the Properties dialog box for a domain.

Mixed mode refers to the domain controllers only in a particular domain. After switching to native mode, you can still use Windows NT domain controllers in the same tree, as long as they are located in different domains.

## Managing Domain Trust Relationships

The trust relationship between domains is managed in the Trusts tab of a domain's Properties dialog box (Figure 11-18). When you establish a trust relationship between two domains, users in one domain can access resources located in another trusted domain. An Active Directory domain tree is a collection of domains that share not only the same schema, configuration, and namespace, but are also connected by trust relationships.

**Figure 11-18.** The Trusts tab of the Properties dialog box for a domain.

Windows 2000 supports two types of trust relationships: the explicit, one-way trusts used by Windows NT, and the transitive, hierarchical trusts provided in Active Directory domains by the Kerberos security protocol. Windows NT trust relationships function in only one direction. For example, when domain A trusts the users in domain B, it doesn't automatically follow that B trusts the users in A. An administrator must explicitly create the trusts in both directions to achieve a mutual relationship between the domains.

Active Directory automatically creates Kerberos trust relationships in all the domains in a tree; they run in both directions, and they are transitive. A *transitive trust relationship* is one that is propagated throughout a tree hierarchy. For instance, when domain A trusts domain B and domain B trusts domain C, then domain A trusts domain C. The creation of each new domain in a tree includes the establishment of trust relationships with all the other domains in the tree, enabling users to access resources in any one of the tree's domains (assuming they have the appropriate permissions) without manual configuration by an administrator.

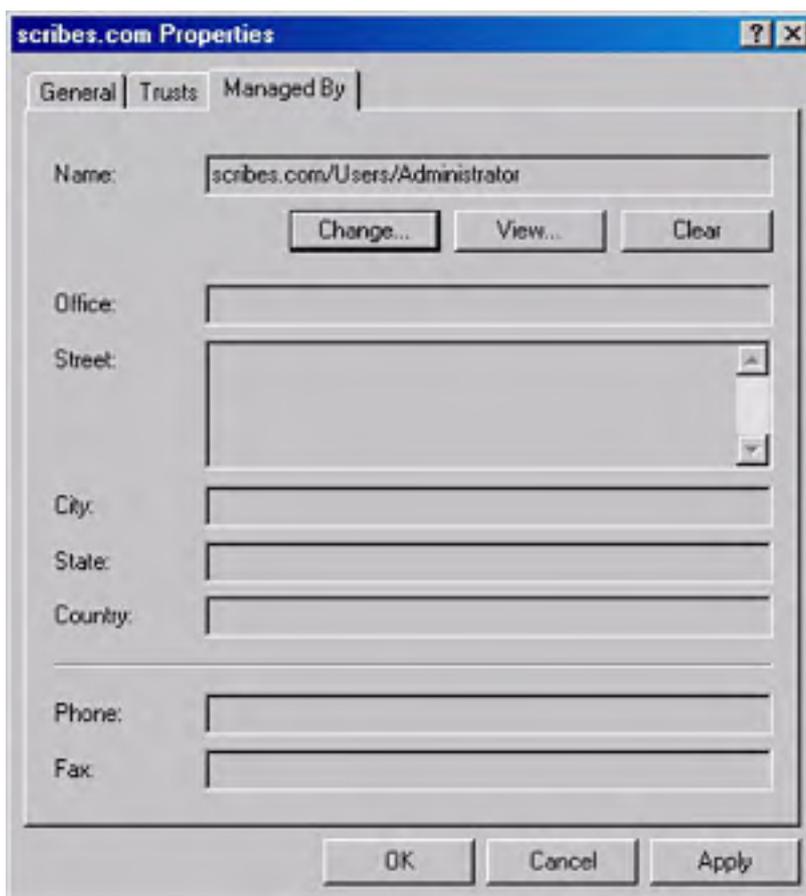

To provide domain access to users in another tree or to grant the users in your domain access to another tree, you can manually establish trust relationships by clicking one of the Add buttons in the Trusts tab and specifying the name of a domain. These are one-way relationships; you must establish a trust for each domain to create a bidirectional trust. Depending on the nature of the domain to trust or be trusted, the relationship might or might not be transitive. You can establish a transitive trust relationship with Windows 2000 domains in another tree, but relationships with Windows NT domains can't be transitive.

To establish a trust relationship with another domain, you specify the name of the domain in the Add Trusted Domain dialog box and supply a password. To complete the process, an administrator of the other domain must specify the name of your domain in the Add Trusting Domain dialog box and furnish the same password. Both domains must approve before the systems can establish the trust relationship.

Some administrators might find that they can improve security by eschewing Active Directory's two-way transitive trusts in favor of old-fashioned one-way explicit trusts.

## Specifying the Domain Manager

The third tab in a domain's Properties dialog box, shown in Figure 11-19, identifies the individual who is the designated manager for the domain. This tab provides contact information about the manager derived from the associated user account in Active Directory. You can change the manager by clicking Change and selecting another user account from the Active Directory display shown.

**Figure 11-19.** The *Managed By* tab of a domain's *Properties* dialog box.

## Configuring User Principal Name Suffixes for a Forest

A UPN is a simplified name that users can supply when logging on to Active Directory. The name uses the standard e-mail address format consisting of a user name prefix and a domain name suffix, separated by an at sign (@), as defined in RFC 822 (for example, user@domain.com). UPNs provide network users with a unified logon name format that insulates them from the Active Directory domain hierarchy and the need to specify the complex LDAP name for their user objects when logging on.

By default, the suffix of the UPN for users in a particular forest is the name of the first domain created in the first tree of that forest, also called the *forest DNS name*. Using Active Directory Domains and Trusts Manager, you can specify additional UPN suffixes that users can employ in place of the forest DNS name when logging on. To do this, you select the root object in the console tree of the main Active Directory Domains and Trusts display (that is, the object labeled *Active Directory Domains and Trusts*), and choose *Properties* from the Action menu. In the UPN Suffixes tab, click *Add* to specify additional suffixes. These suffixes apply to the entire forest and are available to any user in any domain of any tree in that forest.

## Managing Domains

The Active Directory Domains and Trusts snap-in also provides access to the Active Directory Users and Computers snap-in that you use to view and modify the objects in a domain and their properties. When you select a domain in the console tree of the main display and choose *Manage* from the Action menu, the MMC opens the Active Directory Users and Computers snap-in with the focus on the selected domain.

## Using Active Directory Users and Computers

The Active Directory Users and Computers snap-in is the primary tool for Active Directory administrators, and it's the tool that you will use most often for day-to-day directory maintenance. Active Directory Users and Computers displays all the objects in a domain by using a Windows Explorer-style expandable tree display. Dialog boxes for each object provide access to the object's properties, which you can modify to update user information and account restrictions.

You also use Active Directory Users and Computers to create new objects and model the tree hierarchy by creating and populating container objects like organizational units (OUs). The following sections examine the most common tasks that administrators perform using Active Directory Users and Computers.

### Launching Active Directory Users and Computers

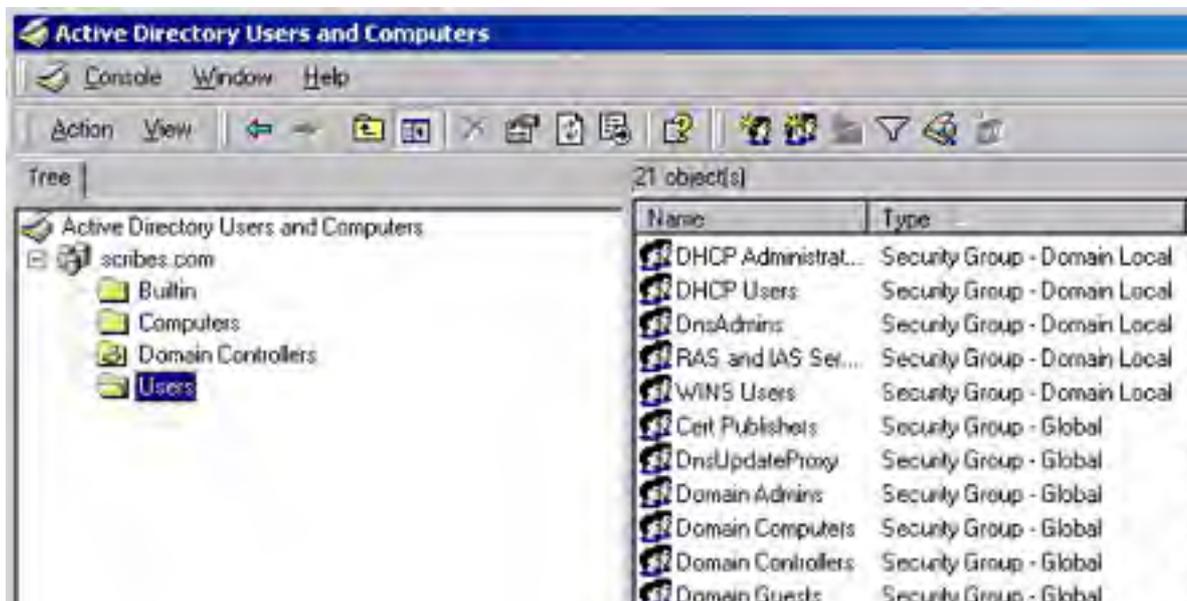

Active Directory Users and Computers, like most of the Active Directory administration tools, is a snap-in for the MMC. The snap-in file is called Dsa.msc, and you can launch the manager in any one of these three ways:

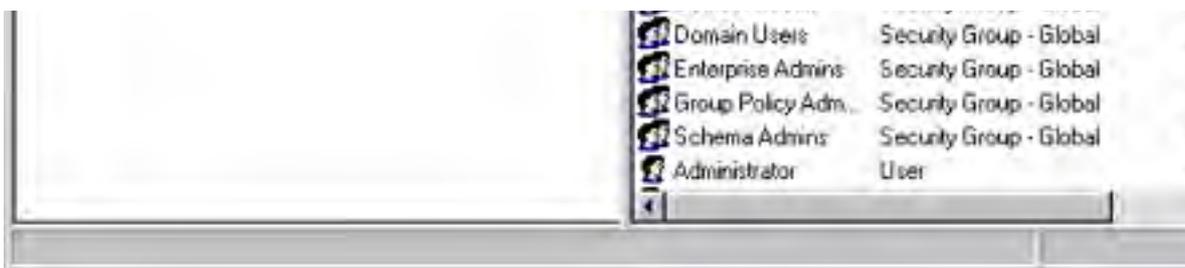

- Launch Active Directory Users and Computers from the Administrative Tools folder in the Start menu's Programs group.
- Select a domain in the console tree of the Active Directory Domains and Trusts snap-in, and choose Manage from the Action menu. This opens a new MMC dialog box called Active Directory Users And Computers, leaving the existing Domains And Trusts window intact.
- Open the Run dialog box from the Start menu and execute the Dsa.msc snap-in file.

To perform many of the functions provided by the Active Directory Users and Computers snap-in, you must be logged on to the domain using an account that has administrative privileges. You can use the Delegation of Control Wizard to delegate administration tasks for specific objects to other users without giving them full administrative access to the domain, as discussed in the section entitled [Delegating Object Control](#), later in this chapter.

### Viewing Active Directory Objects

The main Active Directory Users And Computers dialog box (Figure 11-20) contains many of the standard MMC display elements. The console tree (on the left) lists an Active Directory domain and the container objects within it in an expandable display. The result pane (on the right) displays the objects within the highlighted container. The manager includes a specialized toolbar providing quick access to commonly used functions and a description bar that provides information about the manager's status or the currently highlighted object. The program displays the actions that you can perform on each object in the Action menu once you have clicked the objects.

**Figure 11-20.** The main Active Directory Users And Computers dialog box.

## Active Directory Object Types

The objects in the Active Directory Users And Computers dialog box represent both physical entities, such as computers and users, and logical ones, such as groups and organizational units. The default object types in a newly created Active Directory domain are listed in Table 11-1.

**Table 11-1.** Object types created in a new Active Directory domain

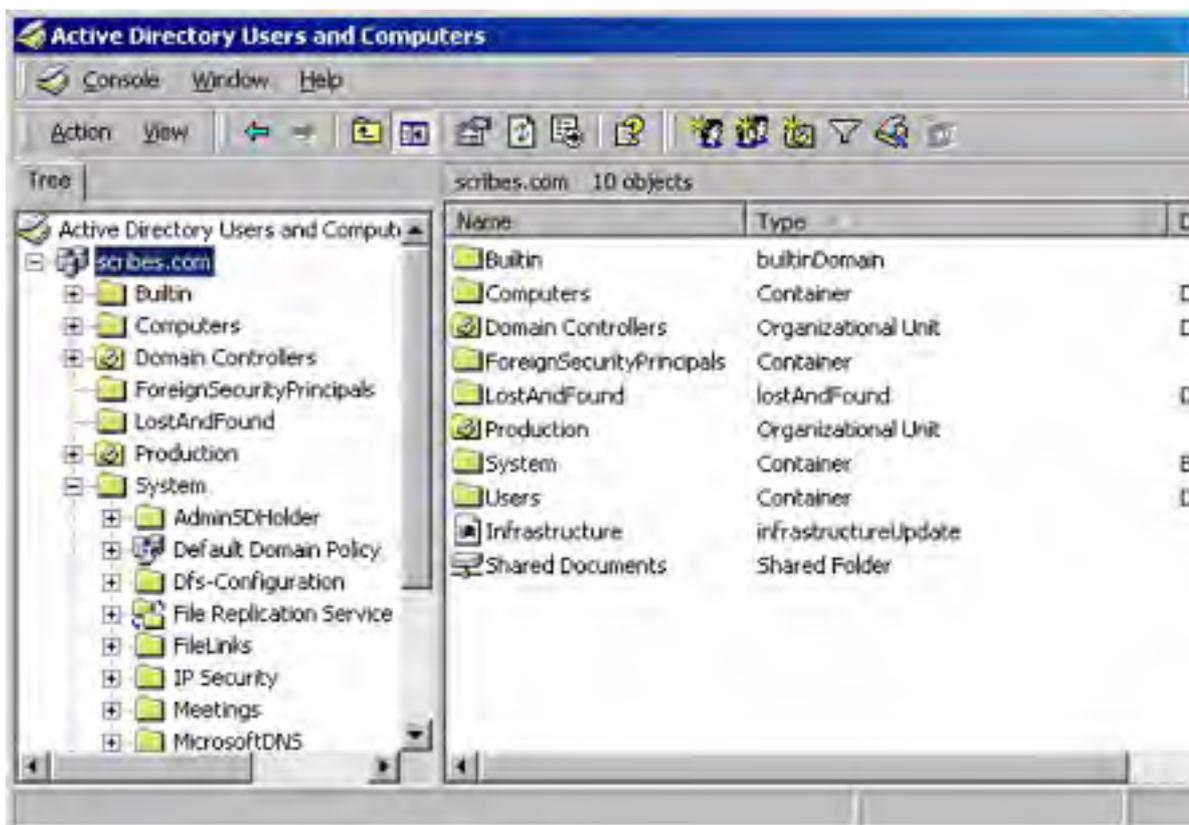

Object Type	Icon	Function
Domain		Root object of Active Directory Users and Computers display; identifies the domain currently being administered by the manager.
Organizational Unit		Container object used to create logical groupings of computer, user, and group objects.
User		Represents a network user and functions as a repository for identification and authentication data.
Computer		Represents a computer on the network and provides the machine account needed for the system to log on to the domain.
Contact		Represents a user external to the domain for specific purposes such as e-mail delivery; doesn't provide the credentials needed to log on to the domain.
Group		Container object representing a logical grouping of users, computers, or other groups (or all three) that is independent of the Active Directory tree structure. Groups can contain objects from different organizational units and domains.
Shared Folder		Provides Active Directory-based network access to a shared folder on a Windows 2000 system.
Shared Printer		Provides Active Directory-based network access to a shared printer on a Windows 2000 system.

By modifying the schema that control the directory service structure, you can create new object types in Active Directory and modify the attributes of existing types. For more information, see "Using Active Directory Schema" in [Chapter 12](#).

## Normal Mode vs. Advanced Mode

By default, the Active Directory Users and Computers display operates in normal mode. Normal mode displays only the objects that administrators are most likely to access during a typical Active Directory maintenance session. This includes the organizational units containing the built-in users and groups created during Active Directory installation and all the objects created by administrators after the installation. Normal mode also hides certain tabs in an object's Properties dialog box from view, including the Object tab and the Security tab that you use to set permissions for the object.

When you choose Advanced Features from the manager's View menu, however, the display changes to include all the system objects in Active Directory, which represent policies, DNS records, and other directory service elements, as well as the LostAndFound container, as shown in Figure 11-21.

**Figure 11-21.** The Active Directory Users and Computers Advanced Features mode displaying all of the system objects in the selected domain.

From this interface, you can view information about the system objects and control access to them by modifying the associated permissions. Because access to these objects isn't required as frequently, you can suppress their appearance by leaving the manager in normal mode. However, when you want to modify the permissions for standard objects like organizational units, users, and groups, you must enable Advanced Features to see the Security tab in an object's Properties dialog box.

## Changing the Domain

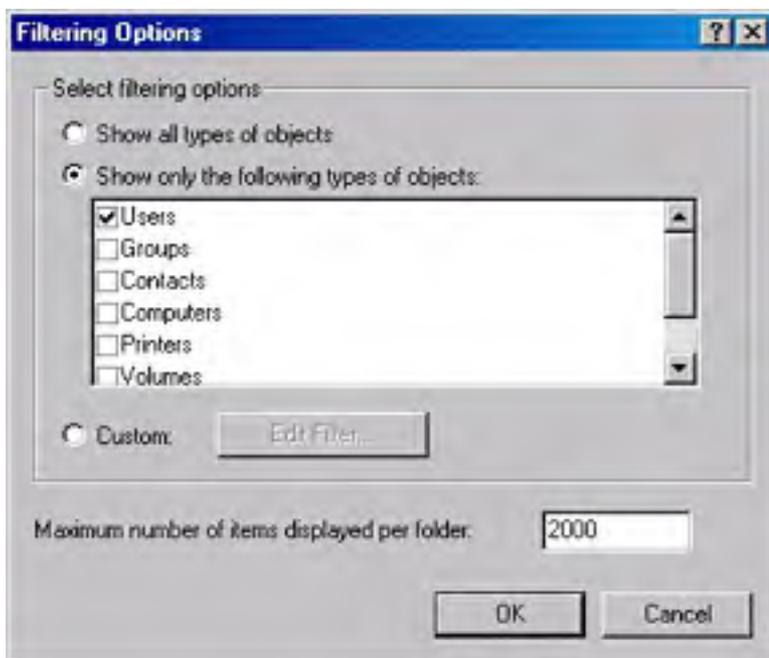

You can use the Active Directory Users and Computers snap-in to administer any domain on the network. To change the currently displayed domain in the manager, select the root or domain object in the console tree and choose Connect To Domain from the Action menu. This displays the Connect To Domain dialog box, where you can enter the name of the domain or browse to another domain.

From the Action menu, you can also choose Connect To Domain Controller to access the selected domain by using a specific domain controller on the network. Unless your domain controllers are out of sync, the information should be the same on all of the replicas, but sometimes you might want to select a domain controller at a different location to avoid a slow or expensive WAN connection.

## Using Filters to Simplify the Display

When you begin to populate Active Directory with new objects, it can rapidly grow to an unwieldy size. The sheer number of objects in the display can make locating the specific object you need difficult. To temporarily suppress the display of objects you don't need to see, you can apply a filter to the Active Directory Users and Computers snap-in based on object types or based on the contents of specific object attributes.

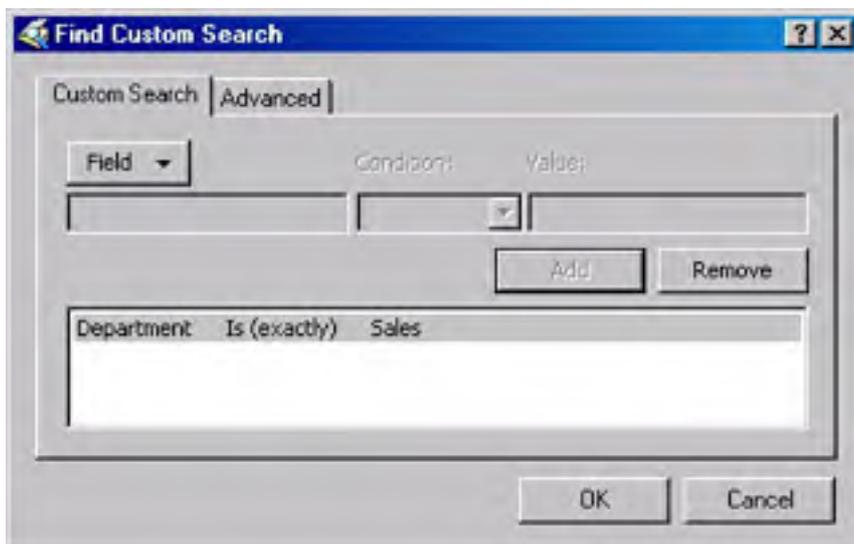

When you choose Filter Options from the View menu, the Filtering Options dialog box appears, as shown in Figure 11-22. Here you can opt to display all object types, select specific object types to display, or build a custom filter based on object attributes.

**Figure 11-22.** The Filtering Options dialog box of Active Directory Users and Computers.

When you select the Custom option and click Edit Filter, you see a Find Custom Search dialog box like the one shown in Figure 11-23. In this dialog box, you can select an object type, choose an attribute of that object, and specify a full or partial value for that attribute.

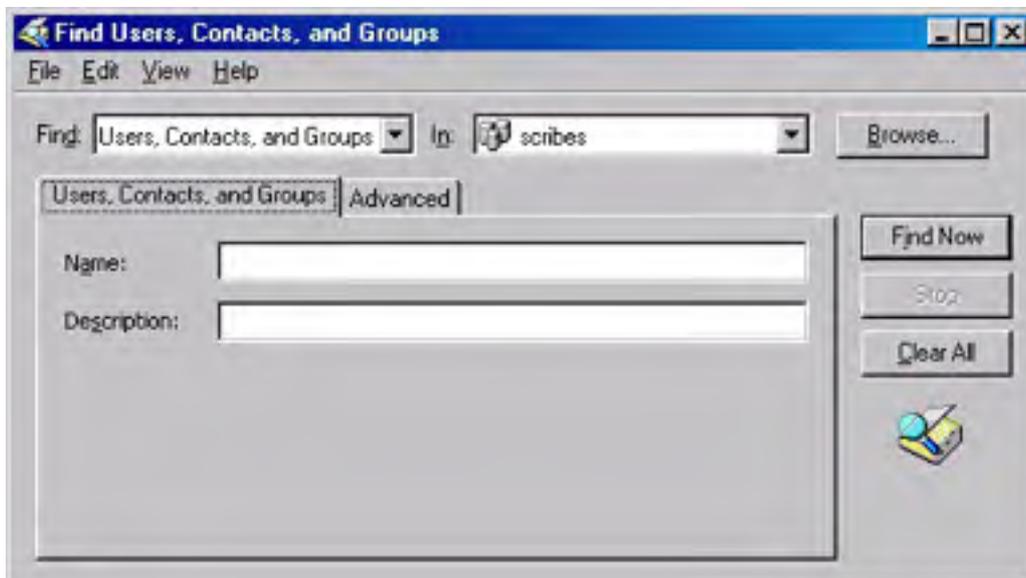

For example, you can display only the user objects that have the value *Sales* in the *Department* attribute (as shown in the figure), or you can choose to display only the users that have a particular area code in the *Telephone Number* attribute. This enables you to quickly zero in on the objects you need to use without scrolling through an unnecessarily cluttered display.

**Figure 11-23.** The Find Custom Search dialog box of Active Directory Users and Computers.

## Finding Objects

You can also search for specific objects in the entire Active Directory without modifying the manager's display. By selecting the domain object and choosing Find from the Action menu, you display the Find Users, Contacts, And Groups dialog box (Figure 11-24), in which you can specify the type of object you want to locate, a specific domain, or the entire directory, and the name and description of the object.

**Figure 11-24.** The Find Users, Contacts, And Groups dialog box of Active Directory Users and Computers.

The program then searches the GC that is automatically created on the first controller in a domain to locate the desired object. The GC is a subset of the entire Active Directory, containing only the most commonly used attributes, which makes it easier to search for a specific object. Without the GC, the task of searching an Active Directory installation that includes domain controllers in remote locations could require extensive WAN traffic that is both slow and expensive.

Although Active Directory always creates the GC on the first domain controller for a domain, you can change its default location by modifying the NTDS settings in the Active Directory Sites and Services snap-in. You can also specify additional attributes that are to be stored in the GC by using the Active Directory Schema snap-in.

The Advanced tab in the Find Users, Contacts, And Groups dialog box uses the same interface as the Custom Filter feature discussed in the previous section. In the same way, you can search for objects based on any of their attributes. If an attribute you select isn't part of the GC, the search will proceed by looking through the actual contents of the domain controllers on your network. In some cases, this can slow down the search process considerably.

Much of the same Active Directory object searching functionality found in the Active Directory Users and Computers snap-in is also available from the Start menu's Search feature.

## Default Active Directory Objects

A newly created Active Directory domain contains organizational unit, computer, user, and group objects that the Active Directory Installation Wizard creates by default. These objects provide access to the system at several levels and include groups that enable administrators to delegate specific network maintenance tasks to others. Even if you don't expect to use these objects in the future, you must use them to create other objects with the appropriate permissions for your network.

If, for example, you don't want to have any single user with the full control granted to the Administrator account, you must still log on as administrator to create new user objects with the rights and permissions you want. With Active Directory, you can "orphan" parts of the directory structure if you modify, delete, or disable the Administrator account without first creating other user objects and granting them equivalent permissions to the various parts of the directory.

The default objects created in an Active Directory domain, along with their functions and their locations in the domain hierarchy, are listed in Table 11-2.

**Table 11-2.** *Objects created by default in an Active Directory domain*

Object Name	Object Type	Location	Function
Builtin	Builtin Domain	Domain root	Default container for groups providing access to server administration functions.
Computers	Container	Domain root	Default container for upgraded computer accounts.
Users	Container	Domain root	Default container for upgraded user accounts.
Domain Controllers	Organizational Unit	Domain root	Default container for new Windows 2000 domain controllers.
Account Operators	Security Group—Builtin Local	Builtin	Members can administer domain user and group accounts.
Administrators	Security Group—Builtin Local	Builtin	Members can fully administer the computer or domain.
Backup Operators	Security Group—Builtin Local	Builtin	Members can bypass file security to back up files.
Guests	Security Group—Builtin Local	Builtin	Users are granted guest access to the computer or domain.
Print Operators	Security Group—Builtin Local	Builtin	Members can administer domain printers.
Replicator	Security Group—Builtin Local	Builtin	Supports file replication in a domain.
Server Operators	Security Group—Builtin Local	Builtin	Members can administer domain servers.
Users	Security Group—Builtin Local	Builtin	Ordinary users.
DHCP Users	Security Group—Domain Local	Users container	Members who have read-only access to DHCP server.
DnsAdmins	Security Group—Domain Local	Users container	DNS administrators.
RAS and IAS Servers	Security Group—Domain Local	Users container	RAS and IAS servers.
WINS Users	Security Group—	Users container	Members that have read-only access to WINS.

	Domain Local		
Cert Publishers	Security Group—Global	Users container	Enterprise certification and renewal agents.
DnsUpdateProxy	Security Group—Global	Users container	DNS clients that are permitted to perform dynamic updates on behalf of some other clients (such as DHCP servers).
Domain Admins	Security Group—Global	Users container	Designated administrators of the domain.
Domain Computers	Security Group—Global	Users container	All workstations and servers joined to the domain.
Domain Controllers	Security Group—Global	Users container	All domain controllers in the domain.
Domain Guests	Security Group—Global	Users container	All domain guests.
Domain Users	Security Group—Global	Users container	All domain users.
Enterprise Admins	Security Group—Global	Users container	Designated administrators of the enterprise.
Schema Admins	Security Group—Global	Users container	Designated administrators of the schema.
Administrator	User	Users container	Built-in account for administering the computer or domain.
Guest	User	Users container	Built-in account for guest access to the computer or domain.
IUSR_xxx	User	Users container	Built-in account for anonymous access to Internet Information Services (IIS).
IWAM_xxx	User	Users container	Built-in account for anonymous access to IIS out-of-process applications.
Krbtgt	User	Users container	Key Distribution Center Service Account.

The next sections examine the procedures for creating new objects in a domain and modifying their attributes.

## Creating an Organizational Unit

The directory service schema dictate which objects you can create in an Active Directory domain, where they can be located, and which attributes they are permitted to have. Active Directory Users and Computers lets you create objects only in locations appropriate to the object type. For example, you can't create an organizational unit (OU) object that is subordinate to a user object, but a user object can be subordinate to an OU object.

OUs can be subordinate to each other, however, and the number of OU layers you can create in your Active Directory domain is unlimited. To create an OU, click the domain object or another OU in the Active Directory Users and Computers scope or result pane, choose New from the Action menu, and select Organizational Unit. You can also click the Create New Organizational Unit button on the Active Directory Users and Computers toolbar to achieve the same effect. After you specify a name for the new object in the Create New Object dialog box, the manager creates an icon with the appropriate name and inserts it into the Active Directory Users and Computers display.

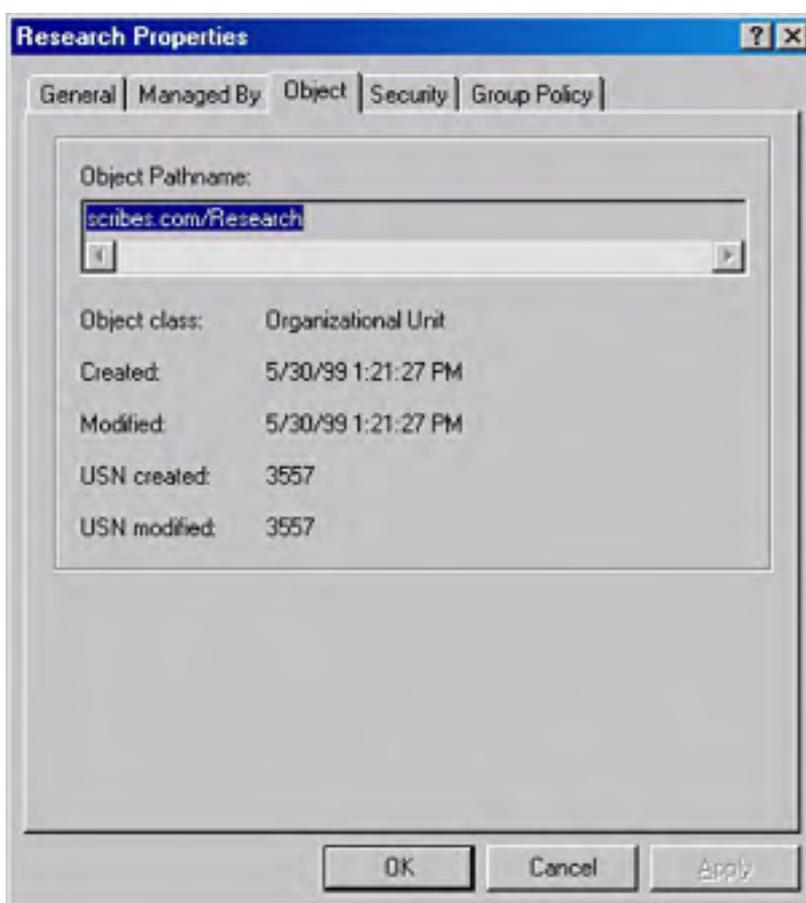

Once you've created an OU, you can populate it with other objects, such as users, computers, groups, and other OUs, or you can modify its attributes by opening the Properties dialog box from the Action menu.

## Configuring OU Objects

The Properties dialog box for an OU includes three tabs. The General tab and the Managed By tab enable you to specify information about the OU such as a descriptive phrase and an address for the location of the object, as well as the identity of the person responsible for managing the OU. The information that you include in these tabs (if any) depends on the criteria you use to design your Active Directory. An OU can be associated with a particular department within an organization; a physical location such as a room, a floor, or a building; or even a branch office in a particular city or country.

The Group Policy tab is where you create and manage the links to Group Policy objects in Active Directory. Group Policy objects are collections of system settings that control the appearance and functionality of network clients. When you apply group policies to OUs, domains, and sites, all the objects contained in those entities inherit the system settings. You can link OUs to multiple Group Policy objects in this tab, and you can control the priorities with which the policies are applied. When you use the Edit button in the Group Policy tab to modify a Group Policy object, Active Directory Users and Computers launches the Group Policy snap-in for the MMC. (For more on setting group policy and using the Group Policy snap-in, see [Chapter 9](#).)

When you enable Advanced Features in the Active Directory Users and Computers View menu, the OU's Properties dialog box also displays the Object tab (Figure 11-25) and the Security tab (Figure 11-26). The Object tab displays the full path to the object in the domain hierarchy, the dates and times of its creation and last modification, and the update sequence numbers from when it was created and last modified.

**Figure 11-25.** The Object tab of the Research Properties dialog box.

The Security tab enables you to control access to the object by assigning permissions to users and groups. With the Allow Inheritable Permissions check box, you can also control whether the object inherits permissions that have been assigned to its parent object.

The Advanced button in the Security tab provides access to the Access Control Settings dialog box, shown in Figure 11-27, from which you can control access to the object in much greater detail. In the Security dialog box, you can specify whether specific users and groups are permitted to create and delete child objects in the OU, but this screen enables you to specify which object types they can create and delete.

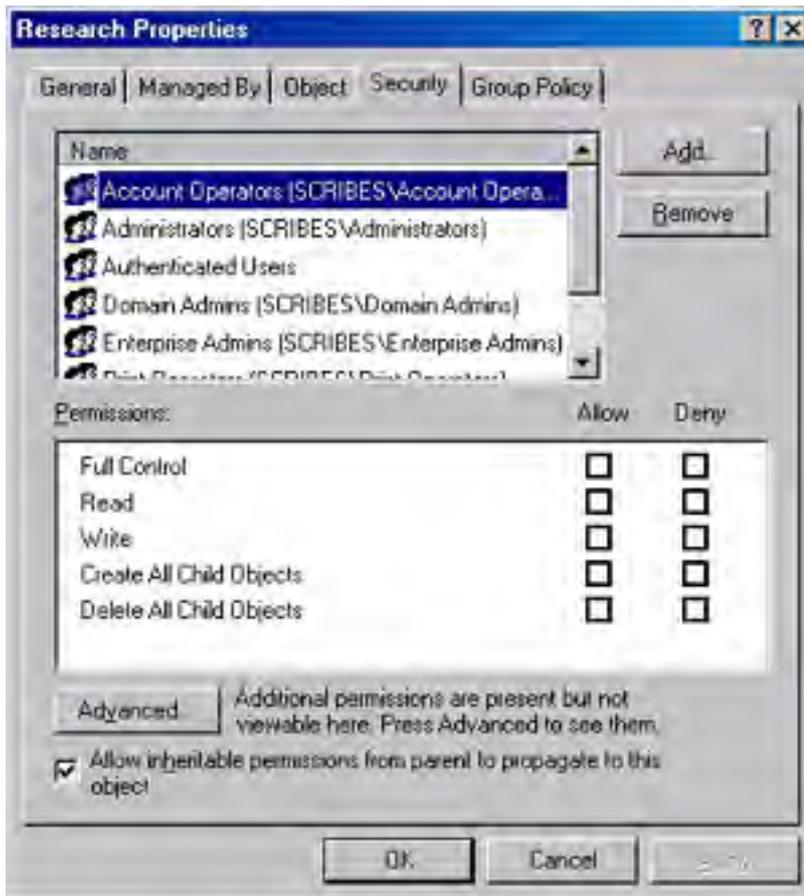

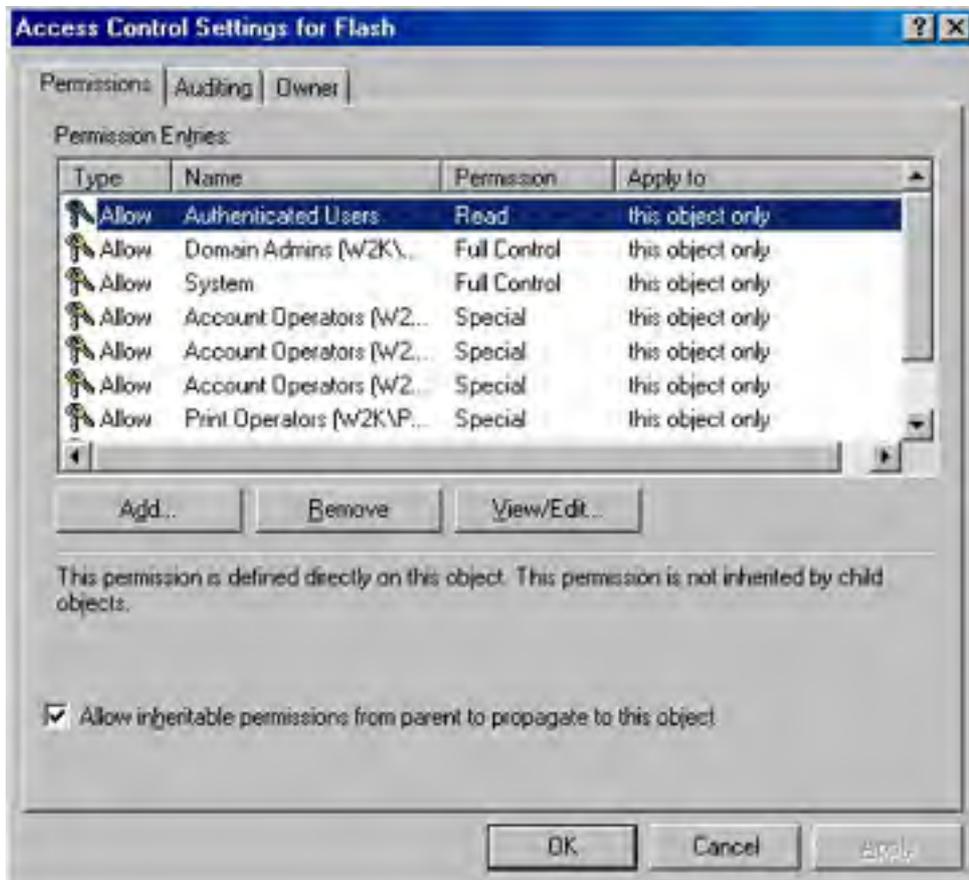

Figure 11-26. The Security tab of the Research Properties dialog box.

**Figure 11-27.** *The Access Control Settings dialog box.*

## Delegating Object Control

Active Directory is designed to support much larger enterprise networks than Windows NT domains, and larger networks naturally require more attention and maintenance from administrators. Active Directory makes it possible for administrators to delegate control over specific container objects to other users without giving them full access to the domain. To do this, launch the Delegation of Control Wizard by choosing Delegate Control from the Action menu for a domain or organizational unit.

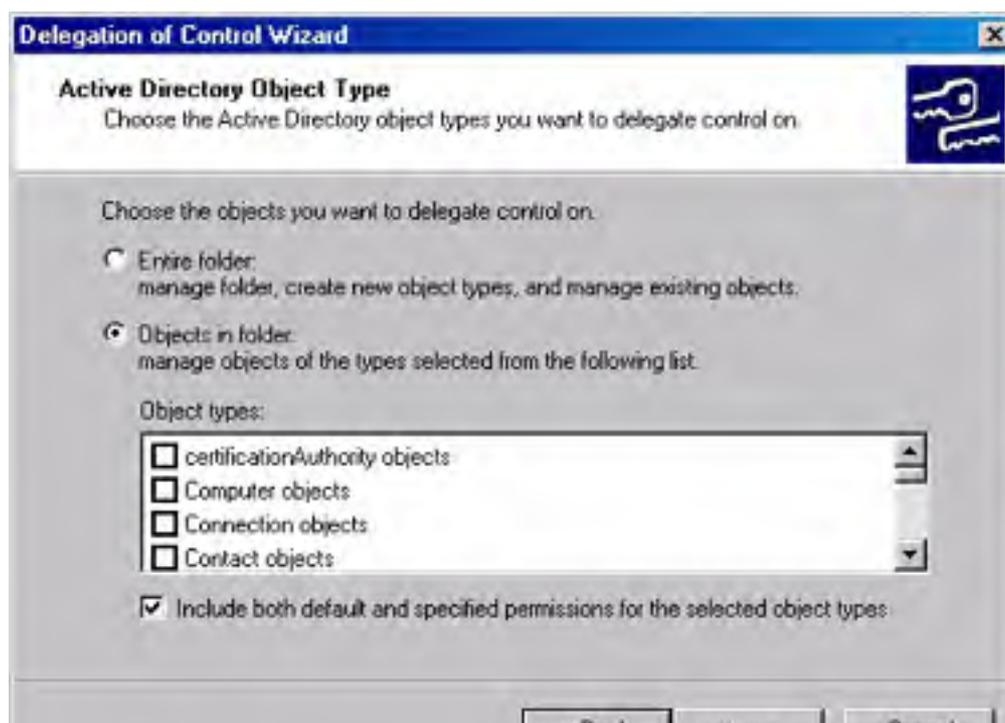

### Real World

#### Think Before You Delegate

The Delegation of Control Wizard makes it easy to delegate control over Active Directory objects and containers—too easy sometimes. Before you start delegating away your administrative authority, take the time to sit down and come up with a maximum of three or four different types of administrators to whom you'd like to delegate control, and create the appropriate groups. Then use the Delegation of Control Wizard to delegate control to the appropriate groups (don't delegate to individual users). Some suggested groups and their functions are as follows:

- **Help Desk Admins** Reset passwords (after all, what's the help desk for?)
- **Active Directory Admins** Manage users, groups, and computer accounts
- **Domain Admins** Windows 2000 built-in group for administration within a domain
- **Enterprise Admins** Windows 2000 built-in group for administering domains, forests, trusts, and replication

The wizard first prompts you to specify the container object over which you want to delegate control and the users, groups, or both to whom you want to delegate control. Once you've done this, the wizard displays the Active Directory Object Type screen (Figure 11-28) that you use to specify which types of objects in the container the selected users or groups should be able to control. You can, for example, grant a specific user or group control over the user objects in only the container, enabling them to update user information but preventing them from modifying other types of objects.

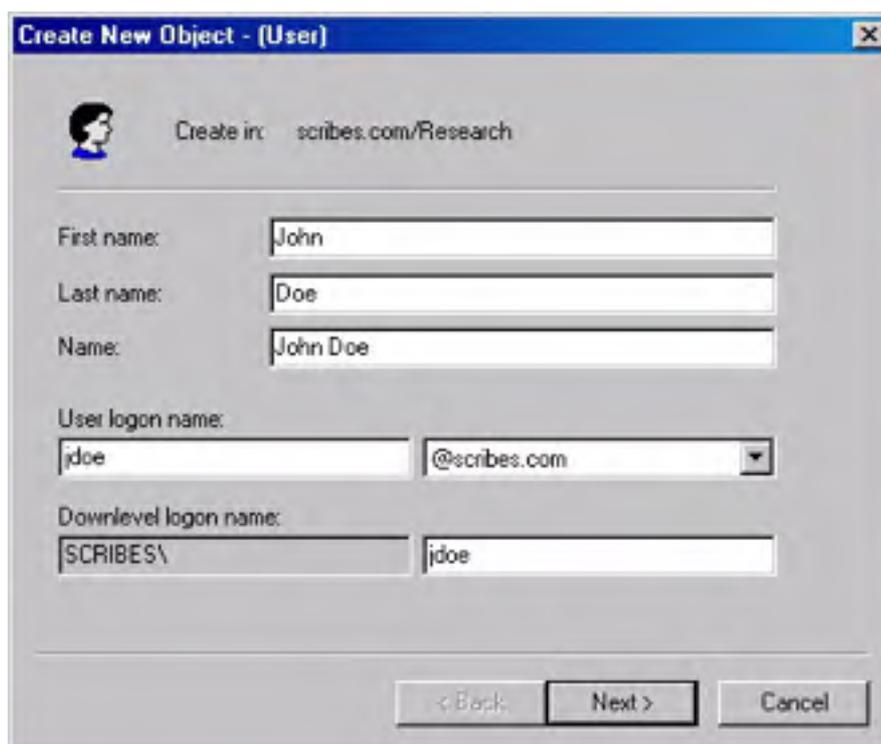

**Figure 11-28.** *The Active Directory Object Type screen of the Delegation of Control Wizard.*

In the Permissions dialog box, you specify the degree of control you want the selected groups to have over the objects you selected. The Filter Options box enables you to select whether you want to work with general permissions that concern the entire object, or property permissions that control access to the object's individual attributes. With this type of permission, you can grant users the ability to modify some of an object's properties while protecting others. This way, you can conceivably allow department managers to perform simple modifications on user objects, such as changing addresses and phone numbers, without endangering any other properties of the object.

Once you've supplied the wizard with the appropriate information, it configures the selected object with the appropriate permissions. If you check out the Security tab in the object's Properties dialog box (which is visible only when Advanced Features is enabled in the Active Directory Users and Computers View menu), you can see the permissions that the wizard has assigned to the users or groups you selected.

## Creating a User Object

A typical Active Directory installation usually consists of more user objects than any other type, and the creation and management of user objects accounts for much of the Active Directory administration burden. The task of manually creating a user object is just like that of creating an organizational unit or any other object. After selecting the container in which the user object will reside (usually an OU), you select the container and choose New from the Action menu and select User or click the Create New User button on the Active Directory Users and Computers toolbar, producing the dialog box shown in Figure 11-29.

**Figure 11-29.** *The Create New Object dialog box.*

In the Create New Object dialog box, you specify the first and last name of the user and the logon name that the user will supply when connecting to the network. The downlevel logon name for the user (that is, the name with which the user will log on at Windows NT or Windows 95/98 workstations) then appears automatically. The next dialog box provides a field for the user object's password and enables you to set basic password and account options for the user, as follows:

- User must change password at next logon
- User cannot change password
- Password never expires

- Account disabled

After a summary screen confirming your input, Active Directory Users and Computers creates the user object in the container you selected.

## Configuring User Objects

Once you've created a user object, you can proceed to the configuration process, in which you add information about the user to the Active Directory database and define the user's access to the network. The Action menu that Active Directory Users and Computers generates when you click a user object contains several of the commands most commonly used by administrators, as well as access to the Properties dialog box for the user. These commands are as follows:

- **Add Members To A Group** Generates a dialog box from which you can select the groups to which the user will belong.
- **Name Mappings** Enables administrators to map X.509 certificates and Kerberos names to the user object. This command is visible only when Advanced Features is enabled.
- **Disable Account** Prevents the user from logging on to the network using the account until it is manually enabled by an administrator.
- **Reset Password** Generates a dialog box with which you can modify the user account's logon password.
- **Move** Enables administrators to move the user object to another container object (that is, domain or organizational unit) in Active Directory.
- **Open Home Page** Opens the default browser on the system and displays the URL listed in the Home Page field in the General tab of the user object's Properties dialog box.
- **Send Mail** Opens the default e-mail client on the system and addresses a message using the e-mail address listed in the E-Mail field in the General tab of the user object's Properties dialog box.

Active Directory Users and Computers provides these functions on the Action menu for the sake of convenience, but you can also access most of them through the user object's Properties dialog box, which provides a complete interface to the object's attributes. The following sections examine the 11 tabs in this dialog box and the functions located on each one.

The attributes appearing in the tabs of the Properties dialog box are those included in the default schema used by Active Directory. You can modify the schema to create additional attributes or change existing ones using the MMC Active Directory Schema Manager snap-in. See [Chapter 12](#) for more information on using this tool.

### The General Tab

The General tab contains basic information about the user, including the first and last names you specified when creating the object. This tab also has fields for a descriptive phrase about the user, office location, and the user's telephone number, e-mail address, and home page URL. Apart from the *name* fields, the information in this tab is optional and is used solely for reference purposes. Users can search Active Directory using the values of the attributes in this (and other) tabs and automatically insert the user's e-mail address and home page URL into the appropriate client applications, but these fields don't affect the user's access to the network in any palpable way.

### The Address Tab

In the Address tab, you find fields where you can insert mailing address information for the user. As in the General tab, these are reference fields that don't play a major role in the object's configuration.

### The Account Tab

The Account tab (Figure 11-30) contains the user logon name you specified during the creation of the object as well as its downlevel user name.

The Logon Hours button and the Logon To button provide access to dialog boxes that enable you to restrict the hours and days of the week that the user is permitted to log on to the network (Figure 11-31) and the workstations from which the user can log on to the network.

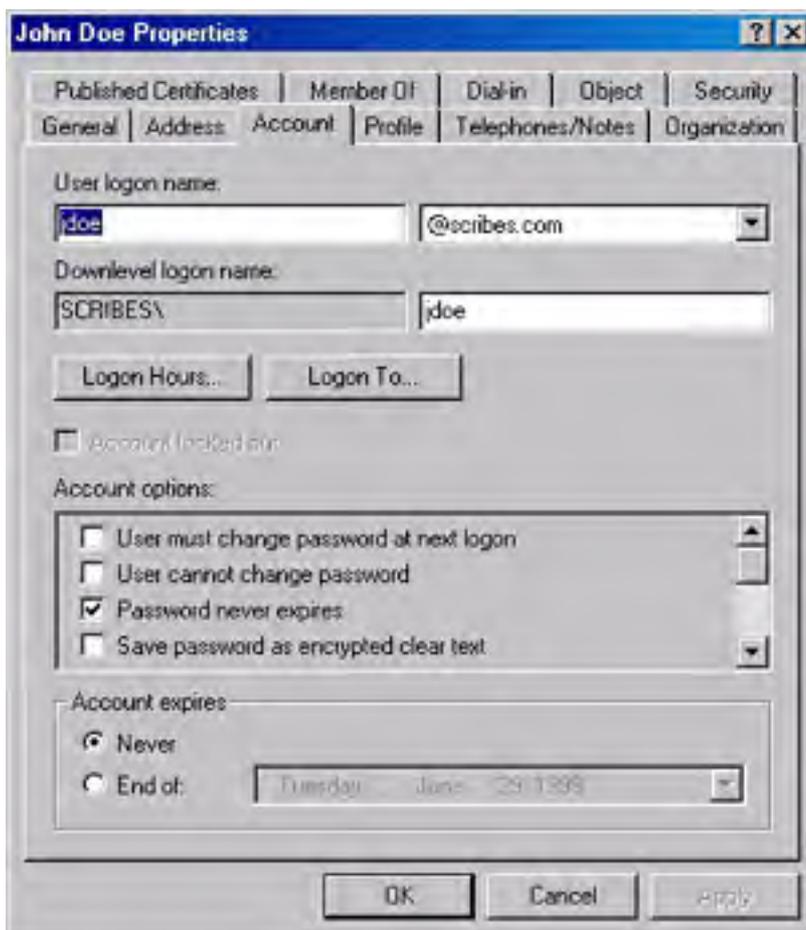

Figure 11-30. The Account tab of the Properties dialog box.

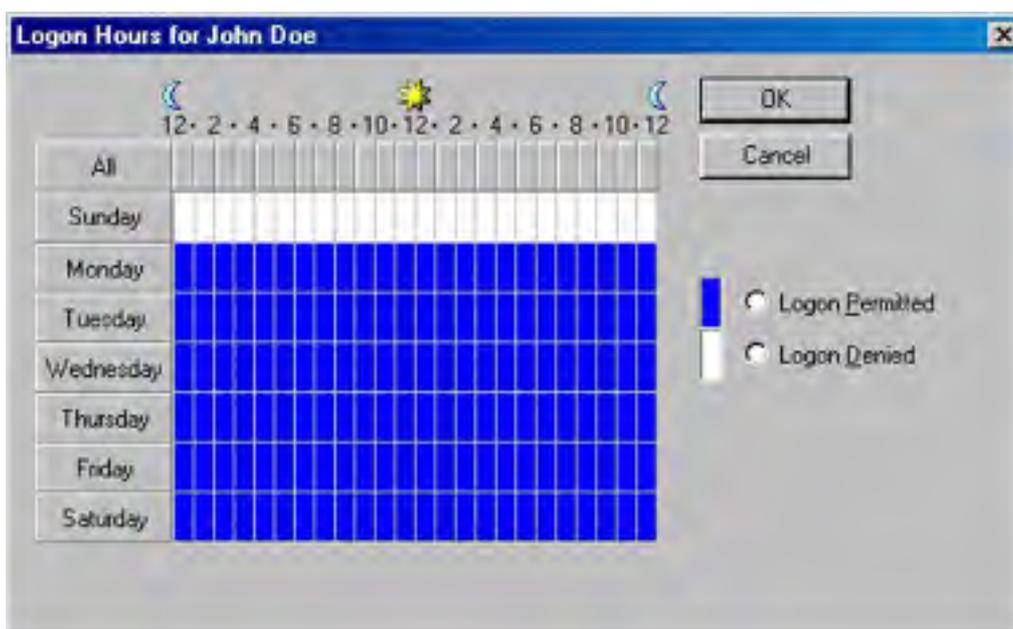

Figure 11-31. The Logon Hours dialog box.

The Account Locked Out check box is selected whenever the user account has been disabled, either deliberately by an administrator or because of repeated logon failures. Clearing this check box releases the account and permits the user to log on again. The Account Options area contains numerous password and account options (some of which are duplicated in the Create New Object dialog box). When creating new user accounts, the following must be selected or cleared:

- **User Must Change Password At Next Logon** Presents the user with a dialog box during the next logon requiring a new password.
- **User Cannot Change Password** Prevents the user from changing his or her own password.
- **Password Never Expires** Prevents the user account from being subject to expiration policies defined in the Account Expires box.
- **Account Disabled** Prevents the user from logging on using this account until it is cleared by an administrator.

### **The Profile Tab**

In the Profile tab, you can specify the location of the user profile associated with the object. By default, every user who logs on to a Windows 2000 system has a profile directory created in the Documents And Settings folder on the system drive. When you specify a profile path on this tab, the system stores a copy of the profile in the specified directory. If this directory is located on a shared network drive, the user can access the profile from any system on the network. The Logon Script field specifies the name of the script that the workstation should execute when the user logs on to the network.

From the Home Directory box, you can create a personal directory on a network drive over which the user has full control. Storing data files on a network drive makes it easier to protect them from tampering and accidental erasure. You can configure the workstation to map a drive to the shared drive automatically during the logon process by specifying a drive letter and the UNC name of a network share in the Connect fields. In the Shared Documents Folder field, you can specify a location where users who require access to the same documents can store files.

### **The Telephones/Notes Tab**

The Telephones/Notes tab contains fields for all the various phone numbers associated with a user, including pager, mobile, fax, and IP phone numbers. A multiline Comments field provides a general-purpose area for notes.

### **The Organization Tab**

The Organization tab provides fields in which you can specify the user's title, department, and company. In the Manager box, you can identify the user's superior by selecting another user object from Active Directory. A multiline Direct Report field can store a supervisor's notes on the user.

### **The Member Of Tab**

The Member Of tab is where you specify the groups of which the user should be a member. Clicking Add displays an object listing from which you can select the appropriate groups. The Set Primary Group button is enabled only for Macintosh users. Windows Services for Macintosh recognizes a single group affiliation—usually the group with which the Macintosh user shares documents on a server.

You can also add a user to a group from the Members tab of the group object's Properties dialog box.

### **The Dial-In Tab**

In the Dial-In tab, you control whether the user should be permitted access to the network through a dial-in Remote Access Service (RAS) connection. With the Allow Access option, you can select whether the user object should require callback or caller ID for security verification, and you can specify a static IP address and static routes for the connection.

### **The Published Certificates Tab**

The Published Certificates tab, which is visible only when you enable the Active Directory Users and Computers Advanced Features display option, lets you manage the X.509 certificates linked to the user object. From this page, you can view the certificates published for the user account, add new certificates, remove certificates, and export certificates to files.

### The Object Tab

The Object tab, visible only when Advanced Features is enabled, displays the full pathname of the user object, the dates it was created and last modified, and the update sequence numbers (USNs) from when it was created and last modified.

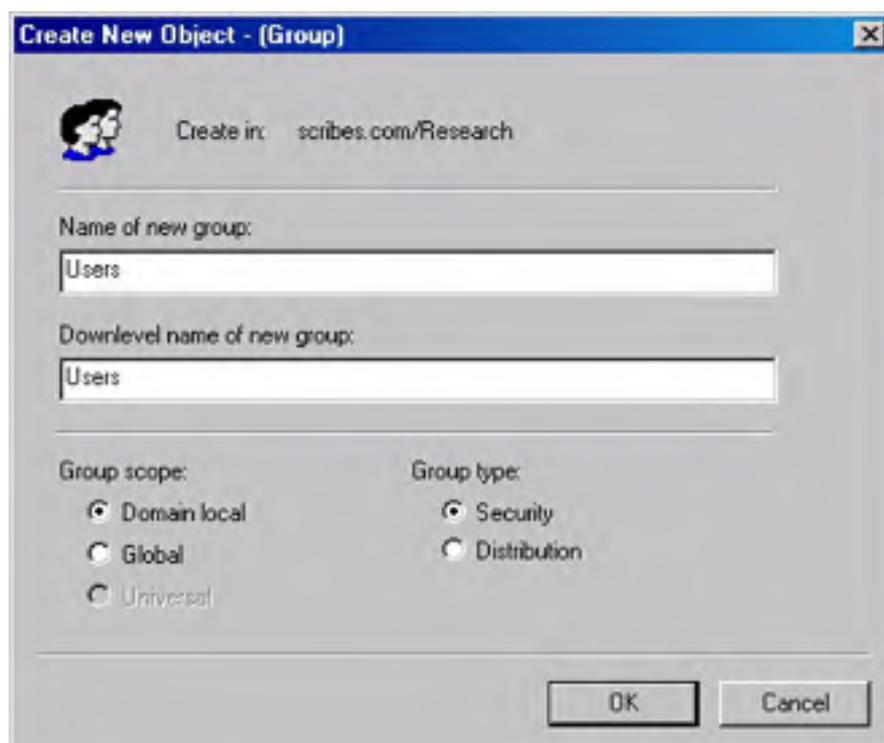

### The Security Tab

The Security tab, also visible only when Advanced Features is enabled, lets you assign permissions that control access to the user object. The tab is virtually identical to the same tab in the Properties dialog boxes for other object types. [Chapter 9](#) has more information on the creation and configuration of user accounts.

## Creating a Group

Group objects make it possible to assign permissions and other object attributes to multiple users in a single operation, as well as to distribute e-mail to a large number of addresses (when Microsoft Exchange Server is installed). When you assign permissions to an Active Directory object (or to an NTFS file or directory), you can add groups to the object's access control list (ACL), which causes the permissions to be propagated to all of the group's members. You create group objects in Active Directory Users and Computers just as you would any other object type, and then you select the objects that you want to be members of the group.

Group objects can exist in organizational units, in other groups (when the domain is operating in native mode), or directly beneath the domain root. When you select one of these container objects in Active Directory Users and Computers, choose New from the Action menu, and select Group, you see the Create New Object dialog box shown in Figure 11-32.

**Figure 11-32.** *The Create New Object dialog box.*

As with other objects, you must first specify a name (up to 64 characters long) for the new group and a downlevel NetBIOS name equivalent (up to 15 characters long). Then with the Group Scope options, select one of the following options:

- **Domain Local** A Domain Local group can contain user objects, other Domain Local groups

in the same domain, Global groups from any domain in the forest, and Universal groups. You can insert Domain Local groups into the ACL for any object in that domain but not objects in other domains. Domain Local groups don't appear in the GC.

- **Global** A Global group can contain user objects and other Global groups from the same domain. Unlike Domain Local groups, you can insert Global groups into the ACL for any object in the forest. Global groups are included in the GC, but their members are not; Global group memberships are replicated only within their domain.
- **Universal** The most comprehensive group scope, a Universal group can contain other Universal groups, Global groups, and users from any domain in the forest. Like Global groups, you can insert Universal groups into the ACL for any object in the forest. Universal groups appear in the GC with their members; using Global groups as members of the Universal group lessens the update traffic to the GC because changes to the Global group memberships (which aren't included in the catalog) are far more frequent than changes to the Universal group memberships.

Group nesting (that is, the storage of groups within other groups) is an Active Directory feature that is available only when the domain is running in native mode (except, of course, the ability to place Global groups in Local groups as was possible with Windows NT 4). To operate in native mode, all of the domain's controllers must be running Windows 2000 Server. For more information on switching from mixed mode to native mode, see the section entitled [Changing the Domain Mode](#), earlier in this chapter.

After selecting the group scope, select one of the following group types:

- **Security** Security groups are intended for inclusion in the ACLs of network resources such as files and printers. They can also serve as distribution lists for e-mail.
- **Distribution** Distribution groups are intended solely for use as e-mail distribution lists.

When you click OK, the manager creates the group object in the container you selected.

## Configuring Group Objects

The Properties dialog box for a group object contains up to six tabs (depending on whether Advanced Features is enabled), as discussed in the following sections.

### The General Tab

The General tab provides fields where you can insert a description of the group object. It specifies the group's type and scope, and includes a multiline field for comments.

### The Members Tab

The Members tab is where you specify the objects that are to be the members of the group. Clicking Add produces a dialog box in which you can browse Active Directory and select the desired objects.

### The Member Of Tab

When operating in native mode, Active Directory group objects can be members of other objects. In the Member Of tab, you can select the groups of which the new group is to be a member.

### The Managed By Tab

The Managed By tab enables you to specify information about the person responsible for administering the group object.

### The Object Tab

The Object tab (which appears only when Advanced Features is enabled in Active Directory Users and Computers) displays the full pathname of the group object, the dates of its creation and last modification, and its USNs at its creation and last modification.

### The Security Tab

The Security tab (which appears only when Advanced Features is enabled in Active Directory Users and Computers) enables you to set the permissions that specify which objects will have access to the group object and how much access they will have.

## Creating a Computer Object

In addition to container objects, group objects, and user objects, Active Directory also has objects representing computers. To log on to a domain, a Windows 2000 computer must have an object representing it in the Active Directory hierarchy. When you promote a system to a domain controller or log on to a domain for the first time, Windows 2000 automatically creates a computer object. (In the case of a first-time logon, the system prompts for the user name and password of an account with sufficient privileges to create new objects. However, you can also create computer objects manually, just as you would create any other object.)

Selecting a container, choosing New from the Action menu, and selecting Computer produces a Create New Object dialog box in which you supply the name for the new computer object (which can be the computer's NetBIOS or DNS name). You can also specify the particular user or group that is authorized to join the computer to the domain.

The Active Directory Users and Computers snap-in creates objects one at a time, but sometimes administrators have to create a great many objects, and this tool becomes impractical. For more information on creating objects en masse, see "Performing Batch Importing and Exporting" in [Chapter 12](#).

## Configuring Computer Objects

Once Active Directory Users and Computers creates the computer object, you can configure its attributes using the following seven properties: General, Operating System, Member Of, Location, Managed By, Object, and Security. Almost all of the tabs have the same purpose as those in other objects. The two that are unique to the computer object are Operating System and Location.

The Operating System tab identifies the operating system running on the computer, the version, and the currently installed service pack. These fields are not editable; they are blank when you manually create a computer object and are filled in when the computer joins a domain. The Location tab enables you to specify which locations are served by the site in the directory setup.

## Using Remote Computer Management

Active Directory Users and Computers provides administrative access to remote computers represented by objects in Active Directory. When you click a computer object and choose Manage from the Action menu, the manager opens the MMC Computer Management snap-in with that computer as its focus. With this capability, you can read the remote system's event logs, manipulate its services, and perform many of the other tasks provided by the Computer Management snap-in.

For more full-featured remote administration of Windows 2000 servers (but not Windows 2000 Professional) or Windows XP Professional desktops, use Terminal Services (also known as Remote Desktop), as described in [Chapter 26](#).

## Publishing a Shared Folder

Shared folder objects enable you to publish shared network directories in Active Directory, allowing users to access them directly by browsing in the Network Neighborhood for the object. This eliminates the need for users to know the exact location of the shared folder. Creating a shared folder object doesn't actually create the share; you must do this manually in the Sharing tab of the drive or folder's Properties dialog box in the Windows Explorer window or the My Computer window. You can also create shared folder objects from Distributed file system (Dfs) folders (discussed in [Chapter 17](#)).

To create a shared folder object, click a container object in Active Directory Users and Computers and choose New from the Action menu, and then select Shared Folder. In the Create New Object dialog box, specify a name for the new object and enter the UNC pathname to the share. After the manager creates the object, you can configure it using the tabs in the object's Properties dialog box.

The permissions that you set in the Security tab of the shared folder's Properties dialog box don't control access to the shared folder itself, only to the shared folder object. To access the folder using Active Directory, a user must have permission to access both the share and the object. The same is true for a printer object.

## **Publishing a Printer**

Creating a printer object enables users to access the printer through Active Directory in much the same way that they can access shared folders. You create a printer object just as you do a shared folder object, by selecting a container and choosing New\Printer from the Action menu and specifying the UNC path to the shared printer. The manager then creates the object, combining the name of the host system and the share to form the object name. For more information on printer administration, see [Chapter 8](#).

## **Moving, Renaming, and Deleting Objects**

Once you've created objects in Active Directory, you can use Active Directory Users and Computers to remodel your tree at any time by moving objects to different containers, renaming them, and deleting them. The Action menu for nearly every Active Directory object contains a Move command that opens a dialog box in which you can browse for a container where you want to place the object. You can also select several objects by holding down the Ctrl key while clicking them and moving them all to the same container.

Moving a container object to a new location automatically moves all of the objects within the container at the same time and also modifies the references to that object in all other Active Directory objects. If, for example, User X is a member of Group Y and you move the organizational unit containing X's user object to a new location, X remains a member of Y, and Group Y's member list is automatically updated to show X in its new location. In the same way, when you rename an object using the Rename command on the Action menu or by clicking the object once, all the references to that object throughout Active Directory change to reflect the new name. When you delete a container object, all of the objects in the container are deleted as well.

To move objects between domains, use the Movetree utility from the Windows 2000 Support Tools on the latest Service Pack CD, or a third-party administration tool. For information on the Movetree command, see Microsoft Knowledge Base Article Q238394.

## **Summary**

This chapter has covered the basic tools and techniques for administering Active Directory in Windows 2000 Server. Active Directory Users and Computers, in particular, is a tool that administrators use frequently to perform day-to-day maintenance tasks. The next chapter covers Active Directory tools that you'll use far less often.

# Chapter 12

## **Managing Active Directory**

Tasks like promoting domain controllers and creating and configuring objects are required in every Active Directory installation, but many administrators of smaller networks never have to deal with the more advanced features of Active Directory. This chapter discusses Active Directory management tools that administrators use only once in a great while, and some administrators never use at all. Tasks like modifying the Active Directory schema and dividing a large network into sites are not to be taken lightly. You should fully understand the ramifications of your actions before you even load tools like Active Directory Sites and Services or Active Directory Schema snap-ins.

## Using Active Directory Sites and Services

Active Directory Sites and Services is a snap-in for the Microsoft Management Console (MMC) that administrators use to create and manage the sites that make up a Microsoft Windows 2000 network as well as to establish links between sites. A *site*, in Active Directory terminology, is defined as a group of computers on one or more Internet Protocol subnets that are well connected. A *subnet* is a network that is a component of a larger network. For more information on subnets, see [Chapter 13](#).

*Well connected* means that the systems share a network transport that provides low-cost, high-speed communications between the machines and typically refers to systems in a single location that are connected by LANs. Systems that aren't well connected are those that use relatively slow, expensive communications. Active Directory consists of one or more sites, but sites aren't part of the namespaces you deal with when you create the Active Directory hierarchy.

When designing trees and forests for Active Directory installation, the boundaries between forests, trees, domains, and organizational units (OUs) are often politically motivated. For example, Active Directory for a large corporation might consist of separate trees corresponding to corporate divisions, domains for individual departments, and OUs for workgroups. Sites, on the other hand, are always based on geographical locations and the types of connections between those locations.

As an example, suppose this imaginary corporation has two divisions, each of which has its own Fast Ethernet LAN running at 100 Mbps. If the two divisions are located in separate buildings on the same campus, they might have a high-speed fiber-optic connection between the two LANs, also running at 100 Mbps. In this case, because all of the computers in the two divisions are equally well connected, they can be said to form a single site. If, on the other hand, the two divisions are located in separate cities and are connected by a T1 line operating at only 1.544 Mbps, the divisions would form two separate sites because all of the computers on the network aren't equally well connected.

Sites don't appear as objects in the Active Directory namespace; they're completely separate from the hierarchy of forests, trees, and domains. A site can contain objects from different domains, and a domain's objects can be split among different sites. The basic reasons for dividing an enterprise network into sites is to take advantage of the efficient communications between well-connected systems while regulating the traffic over slower, costlier connections. Specifically, Active Directory uses sites during *authentication* and *replication*:

- **Authentication** When a user logs on to the network from a workstation, the system authenticates the user with a domain controller at the same site whenever possible. This speeds up the authentication process and helps to reduce WAN traffic.
- **Replication** Domain controller replication activities that must cross site boundaries are subject to special conditions because of the need to use WAN connections.

Sites in Active Directory are associated with particular IP subnets used by your network. During the authentication process, the workstation transmits information about the subnet on which it resides. Domain controllers use this information to locate an Active Directory server on the same subnet as the workstation.

The use of sites during replication is more complex. When two domain controllers are located at the same site, replication takes place at full LAN speed: usually from 10 to 100 Mbps. Two domain controllers located in different buildings or cities, on the other hand, are likely to be connected using WAN technology that is far slower and also far more expensive than LAN technology. Therefore, maximizing the efficiency of the communications between sites is typically a matter of when and how often replications that use WAN links occur.

## Defining Site Objects

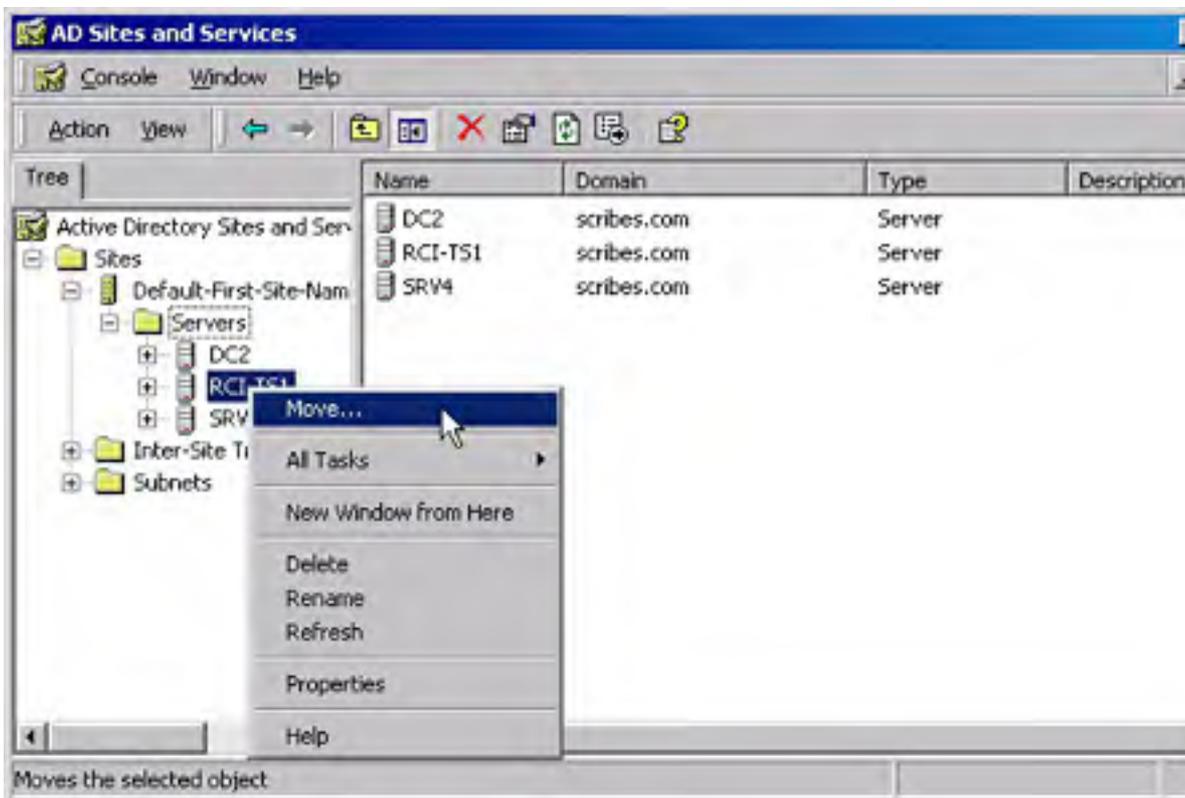

When you create the first Windows 2000 domain controller on your network, the Active Directory Installation Wizard creates your first site, names it Default-First-Site-Name (yes, that's actually the name), and associates it with the server you've just promoted. You can supply a more descriptive name for this site if you want or leave it as is. If all the Active Directory servers on your network will be located near enough to each other to communicate by using LAN connections, you don't need any other sites or the Sites and Services snap-in. As you promote each server on the network to a domain controller, Active Directory will add it to the site and automatically configure the replication topology between the servers.

If you will have servers at remote locations, however, you can create additional sites using Sites and Services. By creating subnet objects and associating them with specific sites, you give Active Directory the information it needs to automatically add each server that is subsequently promoted to a domain controller to the appropriate site, based on the subnet where the machine is located. If you move a server to a new location at a different site, however, you must also manually move the server object to the new site object. Thus, if you plan to install and configure a domain controller at the home office and then ship it to a remote location, you'll have to use Sites and Services to move the server object to the appropriate site.

To move a server to a new site, follow these steps:

1. Open Active Directory Sites and Services.
2. Click the plus sign (+) next to Sites to open the list of available sites.
3. To open the list of servers, click the site where the server currently is.
4. Right-click the server you want to move and choose Move from the shortcut menu (Figure 12-1).
5. In the Move Server window, select the new site for the server and click OK.

**Figure 12-1.** Moving a server from one site to another.

## Subnet Objects

Active Directory uses subnet objects to define the boundaries of a site. Subnet objects each consist of a network address and a subnet mask used by some or all of the computers in a site. You can associate a site with multiple subnet objects so that if your network has multiple subnets in a single location, you can include all of them in a single site. On a network with two or more sites, subnet objects are needed for the Active Directory Installation Wizard to place the server objects for newly promoted domain controllers into the correct sites. Without subnet objects, the wizard is likely to create the server object in the wrong place. If this occurs, you can manually move the server object to the proper site using the method described in the previous section.

## Server Objects

Server objects are always children of site objects and are created by the Installation Wizard whenever it promotes a Windows 2000 server to a domain controller. Don't confuse an Active Directory server object with the computer object that the wizard also creates during the promotion process. The two, although linked, are completely separate objects with different purposes. You can manually create server objects in the Sites and Services snap-in, but this shouldn't be necessary.

When Active Directory installation includes two or more sites, the Installation Wizard uses the subnets associated with the site objects to determine which site is appropriate for the server object. If no site is associated with the subnet used by a new domain controller, the wizard still creates the server object. Afterward, you'll have to create the site where the server belongs and move the server to it, or you'll need to create a new subnet object and associate it with an existing site.

## Understanding Domain Replication

Replication is the process of copying Active Directory data between domain controllers to ensure that all of them possess the same information. The Windows 2000 *multiple-master replication* capabilities make the entire replication process more complex than it is in Microsoft Windows NT. On a Windows NT network, servers write all domain directory changes to the primary domain controller first, which then propagates the information to the backup domain controllers. This process is *single-master replication*. In Windows 2000, administrators can modify Active Directory by writing to any domain controller. All of the domain controllers execute periodic replication events that copy their modifications to all the other domain controllers. The schedule and topology for these replication events differ depending on whether the domain controllers are at the same or different sites. The following sections examine these two different replication scenarios.

### Intrasite Replication

Replication between domain controllers in the same site is known as *intrasite replication* and is completely automatic and self-regulating. A module called the knowledge consistency checker (KCC) creates connections between the domain controllers in the site and triggers replication events whenever anyone modifies the directory information on a domain controller. Because all of the domain controllers in the site are assumed to be well connected, the replication process is designed to keep *latency* (that is, the delay between directory writes and their propagation to the other domain controllers) to a minimum, even at the expense of network bandwidth.

The KCC dynamically creates connection objects in Active Directory; when communication between domain controllers in the same site is disrupted, the KCC immediately creates new connections to ensure timely contact between the systems. *Timely contact* within a site means that no domain controller is more than three connections (or *hops*) away from any other domain controller. Administrators can create additional connection objects, which can improve communication between controllers and reduce latency further by decreasing the maximum number of hops allowed, but this approach also increases the system resources used by the replication process, including processor cycles, disk accesses, and network bandwidth. As a general rule, the replication topology within a site requires no administrative maintenance.

### Intersite Replication

When you create multiple sites in Active Directory, the domain controllers assume that the network connections between the sites are slower than those within a site, more expensive, or both. As a result, the domain controllers use *intersite replication* to attempt to minimize the replication traffic between sites and also to provide administrators with a much more flexible replication topology.

When you have domain controllers in multiple sites, Active Directory still creates a default replication topology automatically during the installation process. However, distinct differences exist between the default replication patterns for intrasite and intersite topologies. These differences include the following:

- **Number of connections** The KCC still automatically creates connections between domain controllers in different sites, but it creates fewer of them. The three-hop-maximum rule isn't observed between sites, in the interests of minimizing the bandwidth used.
- **Replication schedule** Replication activities within a site are triggered by changes to the Active Directory database on a domain controller. Replication between sites takes place at scheduled times and intervals. Administrators can customize the schedule to take advantage of time periods when traffic is low and bandwidth is less expensive.
- **Compression** Domain controllers transmit replication data uncompressed within a site,

thus saving the processor cycles needed to decompress the data at the destination. Traffic between sites is always transmitted in compressed form, to conserve bandwidth.

One of the primary functions of the Sites and Services snap-in is to configure the replication pattern between sites. To do this, you create site link and site link bridge objects that specify how and when replication data should be transmitted between sites. The following sections examine the functions of Sites and Services and how you use it to create a customized domain controller replication topology for your network.

## Launching Sites and Services

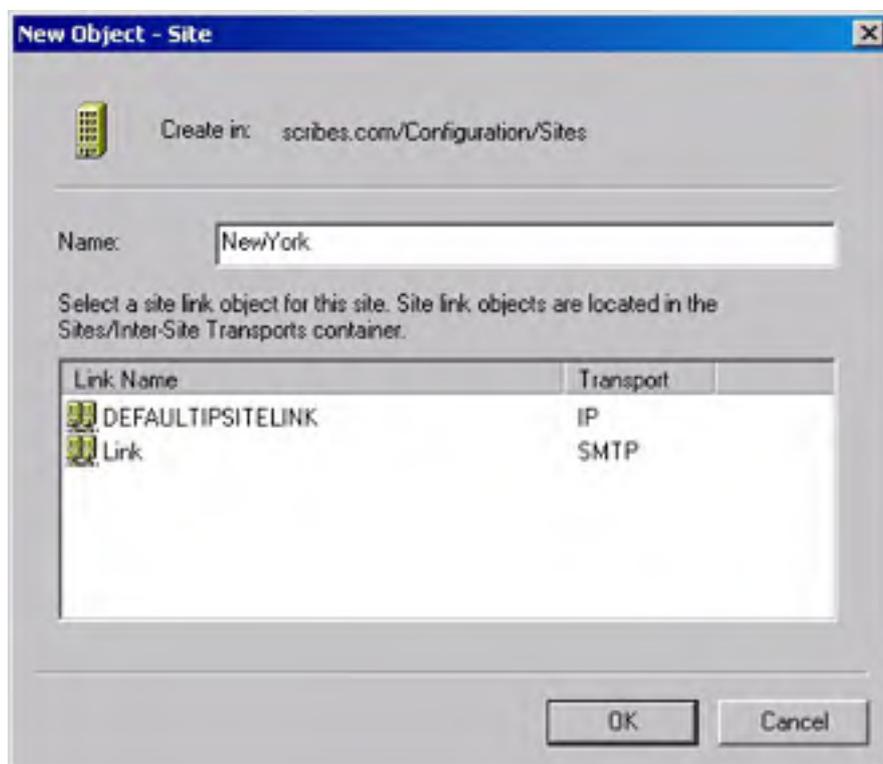

The Sites and Services tool is a standard snap-in for the MMC application, which you launch by selecting Active Directory Sites and Services from the Administrative Tools folder in the Start menu's Programs group. The snap-in module is called *Dssite.msc*; you can also launch Sites and Services by executing that filename from the command line or the Run dialog box.

## Viewing Replication Objects

The Sites and Services interface uses the same console tree and result panes as many of the other Active Directory administration tools. The Sites container in the console tree contains the *Default-First-Site-Name* object automatically created by the Active Directory installation, and two other containers called the Inter-Site Transports container and the Subnets container. When you create additional sites, they appear as separate objects in the Sites container. Administrator-created objects appear in the containers under Sites, subnet objects in the Subnets container, and site link and site link bridge objects in the Inter-Site Transports container.

## Creating Site Objects

Creating additional site objects in Active Directory is simply a matter of right-clicking the Sites container and choosing New Site from the shortcut menu. When the New Object - Site dialog box appears (Figure 12-2), you supply a name for the site object and select a site link that it should use to define the transport mechanism for the site. The Active Directory Installation Wizard creates the *Defaultipsitelink* object during the installation process, so this object is always available if you haven't yet created any other site links. After the site object is created, you can move server objects into it and associate them with the subnets on which they're located.

**Figure 12-2.** The New Object - Site dialog box.

**Examining Site Object Properties** Each site object in Active Directory has a Servers container holding objects representing the servers in the site, a *Licensing Site Settings* object, and an *NTDS*

*Settings* object. The site object's Properties dialog box enables you to specify a description for the site and its location, as well as containing the standard Object, Security, and Group Policy tabs found in the dialog boxes of so many other Active Directory objects.

The *Licensing Site Settings* object specifies the computer and domain licensing the site. In the Properties dialog box for the *NTDS Settings* object, you can disable the KCC's automatic generation of a replication topology either within the site, between this site and other sites, or both. If you want to manually configure the replication behavior for a site, you can enable these options, but this is usually unnecessary. You can create additional connections to supplement those created by the KCC and configure the site's replication behavior in other ways without disabling its core functionality.

## Creating Server and Connection Objects

Server objects are created during the installation of Active Directory on each domain controller, in the site associated with the subnet on which the server is located. Each server object contains an *NTDS Settings* object, which in turn contains the objects that represent that server's connections to other domain controllers on the network. These connections must exist for domain controllers to replicate their Active Directory data. All connections, whether created automatically by the KCC or manually by an administrator, appear as objects associated with a server. A connection object is a unidirectional conduit to another domain controller on the network, either in the same or another site. For replication traffic to travel in both directions, separate connection objects must exist for each of the two servers.

The KCC automatically creates connection objects that ensure the continued replication of Active Directory data to all of the functioning domain controllers in each domain. When the status of your network changes—such as when a domain controller goes down and forces the replication traffic between any other two domain controllers in the site to travel over more than three hops—the KCC creates new connection objects to reduce that traffic path to three hops or fewer. When the nonfunctioning domain controller becomes operational again, the KCC can remove connection objects to bring the replication traffic back to its recommended topology.

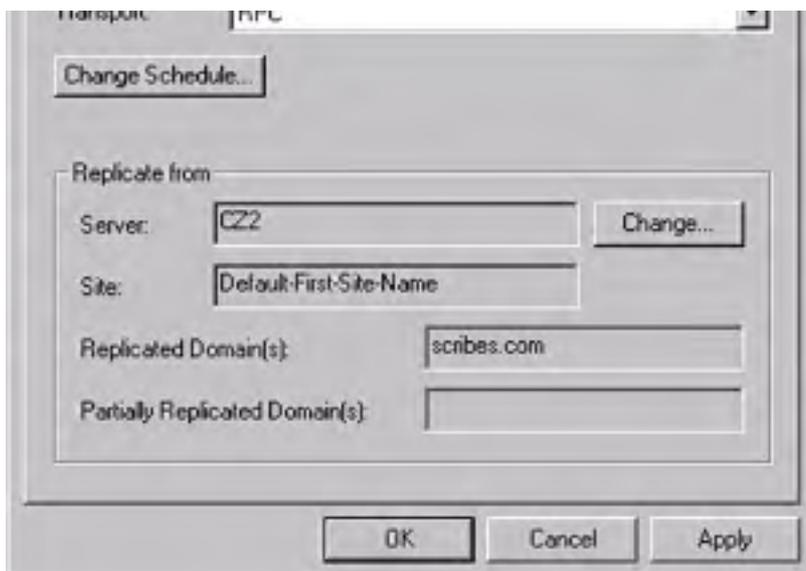

Normally, the only reason you'd manually create connection objects is to customize your network's replication topology. If, for example, you want replication activities to occur only at specific times, you can create a connection object and configure its schedule. You can also create connection objects to decrease the number of hops between specific domain controllers.

The major difference between manually created connection objects and those created by the KCC is that the manual objects remain in place until you remove them manually; the KCC doesn't remove them no matter how the replication topology changes. Connection objects created by the KCC, however, are removed automatically as the replication topology changes. To create a connection object, follow these steps:

1. Right-click a server's *NTDS Settings* object in the Sites and Services console tree and choose New Active Directory Connection from the shortcut menu. This displays the Find Domain Controllers dialog box.
2. Select the domain controller you want to create a connection to and click OK to open the New Object Connection dialog box.
3. Supply a name for the new connection and click OK. The program adds a connection object to the details pane.

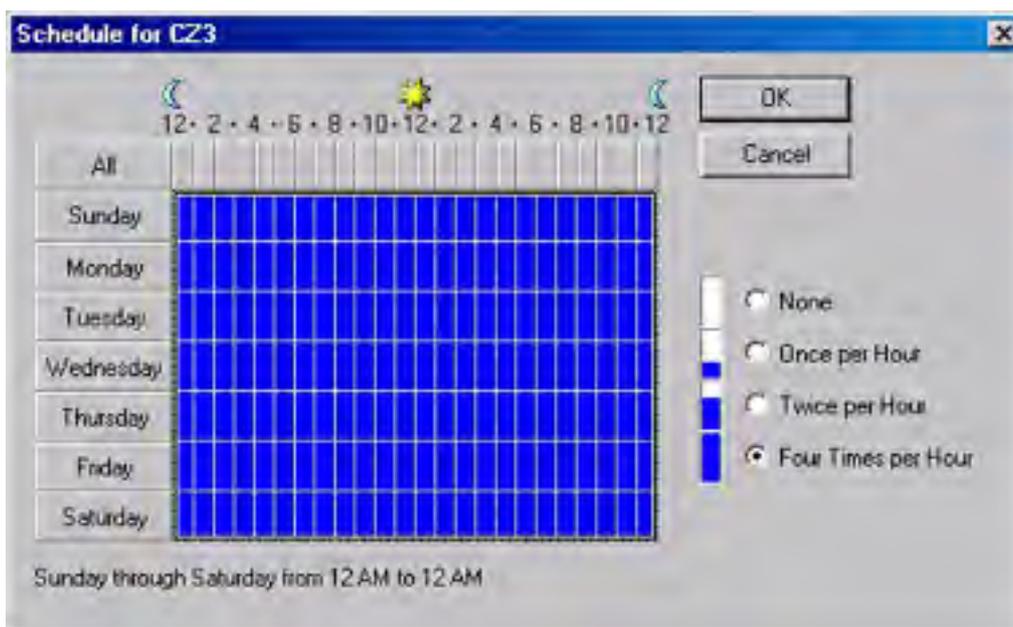

The Properties dialog box for a connection object contains the familiar Object tab and Security tab, as well as an Active Directory Connection tab, shown in Figure 12-3. In this tab, you can supply a descriptive phrase for the connection, select the mode of transport for the replication messages (IP, RPC, or SMTP), and schedule the replication events.

**Figure 12-3.** The Active Directory Connection tab of the Properties dialog box.

The dialog box displayed when you click Change Schedule (Figure 12-4) enables you to specify the hours of the day during which replication should occur and the interval between replication events (either once, twice, or four times an hour). Keep in mind that this connection controls only the replication messages traveling from the server under which the object appears to the server you selected as the destination when creating the object. Traffic going in the other direction is controlled by the other server's connection object (if it exists).

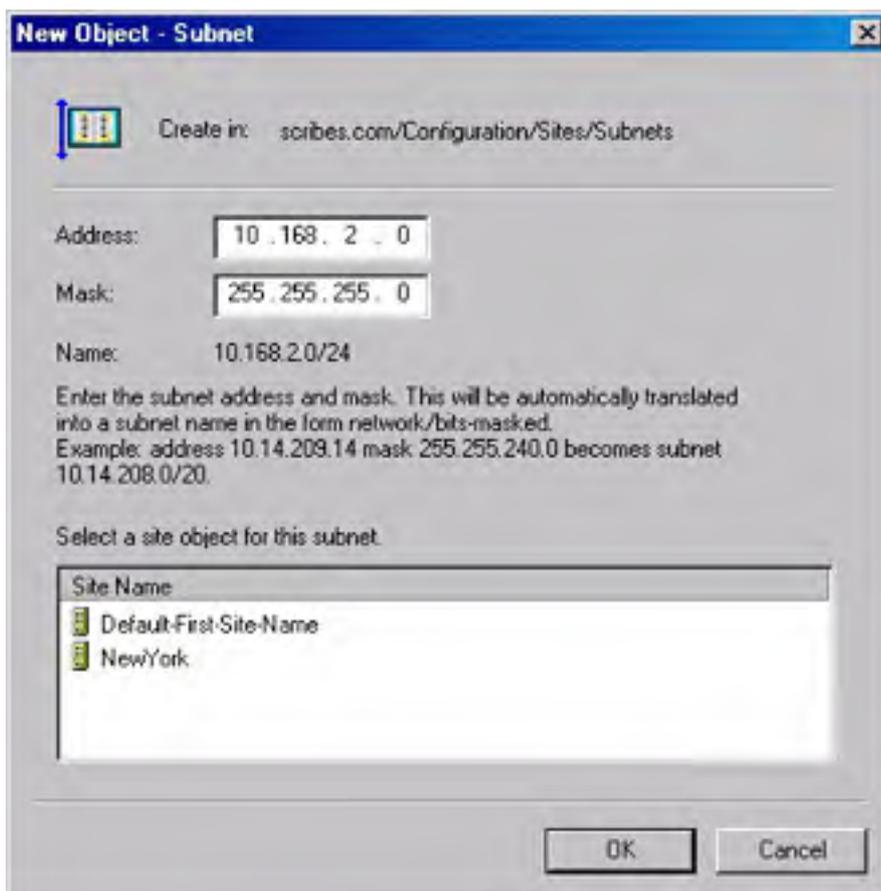

**Figure 12-4.** The Schedule dialog box.

## Creating Subnet Objects

Administrators create objects representing the IP subnets on the network and associate them with specific site objects in the Subnets container. When you promote the first server to a domain controller, the Active Directory Installation Wizard creates a site and places the server object in that site. If you create additional sites, subnet objects are used to ensure that each subsequent domain controller you install is placed in the appropriate site. During the promotion process, the wizard identifies the subnet on which the server resides and searches Active Directory for a corresponding subnet object. When the wizard finds the subnet object, it reads its properties to determine the site with which that subnet is associated, and it creates the new server object in that site.

Subnet objects aren't essential to Active Directory's replication topology. You can create sites and move the server objects into them manually. However, if you'll be installing a lot of servers, subnet objects automate the construction of the replication topology and make the entire site deployment process more manageable. To create a subnet object, follow these steps:

1. Right-click the Subnets container in the console tree of the Sites and Services snap-in and choose New Subnet from the shortcut menu.
2. In the New Object - Subnet dialog box (Figure 12-5), type the name for the object, which must be the subnet's network address and mask.
3. Select the site with which that subnet is to be associated and click OK.

**Figure 12-5.** The New Object - Subnet dialog box.

Any servers on that subnet that you promote to domain controllers will be automatically added to this site. You can associate multiple subnets with a single site to support a network of almost any size.

The network address is the portion of the IP address that identifies the network on which a computer resides. The number of bits masked refers to how many of each IP address's 32 bits the system uses to identify the network. The design of the network and the IP addresses you use for workstations determine the value for this number. For example, if your organization has a class B network address (which uses 16 bits to identify the network) and uses a further 8 bits to identify subnets, the result is a total of 24 out of 32 bits that are devoted to the network address. The value for the subnet object's name field would therefore be something like 10.168.2.0/24.

## Creating Site Link Objects

The Inter-Site Transports container is where you create the site link and site link bridge objects that dictate how replication traffic is to be transmitted between sites. Two containers within Inter-Site Transports represent the two transport protocols supported by Active Directory: IP and Simple Mail Transfer Protocol (SMTP).

A site link object represents the WAN mechanism used to transmit data between two sites, such as a leased T1 connection or an Asynchronous Transfer Mode (ATM) backbone, in the case of IP, or any means by which systems send e-mail using SMTP. Active Directory creates a default site link object called *Defaultipsitelink* when it creates the network's first site during the promotion of the first server to a domain controller. If all your sites are linked using technologies with exactly the same speed, you don't need to create additional site links. When you have different technologies connecting sites, however, you create multiple site link objects to have different replication schedules for each one.

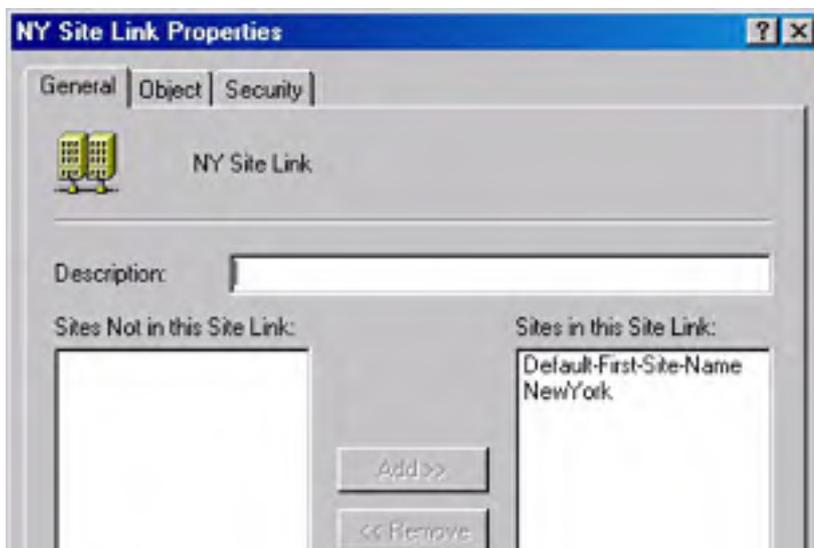

When creating a site link object, you select two or more sites that are connected by the transport mechanism and specify a cost value for the link. The cost value enables you to assign priorities to the various WAN connections, based on their relative speeds. A higher cost value indicates that a connection is more expensive to use, and the KCC schedules less frequent replications on its connections between those two sites as a result. Each increment in the cost value represents 15 minutes in the replication schedule. A cost value of 3, for example, would cause replication to occur every 45 minutes.

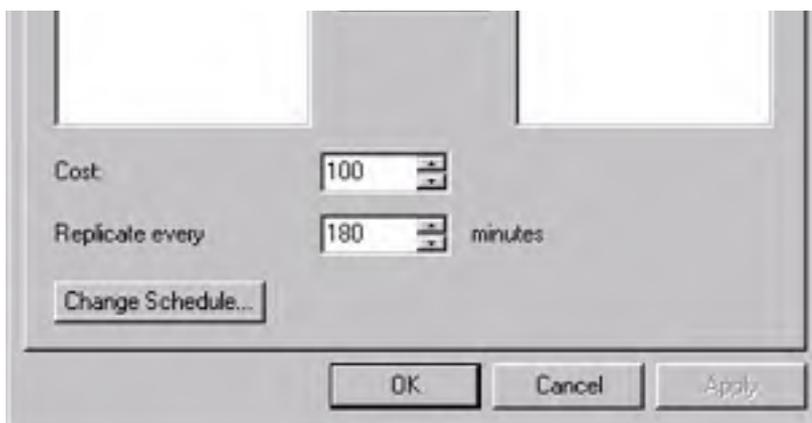

To create a site link object, follow these steps:

1. Right-click either the IP or SMTP transport in the console tree of Sites and Services and choose New Site Link from the shortcut menu.
2. In the New Object - Site Link dialog box, specify a name for the object and select the sites that the link connects. If the link is to represent a point-to-point connection like a T1, you select only two sites. For a technology like an ATM backbone, which can connect several sites, you would select more than two site objects. When the site link object connects more than two site objects, you can assume that any one of the chosen sites can transmit to any other chosen site.
3. Click OK, and the manager creates the link object.

Site link objects can't route replication traffic. This means that if a site link connects site A to site B and another link connects site B to site C, site A can't transmit to site C. For this to occur, you must create a site link bridge, as explained in the section entitled [Creating Site Link Bridge Objects](#), later in this chapter.

**Configuring Site Links** Right-click the new link object and select Properties to configure its properties. The Site Link Properties dialog box for a site link object (Figure 12-6) contains the standard Object tab and Security tab, as well as a General tab in which you can provide a description of the object and specify the sites connected by the link. You can add new sites to the link as needed after creating the object.

**Figure 12-6.** The General tab of the Site Link Properties dialog box.

The General tab also contains fields with which to specify the cost for the link (from 1 to 32,767) and the interval between replication events (from 15 to 10,080 minutes). Clicking Change Schedule enables you to specify time periods during which replication is or is not permitted. If you want to limit replication activities to nonpeak traffic hours, for example, you can specify that replication events not occur between the hours of 9 A.M. and 5 P.M. The KCC observes the site link object's scheduling limitations when it dynamically creates connections between domain controllers.

Although the cost value determines the interval between replication events, you can adjust the frequency of replication by using the Replicate Every selector in the General tab of the Site Link Properties dialog box. If clients are consistently receiving incorrect directory information from domain controllers, increase the frequency of replication.

### Creating Site Link Bridge Objects

Site link bridge objects function much like site links, except that instead of grouping sites, they group site links. A site link bridge object typically represents a router in the network infrastructure. You create a site link bridge object to enable route replication traffic between linked sites. When you create a site link bridge containing two links that connect site A to site B and site B to site C, the bridge makes it possible for site A to transmit replication data to site C through site B.

The procedure for creating a site link bridge object is virtually identical to that of creating a site link object, except that you select two or more site links instead of sites. You don't need to specify a routing cost for a site link bridge because Active Directory automatically computes it by adding up the routing costs of all of the bridge's sites. Thus, a site link bridge object containing two sites with routing costs of 3 and 4 would have a routing cost of 7.

## Using Active Directory Schema

The *schema* is the blueprint of Active Directory, dictating what kinds of objects can exist in the database and what the attributes of those objects are. To customize Active Directory for use on a network, you can modify the schema to create new object types, add new attributes to existing object types, and modify the type of information installed on an attribute. To do this, use the MMC snap-in called Active Directory Schema.

Modifying the schema is a task that the average administrator will never have to perform. At most, you'll change the schema occasionally or perhaps only once. Modifying the schema is subject to the same cautions as modifying a Windows 2000 system's registry, except on a larger scale. Just as improper registry modifications can adversely affect a single system, improper schema modifications can have a devastating effect on the entire network.

Before you can add any Microsoft Windows .NET Server family domain controllers to an existing Windows 2000 forest, you must upgrade the schema using the Windows .NET Server CD-ROM.

## Examining Schema Security

Because modifying the Active Directory schema isn't something you should do casually, Windows 2000 uses several safety mechanisms to prevent the schema from being modified accidentally or injudiciously. You can modify the schema only when the requirements of all three safety mechanisms have been satisfied.

### Schema Administrator Permissions

To modify the schema, you must be logged on to a Windows 2000 server or workstation using an account that is a member of the Schema Administrators group. This is a built-in group created during Active Directory installation that grants its members permission to write to the schema object. The Administrator account is automatically made a member of the Schema Administrators group. Users who aren't members of this group can also modify the schema if an administrator has granted them the appropriate permissions to the schema object.

### Flexible Single Master Operations

Active Directory uses a multiple-master replication system for modifications of the database contents, but for schema modifications, it uses a single-master system. This means that only one domain controller can modify the schema at once. Unlike most single-master replication models, which require all modifications to be written to one designated system and subsequently copied to the other replicas, administrators can modify the Active Directory schema from any domain controller. The mechanism that makes this possible is called Flexible Single Master Operations (FSMO). While an administrator is modifying the schema on one domain controller, write access requests to the schema on all of the other domain controllers will be denied.

To move the FSMO role, see the section entitled [Transferring the Schema Master](#), later in this chapter.

### Read-Only Schema Access

Finally, all domain controllers are configured by default during Active Directory installation to permit read-only access to the schema. To enable write access, you must create a new entry in the registry. Using one of the Windows 2000 registry editors (Regedit.exe or Regedt32.exe), browse to this key:

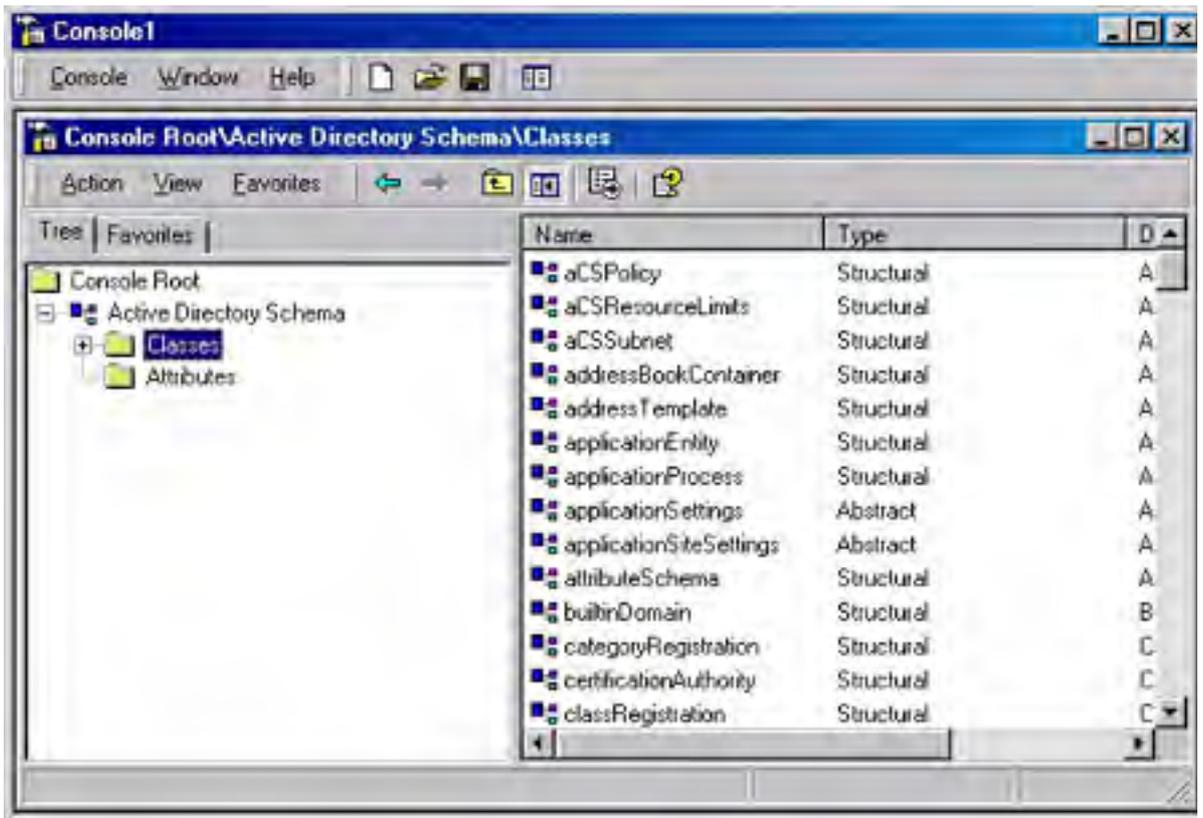

```
HKEY_LOCAL_MACHINE\System\Current Control Set\Services\NTDS\Parameters
```

Create a new DWORD entry called *Schema Update Allowed*. Assign the entry a value of *1* to enable write access to the schema. Change the value to *0* to disable write access again after the modifications are complete.

## Launching Active Directory Schema

Because of its infrequent use and potential dangers, the Schema Manager is two removes from the Administrative Tools menu. To view or change the schema, you must first install the Administrative Tools (as described in [Chapter 10](#)). Then run the Active Directory Schema snap-in in an MMC console by following these steps:

1. Click Start and select Run. Type *mmc* and press Enter.
2. Select Add/Remove Snap-In from the Console menu.
3. Click Add and select Active Directory Schema from the list of snap-ins provided. Once the snap-in is loaded, you can save the console screen to a file to provide easy access to the snap-in in the future. When the view pane opens, you see two containers in the console tree, which hold the object classes and the attributes that make up those classes, shown in Figure 12-7. Selecting either of these two containers displays Active Directory's classes or attributes in the result pane.

**Figure 12-7.** Schema Manager object classes and attributes stored in Active Directory.

However, before changing the schema, be sure that the schema snap-in is accessing the Active Directory database on the domain controller that is currently functioning as the master (that is, the one domain controller to which write access is permitted). To determine which domain controller you are currently accessing, follow these steps:

1. Select Active Directory Schema and choose Change Domain Controller from the shortcut menu. In the Change Domain Controller dialog box (Figure 12-8), you'll see the current domain controller and be able to change the focus to any other domain controller, or you can specify a particular controller.
2. Right-click the Active Directory Schema object in the console tree and choose Operations Master from the shortcut menu.
3. In the Change Operations Master dialog box, you'll see which domain controller is the operations master and specify whether the schema can be modified on that system. To change the schema, either change the master replica to the domain controller you're currently using or change the replica you're using to the master.

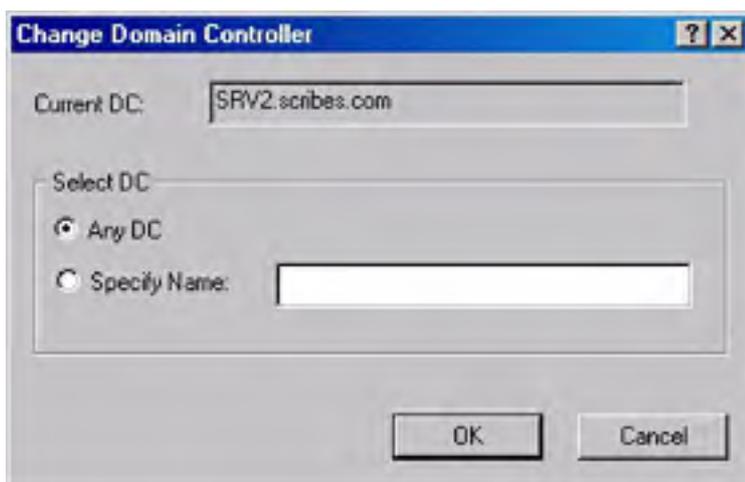

Figure 12-8. The Change Domain Controller dialog box.

## Modifying the Schema

The process of modifying the Active Directory schema involves creating or modifying the classes and attribute object types displayed in Schema Manager. *Classes* are essentially collections of attributes that either form an Active Directory object type by themselves or contribute certain attributes to another object type. The latter instance is known as an *auxiliary class*. To add attributes to an existing object type, the best method is to create a new class containing the new attributes and add it to the object type as an auxiliary. This method is more manageable and less dangerous than modifying the class representing the object type itself.

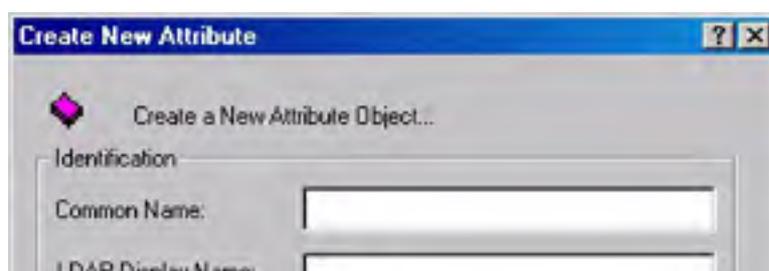

Third-party software products might supply their own schema modifications that create entirely new object types, but adding attributes to an existing object type is the most common form of schema modification manually performed by administrators—for example, adding attributes to the user object type that enable you to store additional information about the user in Active Directory. This relatively easy process consists of the following steps, which are examined in more detail in the following sections:

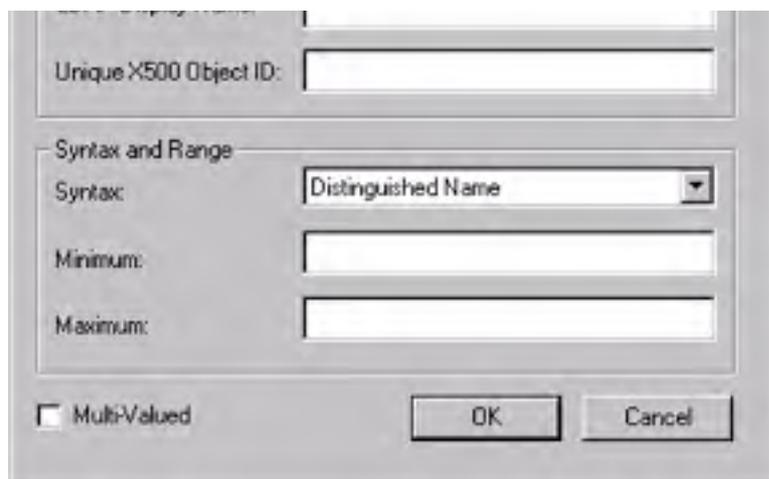

- Creating new attribute objects corresponding to the information fields you want to add to the object
- Creating a new class object to be used as an auxiliary to the existing object type
- Adding the newly created attributes to the new auxiliary class
- Adding the auxiliary class to the existing object class

## Creating Attributes

Creating an attribute is a matter of supplying a name by which the attribute will be identified and specifying the type of data that will be stored there. The data can be text or numerical, and you can apply constraints that limit the data to a particular length or value type. For example, to add an attribute to hold the user's social security number, you would specify that the attribute's data should be in integer form and limited to nine digits. To create an attribute object, follow these steps:

1. Right-click the Attributes container in Schema Manager's console tree and choose New Attribute from the shortcut menu. This produces the Create New Attribute dialog box shown in Figure 12-9.

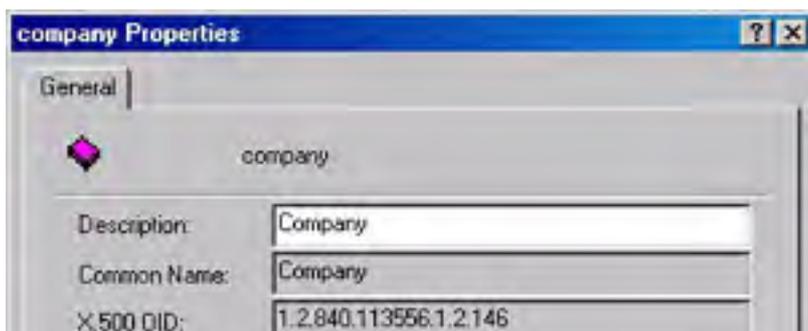

**Figure 12-9.** *The Create New Attribute dialog box.*

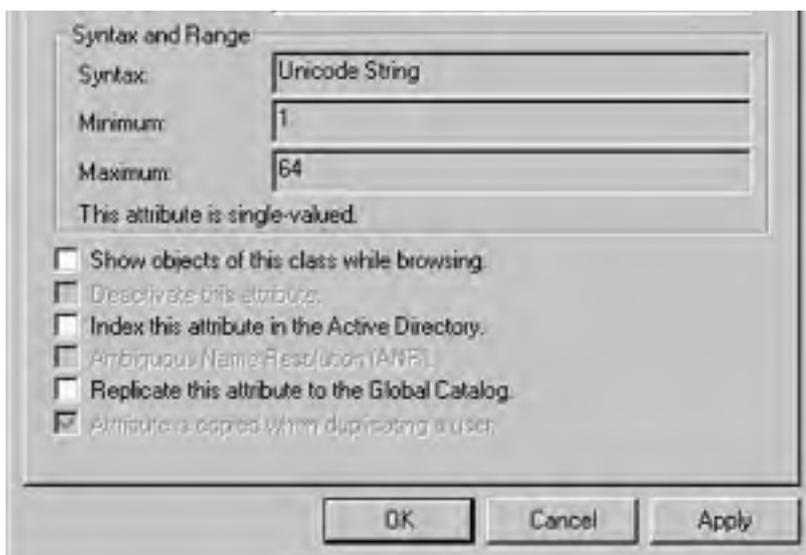

2. In the Identification box, specify the name for the new object. The Common Name field should contain the name by which the attribute will be listed in standard dialog boxes, and the LDAP Display Name field should contain the name by which it is known in the LDAP directory hierarchy. (LDAP stands for Lightweight Directory Access Protocol.) Often, these two names are the same. The Unique X500 Object ID field must contain a numerical string that uniquely identifies the attribute object in the X.500 namespace. Standards bodies like the International Telecommunications Union issue Object IDs (OIDs) to ensure that they have unique values.
3. In the Syntax And Range box, define the nature of the data to be stored in the attribute. The Syntax field provides more than a dozen options that define the types of information that can be stored in an attribute. The Minimum field and Maximum field enable you to define a range of possible values. You can also specify whether the attribute should be able to have multiple values.
4. Click OK, and the manager creates the new attribute object.

Don't be tempted to make up your own OIDs. Even if you're running Active Directory on an isolated network, it's all too easy to supply an OID for a new attribute or class that duplicates one of the hundreds of other OIDs already assigned to Active Directory objects.

Configure the new (or any other) attribute object by opening the Properties dialog box from its shortcut menu, shown in Figure 12-10. From this window, you can specify a description for the object, modify its range of possible values, and enable any of the following options:

- Show objects of this class while browsing
- Deactivate this attribute
- Index this attribute in Active Directory
- Ambiguous Name Resolution (ANR)
- Replicate this attribute to the Global Catalog (GC)
- Attribute is copied when duplicating a user

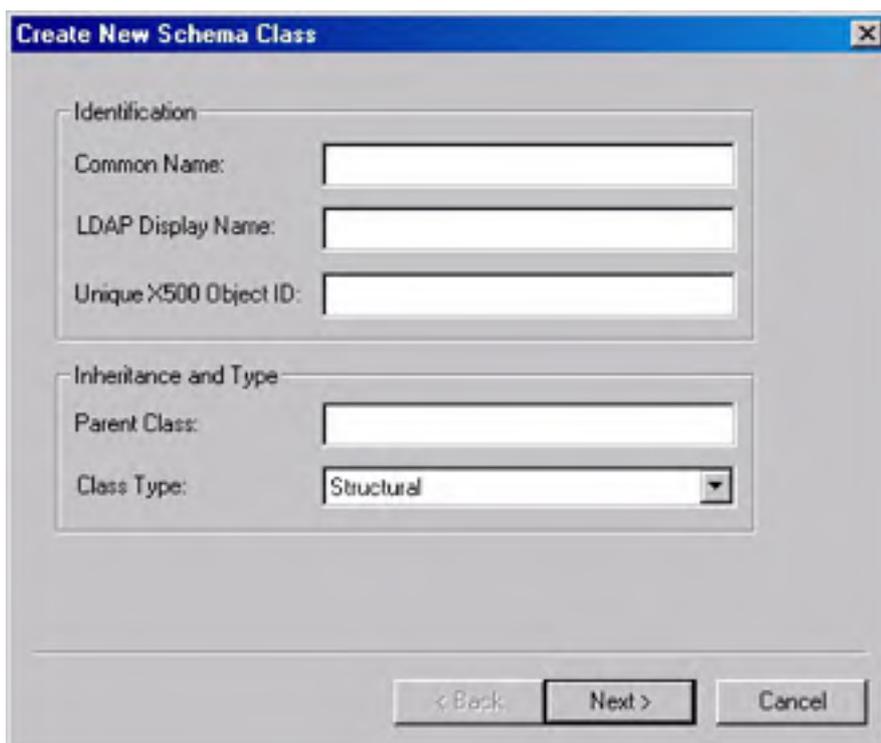

**Figure 12-10.** The Properties dialog box of an attribute object.

## Creating Object Classes

Attribute objects by themselves are useless until they belong to an object class. You can add the attribute objects you've created to an existing class, but creating a new class object for them is generally more practical. To create a class object, right-click the Classes container in the schema snap-in and choose Create Class from the shortcut menu. This displays the Create New Schema Class dialog box shown in Figure 12-11.

**Figure 12-11.** The Create New Schema Class dialog box.

As with an attribute object, you must first specify a common name, an LDAP display name, and a unique X.500 object ID. Then, in the Inheritance And Type box, specify the parent class for the new object (that is, the class from which the new object should be derived), and choose one of the following three class types:

- **Structural class** The typical directory objects that you work with in programs like Active Directory Manager. A structural class object can have either an abstract class or another structural class as its parent object.

- **Abstract class** Objects from which structural class objects are derived. You can also specify an existing abstract class as the parent of a new abstract class object.
- **Auxiliary class** Collections of attributes that you can add to either an abstract or structural class object to augment its capabilities. New auxiliary class objects can be derived only from abstract classes.

To hold your new attributes, you should create an auxiliary class type.

### Adding Attributes to a Class

Once you've created the attribute objects and the class object that will contain them, you must add the attributes to the class. You do this by opening the Properties dialog box for the newly created class object. The dialog box for a class object has four tabs, including the standard Security tab. In the General tab, supply a description for the object and specify whether the object class should show while browsing. You can also disable the object by selecting the Deactivate This Class check box.

In the Attributes tab (Figure 12-12), add your newly created attribute objects to the class by clicking Add for either the Mandatory or Optional list and selecting the objects by name. When an attribute is mandatory, you must supply a value for the attribute when creating a new object of that class. If, for example, you create a *social security number* attribute, add it to your auxiliary class as a mandatory attribute, and then add the auxiliary class to the user class; the next time a new user object is created, a social security number will be required for the user. Values for optional attributes aren't required.

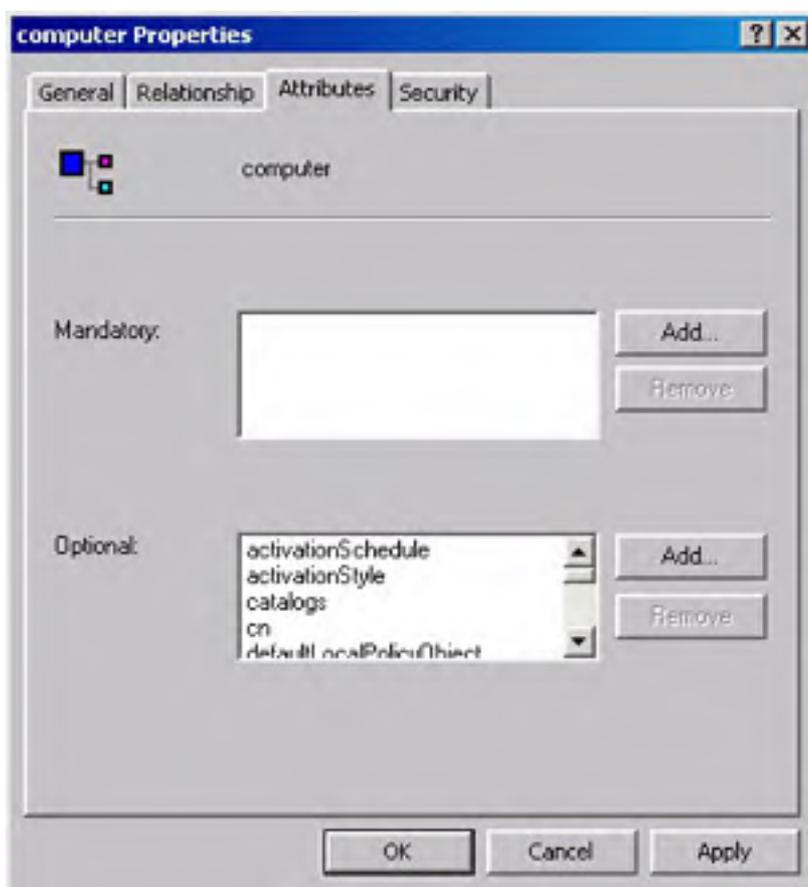

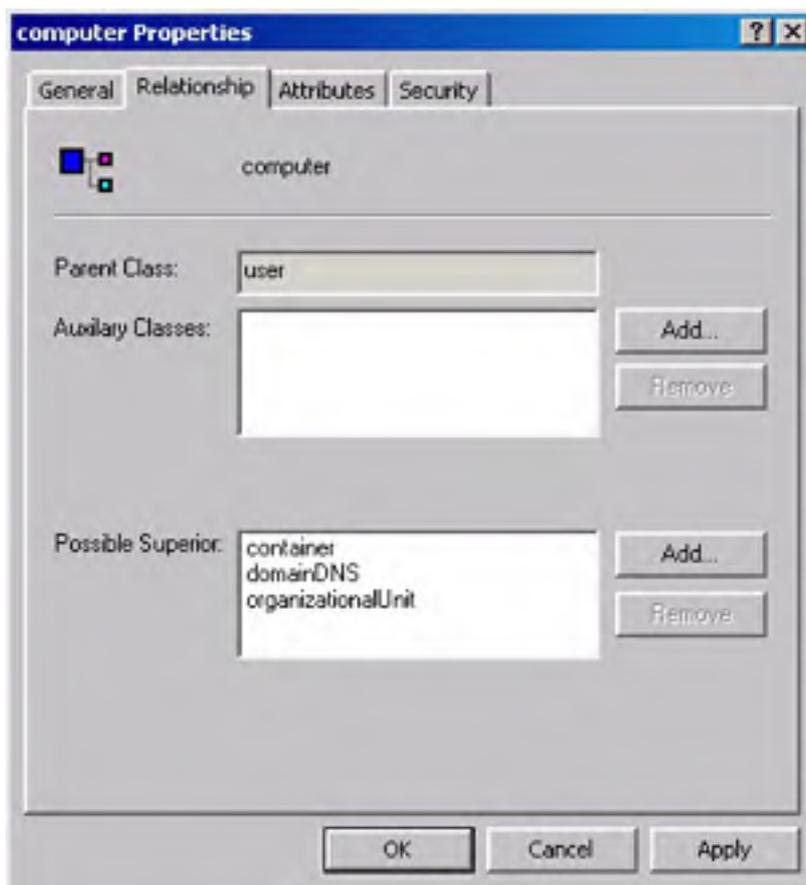

Figure 12-12. The Attributes tab of the Properties dialog box.

### Adding an Auxiliary Class to a Structural Class

An auxiliary class object can't store attribute information until you add the auxiliary class object to a structural class object, like a user or computer. To do this, open the structural class object's Properties dialog box and select the Relationship tab (Figure 12-13).

**Figure 12-13.** The Relationship tab of the Properties dialog box.

In this tab, click Add for the Auxiliary Classes list, and select the class object you just created. This causes Active Directory to add the attributes in the auxiliary class to the structural class. In the Possible Superior list, specify which other object classes can contain the current object class. For example, the user object class has the organizational unit object class in its Possible Superior list, which enables the creation of new users in OUs. The opposite is not true, however; you can't create an OU beneath a user, so the user object isn't a possible superior of the OU object.

## Modifying Display Specifiers

Once you've added new attributes to a class, the attributes exist in the Active Directory database, but you can't see them in utilities like Active Directory Users and Computers. To view, add, or modify the values of the new attributes, you must first alter the display specifiers that control how attributes appear in applications. *Display specifiers* are Active Directory objects that define the labels for the attributes that appear in a dialog box and control the contents of the shortcut menu that appears when you right-click an object of a modified class.

For example, you might create a new attribute intended to store users' social security numbers and name it *SocialSecurityNumber*. You probably don't want the attribute name to appear this way in Active Directory Users and Computers, so you create the display name *Social Security Number* and make it the equivalent of *SocialSecurityNumber*. To modify the display specifier objects, you can use a Microsoft Visual Basic script and execute it from the Windows 2000 command prompt.

The following script assumes that two new attributes, called *SalaryLevel* and *SocialSecurityNumber*, have been created and added to an auxiliary class called *HumanResources*, which has, in turn, been added to the user object class. The first section connects to the display specifiers container in Active Directory.

```
Dim oRoot
Dim oDisp
Dim oCont
Dim aMenu
Dim iCount
```

```
Dim sNewMenu
Dim oFileSystem
Dim sOutFile
Dim sSystemFolder
Set oFileSystem = WScript.CreateObject("Scripting.FileSystemObject")
sSystemFolder = oFileSystem.GetSpecialFolder(1)
Set oRoot = GetObject("LDAP://RootDSE")
Set oCont = GetObject("LDAP://" & "CN=409, CN=DisplaySpecifiers," & _
    oRoot.get("configurationNamingContext"))
Set oDisp = oCont.GetObject("displaySpecifier","cn=user-Display")
MsgBox "Display Specifier: " & oDisp.Name
```

The following routine assigns display names to the two new attributes. These names appear in all dialog boxes providing access to these attributes.

```
oDisp.PutEx 3,"attributeDisplayNames" , _
    Array("SalaryLevel,Annual Salary", _
    "SocialSecurityNumber,Social Security Number")
oDisp.SetInfo
```

The next routine creates a new entry, called *HR Info*, on the shortcut menu that appears when you right-click a user object in the My Network Places window. When you access this shortcut menu item, the program executes another Visual Basic script called Hrshell.vbs that enables users to view the values for the new attributes.

```
MsgBox "Adding Shell Context Menu item"
iCount = 0
If Not IsEmpty(oDisp.shellContextMenu) Then
    aMenu = oDisp.GetEx("shellContextMenu")
    For iCount = LBound(aMenu) to UBound(aMenu)
        MsgBox "Existing Menu item: " & aMenu(iCount)
    Next
    iCount = iCount + 1
End If
sNewMenu = CStr(iCount) & ",&HR Info...,hrshell.vbs"
oDisp.PutEx 3,"shellContextMenu" , Array(sNewMenu)
oDisp.SetInfo
```

This next routine creates the Hrshell.vbs script:

```
MsgBox "Adding Shell Context Menu Program"
Set sOutFile = oFileSystem.CreateTextFile(sSystemFolder & _
    "\hrshell.vbs",True)
sOutFile.WriteLine "Dim Args"
sOutFile.WriteLine "Dim oUser"
sOutFile.WriteLine "Set Args = Wscript.Arguments"
sOutFile.WriteLine "MsgBox " & Chr(34) & "LDAP Path: " & Chr(34) & _
    " & Args(0) "
sOutFile.WriteLine "MsgBox " & Chr(34) & "Object Class: " & _
    Chr(34) & " & Args(1) "
sOutFile.WriteLine "Set oUser = GetObject(Args(0))"
sOutFile.WriteLine "MsgBox " & Chr(34) & "HR Info" & Chr(34) & _
    " & vbCRLF & " & Chr(34) & "Salary: " & Chr(34) & _
    " & oUser.SalaryLevel & vbCRLF & " & Chr(34) & "Soc Sec No: " & _
    Chr(34) & " & oUser.SocialSecurityNumber"
sOutFile.WriteLine "Set oUser = Nothing"
sOutFile.WriteLine "WScript.Quit"
sOutFile.Close
```

The following routine adds a similar entry to the user shortcut menu in Active Directory Users and Computers, causing the application to execute the Hradmin.vbs script. This script creates a dialog box in which administrators can modify the values for the new attributes.

```
MsgBox "Adding Admin Context Menu item"
iCount = 0
If Not IsEmpty(oDisp.adminContextMenu) Then
    aMenu = oDisp.GetEx("adminContextMenu")
    For iCount = LBound(aMenu) to UBound(aMenu)
        MsgBox "Existing Menu item: " & aMenu(iCount)
    Next
    iCount = iCount + 1
End If
sNewMenu = CStr(iCount) & ",&HR Admin...,hradmin.vbs"
oDisp.PutEx 3,"adminContextMenu" , Array(sNewMenu)
oDisp.SetInfo
```

The next section creates the Hradmin.vbs script and terminates the script:

```
MsgBox "Adding Admin Context Menu Program"
Set sOutFile = oFileSystem.CreateTextFile(sSystemFolder & _
    "\hradmin.vbs",True)
sOutFile.WriteLine "Dim Args"
sOutFile.WriteLine "Dim oUser"
sOutFile.WriteLine "Dim temp"
sOutFile.WriteLine "Set Args = Wscript.Arguments"
sOutFile.WriteLine "MsgBox " & Chr(34) & "LDAP Path: " & Chr(34) & _
    " & Args(0) "
sOutFile.WriteLine "MsgBox " & Chr(34) & "Object Class: " & _
    Chr(34) & " & Args(1) "
sOutFile.WriteLine "Set oUser = GetObject(Args(0))"
sOutFile.WriteLine "temp = InputBox(" & Chr(34) & "Old Salary: " & _
    Chr(34) & " & oUser.SalaryLevel & vbCRLF & " & Chr(34) & _
    "New Salary" & Chr(34) & ")"
sOutFile.WriteLine "if temp <> " & Chr(34) & Chr(34) & _
    " then oUser.Put " & Chr(34) & "SalaryLevel" & Chr(34) & ",temp"
sOutFile.WriteLine "temp = InputBox(" & Chr(34) & _
    "Soc Sec Number: " & Chr(34) & " & oUser.SocialSecurityNumber & _
    vbCRLF & " & Chr(34) & "New Number" & Chr(34) & ")"
sOutFile.WriteLine "if temp <> " & Chr(34) & Chr(34) & _
    " then oUser.Put " & Chr(34) & "SocialSecurityNumber" & _
    Chr(34) & ",temp"
sOutFile.WriteLine "oUser.SetInfo"
sOutFile.WriteLine "Set oUser = Nothing"
sOutFile.WriteLine "WScript.Quit"
sOutFile.Close
MsgBox "Quit..."
Set oDisp = Nothing
Set oCont = Nothing
Set oRoot = Nothing
Set oFileSystem = Nothing
WScript.Quit
```

When you save this script to a text file with a .VBS extension and execute it from the command prompt, Windows 2000 adds the shortcut menus to the My Network Places window and the Active Directory Users and Computers snap-in and creates the scripts that selecting those shortcut menus executes. This part of the schema modification process is obviously the most complex. After you create your own scripts, carefully test and debug them on a nonproduction network before executing them on live domain controllers.

## Performing Batch Importing and Exporting

MMC snap-ins like Active Directory Users and Computers make it easy to create and configure new objects in Active Directory, but deploying the directory service on a large scale might require the creation of thousands of objects. In cases like these, manually creating individual objects is impractical. Anticipating the need for the mass creation of Active Directory objects, and particularly user objects, Windows 2000 includes tools that enable administrators to perform batch imports and exports of Active Directory objects. Among these tools is Ldifde.exe, a command-line utility for importing, exporting, and modifying Active Directory objects using the LDAP Data Interchange Format (LDIF).

## Using the Ldifde.exe Utility

Active Directory uses LDAP to define its namespace and it supports LDIF. LDIF is a standardized format for saving directory service information in text files. If you're running another directory service that also supports LDIF on the network, you can import its data into Active Directory by using the Ldifde.exe utility. You can also use Ldifde.exe to export Active Directory objects to LDIF files and modify existing objects.

The syntax for using the Ldifde.exe utility is as follows:

```
Ldifde [-a username password] [-b username domainname password]
[-c FromDN ToDN] [-d RootDN] [-f filename] [-g] [-i] [-j] [-k]
[-l attributes] [-m] [-n] [-o attributes] [-p scope] [-r filter]
[-s servername] [-t] [-v] [-?]
[-a username password] - specifies the user name and password for
simple authentication to the LDAP directory.
[-b username domainname password] - specifies the user name, domain
name, and password for the SSPI bind method (by default, the
utility logs in to the LDAP directory as the current user, with
the SSPI bind method).
[-c FromDN ToDN] - replaces all occurrences of FromDN with ToDN.
[-d RootDN] - specifies the root object where the utility should
commence its search (default = current naming context).
[-f filename] - specifies the name of the LDIF file that the utility
will import data from or export data to.
[-g] - disables paged search.
[-i] - causes the utility to operate in import mode (default = export
mode).
[-j] - specifies the location of the utility's log file.
[-k] - causes the program to ignore "constraint violation" and
"object already exists" errors.
[-l attributes] - specifies the attributes that the utility should
look for during a search of an LDAP directory.
[-m] - enables Windows NT's Service Account Manager (SAM) logic
during export operations.
[-n] - prevents the utility from exporting binary values.
[-o attributes] - specifies the attributes that the utility should
omit from inputting.
[-p scope] - specifies the search scope (Base, OneLevel, or Subtree).
[-r filter] - specifies the objects for which the utility will search
(default = "(objectClass=*)").
[-s servername] - specifies the name of the server to which the
utility will bind (default = domain controller of the currently
logged on domain).
[-t] - specifies a port number to use when communicating with the
LDAP service (default = 389).
[-v] - causes the program to operate in verbose mode.
[-?] - displays help information for the program.
```

**Exporting Objects** To export Active Directory information to an LDIF file, execute a command like the following:

```
ldifde -f research.ldif -s cz2 -d "ou=Research,dc=scribes,dc=com"
-p subtree -r (objectCategory=CN=Person,CN=Schema,CN=
```

```
Configuration,DC=scribes,DC=com) "
```

The *-f* parameter specifies the name of the LDIF file that the utility will create. The *-s* and *-d* parameters identify the server that the utility should use to access Active Directory and the OU where the export process should begin. The *-p* parameter specifies that the utility should export the entire subtree below the Research OU, and *-r* specifies that the program should export only person (that is, user) objects. When you execute the command, Ldifde.exe searches Active Directory, starting in the Research OU and traveling down the subtree to the bottom, writing the information about each user object it finds to the Research.ldif file. A typical LDIF entry for a user object (in this case the *Administrator* object) appears as follows:

```
dn: CN=Administrator,CN=Users,DC=scribes,DC=com
changetype: add
accountExpires: 9223372036854775807
badPasswordTime: 0
badPwdCount: 0
codePage: 0
cn: Administrator
countryCode: 0
description: Built-in account for administering the computer/domain
instanceType: 4
isCriticalSystemObject: TRUE
memberOf: CN=Domain Admins,CN=Users,DC=scribes,DC=com
memberOf: CN=Enterprise Admins,CN=Users,DC=scribes,DC=com
memberOf: CN=Schema Admins,CN=Users,DC=scribes,DC=com
memberOf: CN=Administrators,CN=Builtin,DC=scribes,DC=com
lastLogoff: 0
lastLogon: 125652212356113520
logonCount: 7
distinguishedName: CN=Administrator,CN=Users,DC=scribes,DC=com
objectCategory: CN=Person,CN=Schema,CN=Configuration,DC=scribes,DC=com
objectClass: user
objectGUID:: RedjUwbB0hGJSwBgl7B3yg==
objectSid:: AQUAAAAAAAAUVAAAIqcyP/CUyF8WwOoy9AEAAA==
primaryGroupID: 513
pwdLastSet: 125631016521025648
name: Administrator
sAMAccountName: Administrator
sAMAccountType: 805306368
userAccountControl: 66048
uSNChanged: 2113
uSNCreated: 2113
whenChanged: 19990210163330.0Z
whenCreated: 19990210163330.0Z
```

**Importing Objects** To import users or other objects from another LDAP directory service, you must first export the information using whatever tools the other product provides, and then import the LDIF file into Active Directory using a command like the following:

```
Ldifde -i -f newusers.ldif
```

In this example, the *-i* parameter puts the program into import mode, and the *-f* parameter specifies the name of the LDIF file you created from the other directory service.

**Modifying Objects** You can also use Ldifde.exe to modify the information stored in Active Directory objects, albeit in a roundabout way. After exporting Active Directory object information to an LDIF file, modify the attribute values in the file using any text editor, and then import it back into Active Directory. The new information overwrites the old, effectively modifying the Active Directory object information. If faced with a situation in which you have to make a great many similar changes to the directory, such as a company move requiring new mail addresses for all users, use Ldifde.exe and a text editor with search and replace capabilities to quickly modify thousands of objects in the Active Directory database.

## Understanding Operations Master Roles

Domain controllers must handle five operations master roles in every Active Directory forest. Some of the operations master roles are critical to your network, and if the machine providing them fails, you'll know about it at once. Others can be unavailable for a long time without you or your users being any the wiser. The roles are as follows:

- **Primary domain controller (PDC) emulator** Acts as a Windows NT primary domain controller in domains that have Windows NT backup domain controllers or computers without Windows 2000 client software
- **Schema master** Controls all updates and modifications to the schema
- **Domain naming master** Controls the addition or removal of domains
- **Relative identifier (RID) master** Allocates relative IDs to each domain controller
- **Infrastructure master** Updates changes to group-to-user references when memberships in groups are changed

Normally, you have no reason to interfere with the operations master roles. Transferring of roles is relatively trivial. You make a transfer when the original role holder is available. In serious circumstances when the controller holding the role is unavailable, you can seize a role, but it's a drastic measure and you should not take it lightly. In all cases, except with the PDC emulator, when an operations master role is seized (rather than transferred), you must not bring the original holder of the seized role back online without completely reformatting the boot disk and reinstalling Windows 2000. The next several sections explain the operations master roles in more detail.

### Primary Domain Controller Emulator

When upgrading a Windows NT domain, only one domain controller can create users, groups, and computer accounts—the basics of security. This Windows 2000 domain controller is configured as the PDC operations master and emulates a Windows NT primary domain controller. The PDC emulator supports the Kerberos and NTLM protocols, allowing Windows NT domain controllers to synchronize with a Windows 2000 environment running in mixed mode.

Every domain must have a domain controller that acts as a PDC emulator as long as the domain contains either clients without Windows 2000 client software or Windows NT backup domain controllers. If the controller acting as the PDC emulator isn't available, it will affect users because the network itself will be disrupted. So if you know that the controller acting as the PDC emulator will be unavailable, transfer this role.

**Transferring the PDC Emulator** To transfer the role of PDC emulator, follow these steps:

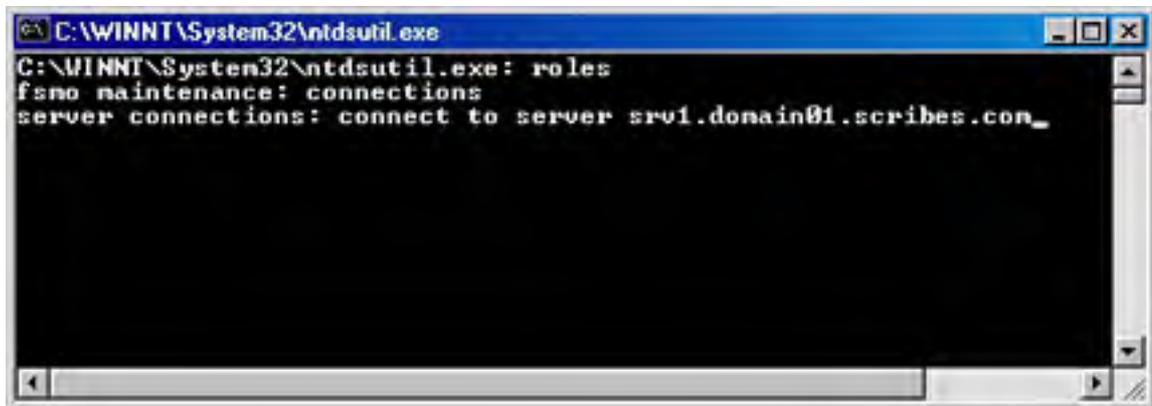

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the domain node and choose Connect To Domain Controller from the shortcut menu.
3. Select the domain controller that you want to give the role of PDC emulator. Click OK.
4. Right-click the domain node and choose Operations Masters from the shortcut menu. Click the PDC tab to see the current focus (the controller that will become the PDC emulator) and the controller that is the current operations master.
5. Click Change and then click OK.

**Seizing the PDC Emulator** If the PDC emulator becomes unavailable unexpectedly and it can't be returned to service quickly, you'll need to seize the role of the PDC emulator and force it to another domain controller. To seize the PDC emulator, follow these steps:

1. Choose Run from the Start menu (or open a command window), type *ntdsutil*, and press Enter.
2. At each prompt, supply the following information and then press Enter:
  - At *ntdsutil*, type *roles*
  - At *fsmo maintenance*, type *connections*
  - At *server connections*, type *connect to server* followed by the fully qualified domain name of the controller that is to be the new PDC emulator (Figure 12-14)

- At server connections, type *quit*
- At fsmo maintenance, type *seize PDC*
- At ntdsutil, type *quit*

When the original PDC emulator becomes available again, you can use the same procedure to return the PDC emulator role.

**Figure 12-14.** Using *Ntdsutil* to seize and move the PDC emulator role to a new server.

## Schema Master

Not surprisingly, the schema master handles all updates to the schema. Only one schema master exists in an entire forest. The schema master role is assigned to the first domain controller in a domain and remains there unless you change it. Because modifications of the schema are uncommon, the schema master can be nonfunctional for an extended period without affecting users.

### Transferring the Schema Master

To transfer the schema master role, follow these steps:

1. Open the Active Directory Schema snap-in.
2. Right-click Active Directory Schema in the console window and choose Change Domain Controller from the shortcut menu. Change the focus to the controller that will assume the schema master role.
3. Right-click Active Directory Schema in the console window and choose Operations Master from the shortcut menu. Click Change and then click OK.

### Seizing the Schema Master

Don't seize the schema master unless there's no hope of returning the original controller to service. Before seizing the schema master role, the original schema master must be disconnected from the network. To seize the schema master role, follow these steps:

1. Choose Run from the Start menu (or open a command window), and then type *ntdsutil* and press Enter.
2. At each prompt, supply the following information and then press Enter:
  - At ntdsutil, type *roles*
  - At fsmo maintenance, type *connections*
  - At server connections, type *connect to server* followed by the fully qualified domain name of the controller that is to be the new schema master
  - At server connections, type *quit*
  - At fsmo maintenance, type *seize schema master*
  - At ntdsutil, type *quit*

Seizing the schema master role is a radical step. Don't do it unless the original schema master is permanently out of service. If you ever bring the original schema master back online, you must reformat its boot disk and reinstall Windows 2000 to prevent serious problems with the updating of the schema.

## Domain Naming Master

Only one server in the enterprise performs the role of domain naming so that the domain naming master is created in the first domain and the role remains there no matter how large the forest. The domain naming master can be unavailable for some time, and the network will be unaffected until there's a need to establish a new domain. Therefore, unless the controller playing this role is to be permanently removed from the network, you usually won't need to either transfer or seize this role.

**Transferring the Domain Naming Master** If you need to transfer this role to another controller, follow these steps:

1. Launch Active Directory Domains and Trusts from the Administrative Tools folder.
2. Right-click Active Directory Domains and Trusts and choose Connect To Domain Controller from the shortcut menu.
3. Select the domain controller that you want to give the role of domain naming master. Click OK.
4. Right-click Active Directory Domains and Trusts again and select Operations Master from the shortcut menu. A dialog box opens, showing the current domain naming master and the computer that will become the domain naming master.
5. Click Change and then click OK.

**Seizing the Domain Naming Master** If the domain naming master must be unexpectedly and permanently removed from the network, you can seize the domain mastering role and reassign it to another domain controller. To seize the role, follow these steps:

1. Choose Run from the Start menu (or open a command window), and then type *ntdsutil* and press Enter.
2. At each prompt, supply the following information and then press Enter:
  - At *ntdsutil*, type *roles*
  - At *fsmo maintenance*, type *connections*
  - At *server connections*, type *connect to server* followed by the fully qualified domain name of the controller that is to be the new master
  - At *server connections*, type *quit*
  - At *fsmo maintenance*, type *seize domain naming master*
  - At *ntdsutil*, type *quit*

Before seizing the domain naming master, the controller holding the domain naming master role must be disconnected completely from the network. Seizing the domain naming master role is a radical step, and you should not do it unless the original domain naming master is permanently out of service. If you ever bring the original domain naming master back online, you must first reformat its boot disk and reinstall Windows 2000.

## Relative Identifier Master

When a domain controller creates a security object—a user, a group, or a computer account—it assigns a unique security identifier (SID) to the object. The SID is made up of two parts: the domain security ID that is common to all security objects in the domain, and the relative ID that is unique to each object. The RID master is the controller in each domain that allocates and tracks the sequences of relative IDs.

Users won't notice temporary loss of the RID master. Administrators are also unlikely to notice unless they're creating security objects and the domain runs out of relative ID numbers. So transferring the RID master role isn't usually necessary unless the RID master is to be removed permanently from the network.

**Transferring the RID Master** If you need to transfer this role to another controller, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the domain node and choose Connect To Domain Controller from the shortcut menu.
3. Select the domain controller that you want to give the role of RID master. Click OK.
4. Right-click the domain node and choose Operations Masters from the shortcut menu. A dialog box will open. In the RID tab, the current focus (the controller that will become the RID master) is shown, as well as the current operations master (Figure 12-15).
5. Click Change and then click OK.

**Figure 12-15.** The RID tab of the Operations Master dialog box.

**Seizing the RID Master** If the RID master must be unexpectedly and permanently removed from the network, you can seize the RID mastering role and reassign it to another domain controller. To seize the role, follow these steps:

1. Choose Run from the Start menu (or open a command window), and then type *ntdsutil* and press Enter.
2. At each prompt, supply the following information and then press Enter:
  - At *ntdsutil*, type *roles*
  - At *fsmo maintenance*, type *connections*
  - At *server connections*, type *connect to server* followed by the fully qualified

domain name of the controller that is to be the new master

- At server connections, type *quit*
- At fsmo maintenance, type *seize RID master*
- At ntdsutil, type *quit*

Before proceeding with the seizure, the controller holding the RID master role must be disconnected completely from the network. Seizing the RID master role is a radical step. Don't do it unless the original RID master is permanently out of service. If you ever bring the original RID master back online, you must first reformat its boot disk and reinstall Windows 2000.

## Infrastructure Master

The infrastructure master is responsible for keeping up with the changes in group membership and distributing updates to other domains. One infrastructure master exists in each domain. If the controller holding the infrastructure master role becomes unavailable, it won't affect users. Even administrators won't notice until a number of user account changes don't show up in other domain controllers. Therefore, it's best not to transfer the infrastructure master role unless the controller is going to be unavailable for a considerable period.

### Real World

#### Placing the Infrastructure Master Role

Unless the domain has only one domain controller, don't assign the infrastructure master role to the controller hosting the Global Catalog (GC). To find out whether changes need to be distributed to other domains, the infrastructure master looks to a GC and updates itself using the GC information. If the GC and the infrastructure master are on the same controller, the infrastructure master will never find any outdated data, so nothing is replicated to other domains. See [Chapter 11](#) for more on the GC.

**Transferring the Infrastructure Master** To transfer the infrastructure master role to another controller, follow these steps:

1. Launch Active Directory Users and Computers from the Administrative Tools folder.
2. Right-click the domain node and choose Connect To Domain Controller from the shortcut menu.
3. Select the domain controller that you want to give the role of infrastructure master. Click OK.
4. Right-click the domain node and choose Operations Masters from the shortcut menu. Click the Infrastructure tab to see the current focus (the controller that will become the infrastructure master) as well as the controller that is the current operations master.
5. Click Change and then click OK.

**Seizing the Infrastructure Master** If the infrastructure master is unexpectedly and permanently removed from the network, you can seize the infrastructure master role and reassign it to another domain controller. To seize the role, follow these steps:

1. Choose Run from the Start menu (or open a command window), and then type *ntdsutil* and press Enter.
2. At each prompt, supply the following information and then press Enter:
  - At ntdsutil, type *roles*
  - At fsmo maintenance, type *connections*
  - At server connections, type *connect to server* followed by the fully qualified domain name of the controller that is to be the new master

- At server connections, type *quit*
- At fsmo maintenance, type *seize infrastructure master*
- At ntdsutil, type *quit*

Before proceeding with the seizure, the controller holding the infrastructure master must be disconnected completely from the network. Seizing the infrastructure master role is a drastic step. Don't do it unless the original infrastructure master is permanently out of service. If you ever bring the original infrastructure master back online, you must first reformat its boot disk and reinstall Windows 2000.

## Summary

Active Directory is a major part of the Windows 2000 enterprise network infrastructure, and planning, deploying, and maintaining it is a major part of the network administrator's burden. Learning to use the Active Directory tools included with Windows 2000 makes it possible to create and maintain a directory service infrastructure that is efficient and largely self-regulating. With Active Directory solidly in place, you can move on to other administrative responsibilities, which are discussed in following chapters. [Chapter 13](#) covers network addresses and Internet protocols.

# Chapter 13

## **Understanding TCP/IP**

After years of proprietary protocols vying for popularity, TCP/IP has emerged as the only protocol needed by many networks. Every modern computer supports TCP/IP, as do a growing number of other devices such as printers, network appliances, personal digital assistants (PDAs), and cell phones. Additionally, Novell NetWare, Microsoft Windows, *and* Apple's Mac OS have been using TCP/IP as their preferred network protocol for some time now. The only reason to use another protocol suite is to achieve compatibility with earlier systems.

Although the basics of setting up TCP/IP on a server are covered in [Chapter 6](#), you need to know more to deal with even a slightly more complex network environment. This chapter covers some of the theory behind TCP/IP and the tools you use to handle IP addresses on your network.

## The TCP/IP Protocol Suite

Whole books have been written about TCP/IP, and justifiably so. Although most administrators don't need to know every detail of programming a TCP connection or what to expect as a return value from a *gethostbyname()* call, they do need to understand enough to configure the protocol and make it work properly.

The important fact to remember about TCP/IP is that it isn't a single entity. TCP/IP is short for Transmission Control Protocol/Internet Protocol, but these are only two of the protocols included in the TCP/IP suite. There are a variety of other protocols, each with its own specialized area of importance and use.

Another important aspect of TCP/IP is that it isn't controlled by any one company or vendor, unlike other protocols such as Internetwork Packet Exchange/Sequenced Packet Exchange (IPX/SPX) and the now nearly obsolete NetBIOS Extended User Interface (NetBEUI) protocol. TCP/IP is an open standard controlled by the Internet Engineering Task Force (IETF) and by the users of the Internet itself in the form of RFCs (requests for comments). Anyone can submit an RFC for consideration and inclusion into the written definitions of the protocols and policies of the Internet and TCP/IP.

### Internet Protocol

IP is the core protocol of the TCP/IP suite. To quote from RFC 791, "The Internet Protocol is designed for use in interconnected systems of packet-switched computer communication networks." IP performs only one basic function: to deliver a packet of bits (called a *datagram*) from point A to point B over any network "wire" it happens to encounter along the way.

The term *wire* is used very loosely here and elsewhere to indicate the actual—usually physical—network connection between two points. In fact, that wire can just as easily be a piece of optical fiber or even a radio or infrared signal. In all cases it functions as the transmission medium through which the packets travel.

IP doesn't in and of itself know anything about the information in the datagram it carries, nor does it have any provision beyond a simple checksum to ensure that the data is intact or that it has reached its destination. That is left to the other protocols in the TCP/IP suite.

### Transmission Control Protocol

According to RFC 793 (the defining RFC for the protocol), TCP is "a connection-oriented, end-to-end reliable protocol designed to fit into a layered hierarchy of protocols which support multinetwide applications." The following list elaborates on some of those terms:

- **Connection-oriented** TCP provides for the communication of packets between two points, sending the datagram specifically from one computer or device to another, and sending an acknowledgment back to the sending computer on receipt of intact packets.
- **End-to-end** Each TCP packet designates a specific endpoint as its destination. Packets are passed along the wire and ignored except by the actual endpoint of the packet and any device that needs to direct it.
- **Reliable** This is the key point of TCP. When a program such as FTP uses TCP for its protocol, TCP takes responsibility for the reliability of the communications. The protocol itself provides for interprocess communication to ensure that packets that are sent out not only get there, but also that they get there in the order in which they were sent. If a packet is missed, the protocol communicates with the sending device to ensure a resend of the packet.

Because TCP has to create a reliable connection between two devices or processes, each packet involves substantially more overhead than is needed with other, less reliable protocols within the suite. But by the same token, the programmer writing the application that uses TCP doesn't have to include a lot of error checking and handshaking in the application itself.

### User Datagram Protocol

The User Datagram Protocol (UDP), another protocol in the TCP/IP suite, is a connectionless, transaction-oriented protocol designed to send packets with a minimum of protocol overhead. It provides no guarantee that its intended recipient received the packet, or that packets were received in the order in which they were sent. UDP is frequently used in broadcast messages where there is no specific intended recipient, such as Boot Protocol (BOOTP) and Dynamic Host Configuration Protocol (DHCP) requests, but it can also be used by applications that prefer to ensure reliable delivery internally rather than in an underlying protocol. UDP is defined in RFC 768.

## Windows Sockets

Windows Sockets (commonly referred to as Winsock) provides a standard way for application programs to communicate with a TCP/IP stack without having to consider any underlying variations in the TCP/IP stack implementation.

In the past there were many different vendors of TCP/IP protocol and applications suites for MS-DOS-based computers, each slightly different from the others. This situation made it extremely difficult to write an application that required TCP/IP and yet worked with all the TCP/IP implementations that existed. Winsock was designed to get around this problem by providing a uniform set of application programming interface (API) calls that would be the same regardless of the underlying differences in the actual implementation of TCP/IP.

The original Winsock version 1 had a fair number of difficulties, and version 1.1 was released soon after its initial implementation. The current version of Winsock supported by the Windows 2000 Server family is version 2, which provides for full backward compatibility with earlier versions while offering improved functionality and support for additional features and expandability. Note that Winsock 2 has been around since Microsoft Windows NT 4, so applications are widely available that use this API, something that will become more important as IP version 6 (discussed later in the chapter) is rolled out.

## Network Basic Input/Output System

NetBIOS is a networking API used by legacy applications and operating systems to communicate across a network using the NWLink (IPX/SPX compatible), NetBEUI, or TCP/IP protocols.

Until the advent of Windows 2000, NetBIOS was the primary networking API used by all Microsoft operating systems. NetBIOS names were used for name resolution within Windows-based networks. Any time a computer wanted to communicate with another computer on the network, the computer had to resolve the NetBIOS name for the other computer either by querying a Windows Internet Name Service (WINS) server, using a NetBIOS broadcast, or referring to the computer's local Lmhosts file.

With Windows 2000, Microsoft changed the Windows networking infrastructure to one based on TCP/IP, with no NetBIOS support required. Networks based on Windows 2000 can use DNS to resolve network names, and network applications can use the Winsock interface to communicate using a network.

Unfortunately, because earlier versions of Windows require NetBIOS support to function properly on a Windows-based network, many companies still need to support NetBIOS over TCP/IP and provide WINS services for downlevel (older) clients and servers.

If you have only a small number of downlevel computers, you might be able to make do without WINS by relying on NetBIOS broadcasts for name resolution—just keep in mind that broadcasts generally aren't routable, so downlevel computers will have access only to their local subnet.

## Requests for Comments

RFCs come in many guises, but all of them have the same intent and a somewhat similar format. They are designed to provide a way for an extremely diverse group—the users of the Internet—to communicate and agree on the architecture and functionality of the Internet. Some RFCs are official documents of the IETF, defining the standards of TCP/IP and the Internet; others are simply proposals trying to become standards; and others fall somewhere in between. Some are tutorial in nature, others are quite technical, and some are even humorous (such as RFC 2324, "Hyper Text Coffee Pot Control Protocol"). But all are a way for the Internet, an essentially anarchic entity, to organize and communicate.

There's no need to list all the RFCs here, and you certainly don't need to read them all, but you should know where to find them and be aware of the most important ones. You can find listings of RFCs in a number of places; an excellent site is <http://www.cis.ohio-state.edu/cs/Services/rfc/index.html>. The RFCs at this location are organized and linked logically to

make it easy to find the information you're looking for. This site, however, isn't nearly as up-to-date as the official RFC editor site, <http://www.rfc-editor.org>. If you want to be sure you have the most current information, use the latter site. Table 13-1 lists some important RFCs and their subject matter.

**Table 13-1.** *Some key RFCs and what they cover*

<b>RFC Number</b>	<b>Subject</b>
RFC 768	User Datagram Protocol (UDP)
RFC 791	Internet Protocol (IP)
RFC 792	Internet Control Message Protocol (ICMP)
RFC 793	Transmission Control Protocol (TCP)
RFC 821	Simple Mail Transfer Protocol (SMTP)
RFC 822	Standard for the Format of Advanced Research Project Agency (ARPA) Internet Text Messages
RFC 854	Telnet Protocol
RFC 959	File Transfer Protocol (FTP)
RFC 1001, 1002	Network Basic Input/Output Operating System (NetBIOS) over TCP/IP
RFC 1011	Official Internet Protocols
RFC 1034	DNS Concepts and Facilities
RFC 1035	DNS Implementation and Specification
RFC 1166	Internet Numbers
RFC 1542	Clarifications and Extensions for the Bootstrap Protocol
RFC 1886	DNS Extensions to Support IP version 6
RFC 1918	Address Allocation for Private Internets
RFC 2131	Dynamic Host Configuration Protocol (DHCP)
RFC 2136	Dynamic Updates in the DNS System (Dynamic DNS)
RFC 2251	Lightweight Directory Access Protocol (LDAP)
RFC 2460-2463	Internet Protocol version 6 (IPv6) Specifications
RFC 2492	IPv6 over Asynchronous Transfer Mode (ATM) networks
RFC 2661	Layer Two Tunneling Protocol (L2TP)
RFC 2782	A DNS Resource Record (RR) for Specifying the Location of Services (DNS SRV)
RFC 3007	Secure DNS

## IP Addresses and What They Mean

Your IP address is to the Internet (or to the other computers on your local network) much the same as your street address is to your mail carrier. It uniquely identifies your computer using a simple, 32-bit addressing scheme. This scheme, which originated in the late 1960s and early 1970s, uses four octets separated by dots, in the form *w.x.y.z* (we'll refer to these letters representing each octet throughout the chapter), to describe both the network's address and the local machine's address on that network. Each octet is represented by a single decimal number but is called an octet because it requires 8 bits to describe.

In terms of IP addresses, all networks fall into one of three classes: A, B, or C. These different classes describe networks (sometimes referred to as licenses) of very different sizes and complexities. The licenses to use a range of IP addresses are controlled by Network Solutions, successor to the Internet Network Information Center (InterNIC).

### Class A Networks

A class A network has an address that begins with a number from 1 through 127 for the first octet—the *w* portion of the address. This octet describes the network itself, and the remainder of the address is the actual local device's address on that network. A class A network with the network address of 10 (the *w* portion) contains all IP addresses from 10.0.0.0 to 10.255.255.255.

The class A address 127 has a special meaning and isn't available for use. This means there are a total of 126 possible usable class A addresses in the world (from 1 through 126), and that each class A network can contain more than 16 million unique network devices.

The class A addresses were spoken for long ago and are assigned to such entities as the Department of Defense, Stanford University, and Hewlett-Packard.

#### Real World

##### 127: The Loopback Address

All IP addresses that begin with the network number 127 are special. Your network card interprets them as loopback addresses. Any packet sent to an address beginning with 127 is treated as if it had gotten to its intended address, and that address is the local device. So packets addressed to 127.0.0.1 are treated the same as packets to 127.37.90.17; both are actually addressed to your current machine, as are all the other 16 million addresses in the 127 class A network. (You too can have your very own class A network. Of course, you can talk only to yourself, but so what?)

### Class B Networks

A class B network uses the first two octets, *w* and *x*, to describe the network itself, and the remainder of the address is the actual local device's address on that network. The first octet in a class B network must begin with a number from 128 through 191, resulting in approximately 16,000 class B networks, each of which can have approximately 64,000 unique addresses. This is still a pretty large network, and most of the class B networks were assigned long ago to large organizations or companies such as Rutgers University and Toyota Motor Corporation.

Many of the addresses in the class B address space have been broken up into smaller groups of addresses and reassigned. Large Internet service providers (ISPs), for example, use this technique to more efficiently use the available address space.

### Class C Networks

A class C network has an address that begins with a number from 192 through 223 for the *w* octet of the address and uses the first three octets (*w.x.y*) to describe the network itself. The last octet, *z*, describes the actual local device's address on that network. This arrangement makes for roughly 2 million class C networks, each of which can have a maximum of 254 devices on the network. That's enough for a small business or a department, but not for a major corporation.

### Class D and Class E Addresses

An IP address with a number from 224 through 239 for the w octet of the address is known as a class D address, which is used for multicast addresses. With multicast addresses, a number of computers can share a single multicast address, in addition to their normal IP addresses. This makes it easy to send identical data to multiple hosts simultaneously—just send the data to the shared multicast address and every member of the multicast group receives it.

The IP address space that uses the numbers from 240 through 247 for the w octet is referred to as a class E address. This space is reserved for future use.

## **Real World**

### **IP Addresses for Networks that Use Firewalls or Internet Gateways**

Suppose you know that your internal, private network will never be directly connected to the Internet. This is becoming increasingly common, as companies are moving toward sheltering their entire network behind proxy servers and firewalls. Should you use any old numbers then? No, you really shouldn't. There is a special set of network addresses reserved for just such uses. These addresses

are defined in RFC 1918, and by using these addresses you can comfortably employ a substantially larger address space than you would otherwise be able to access.

Using these special network addresses also protects the integrity of the Internet. There have already been instances in which networks using addresses that were already assigned to other organizations were connected to the Internet, causing substantial problems. Because these special addresses are officially only for private networks, they are automatically filtered at routers, protecting the Internet. The following is a list of these special addresses:

- 10.0.0.0 through 10.255.255.255 (a class A network)
- 172.16.0.0 through 172.31.255.255 (16 contiguous class B networks)
- 192.168.0.0 through 192.168.255.255 (256 contiguous class C networks)

If you need to create a test network, for example, or have some other reason to be sure you won't ever be connecting to the Internet, but you need to use TCP/IP for your network protocol, choose from this special set of addresses. You should also use these addresses for your internal network when you connect to the Internet only through a proxy server or firewall that shields your actual IP address from being seen. Microsoft Internet Security and Acceleration Server is such a firewall. When you use a firewall or proxy server, you require "real" IP addresses only for machines that are outside your firewall and are visible to the Internet as a whole, saving on IP address space.

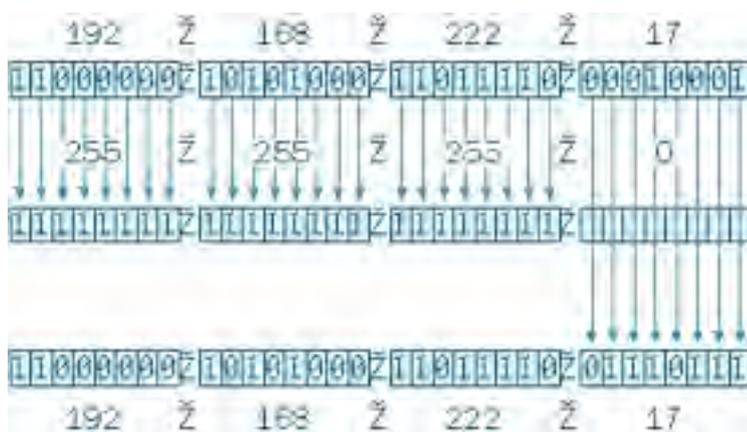

## Routing and Subnets

If every computer on the Internet had to know the location of every other computer on the Internet and how to get from here to there, the entire Internet would have come to a grinding halt long ago. Early on, it became apparent that a method was needed to filter and route packets so you can easily not only print to your network printer, but also reach any other computer on the Internet without having to know a whole lot about how to get there. Enter subnets, routers, and gateways.

### What Is a Subnet?

A *subnet* is simply a portion of the network that operates as a separate network, without regard to what happens outside and without affecting the rest of the network. A subnet is usually a separate physical "wire" that has only a single point of contact with other areas of the network, through a router or bridge.

Setting up a subnet involves using what is known as a *subnet mask* to allow computers in a subnet to see and directly communicate only with other computers in the same subnet. A subnet mask is an address, again in *w.x.y.z* form, that masks or blocks areas outside the subnet from sight. The mask works by letting you see only those portions of the IP address space that aren't masked by a 1. (Remember that each octet is actually an 8-bit binary value. To "mask by 1" means to ensure that the appropriate bit has been set to a value of 1.) For example, if you have a class C address of 192.168.222.17, and your subnet mask is 255.255.255.0 (a typical class C subnet), as shown in Figure 13-1, you can see only addresses in the last octet of the address (the *z* portion).

**Figure 13-1.** Subnet masking.

If your IP address is 192.168.222.17, the address at 192.168.223.25 is hidden from you by your subnet mask of 255.255.255.0. You can send a packet to that address only by first passing that packet to a gateway or router that knows both where you are and either where the other network is or how to find it. If, on the other hand, you send a packet to a printer with the IP address 192.168.222.129 or to a computer at 192.168.222.50, you have no problem. The system can see that address, and the packet goes directly to its destination.

If you can assign an entire class of addresses to a subnet, it's easy to figure out what your mask is; however, if you can assign only a portion of a class, you need to sit down with your binary-to-decimal conversion tables and determine exactly what the correct subnet mask should be. (Remember that this is all done in binary.) If you understand how it works, you can customize your subnet mask or figure out what the one you have is actually doing.

We recommend using the default subnet mask for your network class, unless you have a specific reason not to. For a class A network, this is 255.0.0.0; for a class B network, it's 255.255.0.0; and for a class C network, use 255.255.255.0. For in-depth information about subnet masks, see the *Microsoft Windows 2000 Server TCP/IP Core Networking Guide* (Microsoft Press).

All the subnet masks on a single portion of your network must be the same. If they aren't, this causes all sorts of problems. One machine might be able to send a packet to another, but the other might not be able to send the packet back.

## Gateways and Routers

A gateway can have different functions on a network, but for the moment we're going to focus on the subnet and routing functions. As we mentioned, if you have a subnet mask of 255.255.255.0 and the *y* octet of your IP address is 222, you can't see an IP address on the network with a *y* octet of 223.

How, then, do you get to an IP address on another subnet? The answer is a *gateway* or *router*. This is a physical device—usually a router device, or sometimes a computer with more than one network card—that's physically connected to both portions of the network. It takes your packets from the 222 subnet and sends them over to the 223 subnet for delivery to the address on that subnet. Thus, it acts as a gatekeeper between the two separate portions of the network, keeping the traffic with 222 addresses in the 222 subnet and letting only traffic with 223 addresses cross over to the 223 segment.

Although the terms *gateway* and *router* are often used interchangeably, strictly speaking a gateway is a device or computer that translates between networks of different architectures, such as NetWare and Windows. A router is a device or computer that sends packets between two or more network segments as necessary using logical network addresses (typically IP addresses).

## Routers

A *router* is a device that connects to more than one physical segment of the network and sends packets between those segments as required. If a router doesn't know where to direct a packet, the router knows which entity to ask for directions—another router. It constantly updates its routing tables with information from other routers about the best way to get to various parts of the network.

In addition to gateways and routers, there are also bridges. Bridges are devices or computers that direct traffic between two network segments based on physical (media access control) addresses and are generally used to isolate two sections of a network to improve performance. Bridges are cheaper and less capable than routers.

## Routing Protocols

Detailed information about how routing protocols work and the algorithms involved in routing and address resolution are beyond the scope of this book, but it's useful to know what some of the protocols are, if only to recognize acronyms when they're thrown about. In that spirit, the following list consists of the most common TCP/IP address resolution and routing protocols:

- **Address Resolution Protocol (ARP)** Maps the IP address to the physical hardware address (the media access control [MAC] address) of that IP address, permitting you to send something to an IP address without having to know what physical device it is.
- **Routing Information Protocol (RIP)** A vector-based routing protocol that is mostly provided for backward compatibility with existing RIP-based networks. As with most vector-based routing protocols (which make extensive use of broadcasts to discover what other devices and routers are nearby), RIP is being replaced by newer routing protocols that scale better and have lower network traffic overhead.
- **Open Shortest Path First (OSPF)** A link-state routing protocol that is suitable for use in large and very large networks, such as those common in large enterprises. Link-state routing protocols maintain a map of the network topology that they share with other routers. As the topology changes, routers update their link-state database and then inform neighboring routers of the topology change, reducing the amount of network bandwidth consumed when compared to vector-based routing protocols.

**Real World**

**Routing Flaps**

The Internet has grown exponentially in the last few years, stretching the technology for resolving addresses to the limit, and sometimes past the limit. When a major router on the Internet goes down—even momentarily—all the other routers on the Internet have to tell one another about it and recalculate new routes that bypass that router. This adjustment results in large numbers of packets passing back and forth, causing traffic to become so heavy that the routing updates can't occur properly because the information doesn't make it through the traffic. Such a situation is called a *routing flap*, and it can cause a large portion of the Internet to come to a virtual halt.

Routing flaps don't happen very often, but they are becoming more and more of a problem. In addition, current router technology is reaching the limit of its ability to calculate the best route from all the possible routes when major changes are caused by the failure of a key router. The next generation of TCP/IP (known as IP version 6, discussed later in this chapter) will help, as will new algorithms for performing the routing calculations.

## Name Resolution

As useful as the 12-decimal-digit IP numbers (192.168.101.102) are when it comes to computers recognizing other computers, they're not the sort of information that human minds process very well (short-term memory can store a maximum of roughly seven "chunks" of information). Not only is there a limit to how many 12-digit numbers one can memorize, but also numbers can easily change.

IP version 6 addresses are 128 bits expressed in strings that can have as many as 32 hexadecimal characters, although they're often shorter. (Actually, IP version 6 addresses can even be written as 128 ones and zeroes, but that's not likely to catch on.)

Obviously, easy-to-remember names are preferable to strings of numbers or strings of characters and numbers. This section looks at how names are handled in the TCP/IP and Internet world.

## The Domain Name System

The Domain Name System (DNS) was designed in the early 1980s, and in 1984 it became the official method for mapping IP addresses to names. With Windows 2000, DNS became the method clients use to locate domain controllers using Active Directory service. (The Lightweight Directory Access Protocol [LDAP] is used by clients to actually access the data stored in the Active Directory database.) Although there have been modifications to the overall structure of DNS, the overall result is still remarkably like the original design.

### More Info

See RFC 1591 for an overall description of DNS, and RFCs 1034 and 1035 for the actual specification. RFC 2136 provides the specification for dynamic updates (Dynamic DNS), with which Windows 2000, Microsoft Windows XP, and later versions of Windows comply.

## The Domain Namespace

The domain namespace describes the tree-shaped structure of all the domains from the root ( "." or "dot") domain down to the lowest level leaf of the structure. It is a hierarchical structure in which each level is separated from those above and below with a dot, so you always know where you are in the tree.

Before the Internet moved to DNS, a single master file (Hosts.txt) had to be sent using FTP to everyone who needed to convert from numbers to names. Every addition or change required a revised copy to be propagated to every system. This obviously created enormous overhead even when the Internet was still quite small.

DNS overcomes the limitations of Hosts.txt files by maintaining a distributed database that is extensible to add information as needed. It permits local administration of local names while maintaining overall integrity and conformance to standards.

## Root Domains

The root domains are the first level of the tree below the root. They describe the kinds of networks that are within their domain in two or three letters, such as .com for commercial domains and .edu for educational domains. The original root domains were functionally based and had a decidedly American slant. That's not surprising, given that most of the namespace was originally set up and administered by the U.S. Department of Defense.

As the Internet grew, however, this approach made less and less sense, especially with a distributed database like DNS that allowed for local administration and control. Geographical root domains were added to the functionally based ones, such as .it for Italian domains, and so on. See [Chapter 3](#) for information about planning your namespace and domains.

## How Names Are Resolved into Addresses

When you click a link to <http://www.microsoft.com> and your browser attempts to connect to that site, what actually happens? How does it find *www.microsoft.com*? The short answer is that it asks

the primary DNS server listed in the TCP/IP Properties dialog box on your workstation. But how does that DNS server know where the site is?

## Real World

### Where Domain Names Come From and How You Get One

These days virtually every business (and many individuals) wants its own domain. The keeper and distributor of domain names used to be Network Solutions, formerly called InterNIC. Recently this task was opened up to competition, and there are now a myriad of companies that will register your domain name for you. The list is too big and volatile to include here—for a complete listing, visit the Internet Corporation for Assigned Names and Numbers (ICANN) Web site at <http://www.icann.org>. You can link to any of the accredited registrars from this site and perform a search to find out if your chosen name is taken.

Have alternative names in mind as well; you'll probably need them. After you research existing names and choose one that isn't taken, simply register the name with your chosen registrar.

After you acquire a domain name from a registrar such as Network Solutions, you need to properly set up the DNS hosting for the domain name. If you acquired the domain name through your Web hosting company, this is probably done automatically for you. Otherwise, follow the directions provided by your registrar to enter the addresses of two DNS servers that have DNS records for your domain name. If you're using a Web hosting company, these are that company's DNS servers. If you're hosting your Web site in-company, type the addresses of two company DNS servers that are accessible from the Internet and create the necessary DNS records on your DNS servers.

Long ago, domain names were free and forever, but those days are gone. If you don't pay your bill from your chosen registrar, your domain name is put up for grabs, and chances are that someone else will claim it before you're able to reregister it. The available short names are disappearing at a rapid rate, and many people are finding that they need to think up longer versions to find something that isn't taken.

When a TCP/IP application wants to communicate with or connect to another location, it needs the address of that location. However, it usually knows only the name it's looking for, so the first step is to resolve that name into an IP address. The first place it looks for the name is in the locally cached set of names and their IP addresses that it has resolved recently. After all, if you asked about <http://www.microsoft.com> just a few minutes ago, why should it go through the trouble of looking that name up again? It's not likely that the IP address will have changed in that time.

Suppose, however, that you haven't been on the Internet for a couple of days, and your computer doesn't have the address for <http://www.microsoft.com> cached. In this case, Windows queries your primary DNS server (specified in the connection properties for your Internet connection). If your DNS server doesn't have any recent information about <http://www.microsoft.com> the DNS server asks around to see whether anyone else knows the IP address.

This can happen in a couple of ways. The default method is to use recursion, in which the DNS server queries the root server of the domain, which passes back the location of the DNS server that is authoritative regarding the next level down in the domain, which the original DNS server then queries. This process recurs until it reaches a DNS server that contains the IP address of the desired host in its zone data.

You might want to disable the use of recursion on your DNS server if it is in use on an internal network and you want your clients to fail over to a secondary DNS server that handles name resolution for hosts outside your local network.

If you disable recursion on the DNS server, or if the client doesn't request the use of recursion, the DNS entry for the desired host is found by iteration. When using iteration, the DNS server checks its zone and cache data, and when it finds that it cannot complete the request, it sends the client a list of DNS servers that are more likely to have the host name in their zones. The client then contacts those servers, which might in turn respond with their own list, possibly even to the point that the client might query the Internet root servers looking for the appropriate DNS server.

You might want to enable the use of WINS lookup to search the WINS database for any names not located in the DNS zone data, providing for a complete search of both the DNS and NetBIOS namespaces.

## Reverse Lookups

In most cases, you have a host name for which you need to locate the IP address, but in some instances you might have only an IP address for which you need to look up the host name. Reverse lookup was added to the DNS specification for this reason. The only problem with creating reverse lookups is the difference between the way the DNS namespace is organized and the way in which IP addresses are assigned. DNS names go from specific to general, beginning with the host name and ending with the root of the domain (the period at the end of a fully qualified domain name [FQDN]). IP addresses work in reverse fashion, so to facilitate the lookup of a host name from an IP address, a special domain, the *in-addr.arpa* domain, was created.

In the *in-addr.arpa* domain, the octets of an IP address are reversed, with *in-addr.arpa* appended to the address. For example, the IP address 10.230.231.232 is queried as 232.231.230.10.in-addr.arpa.

The reverse lookup zone is maintained as a separate database within the DNS database. The resource records (RRs) in the reverse lookup zone are of the type PTR (pointer). Much like pointers in common programming languages, or shortcuts in Windows, these PTR RRs simply refer to a different record—the associated A (address) record in the forward lookup zone. For example, the following list describes two records that a host might have:

- **A record (forward lookup zone)** srv1.scribes.com IN A 10.230.231.232
- **PTR record (reverse lookup zone)** 232.231.230.10.in-addr.arpa. IN PTR srv1.scribes.com

You can perform a reverse lookup of an IP address by typing *nslookup* followed by the IP address you want to look up at a command prompt. For example, if you type *nslookup 10.230.231.232*, the DNS server responds with the name and address of the DNS server, followed by the name and address of the host.

## Dynamic DNS and Active Directory Integration

Dynamic DNS, which was new to Windows 2000 Server, makes DNS more flexible by permitting clients to update their DNS records dynamically. This capability eliminates the need to update DNS entries manually when clients change IP addresses. Unfortunately, the standard dynamic DNS service described in RFC 2136 allows for only a single-master model, in which a single primary DNS server maintains the master database of zone data (the addresses and host names for a particular domain). This database can be replicated with secondary DNS servers, but only the primary server can manage dynamic updates to the zone. If the primary server goes down, client updates to the zone aren't processed.

The dynamic DNS server in Windows 2000 Server can overcome the limitations of a single-master model and use Active Directory to store its zone data, permitting a multiple-master model. Because the Active Directory database is fully replicated to all Active Directory-enabled domain controllers, any domain controller in the domain can update DNS zone data. Using Active Directory to store the zone data also allows for added security features and simplified planning and management, as well as faster directory replication than is possible using a single-master model, because Active Directory replicates only relevant changes to the zone.

## Zone Storage and Active Directory

A DNS server is required to support the use of Active Directory, so if a DNS server can't be found on the network when a server is being promoted to domain controller, the DNS service is installed by default on the domain controller. After Active Directory is installed, the storage and replication of your zones can be done in one of two ways:

- **Standard zone storage using a text-based file** With this method, zones are stored in .DNS text files located in the *%SystemRoot%\System32\DNS* folder. The filename is the same as the zone name you chose when creating the zone. Figure 13-2 shows part of a text DNS zone file.
- **Directory-integrated zone storage** Zones are stored in a *dnsZone* container object

One of the problems facing organizations using TCP/IP these days is deciding how to manage internal IP addresses. This is a special concern for companies that hand out addresses that are Internet-valid. However, even if your company uses a private network, the chore of managing all the IP addresses can quickly become an administrator's nightmare, especially if you deal with intermittently connected computers such as laptops and remote computers. DHCP provides a simpler way to handle addresses for computers that are connected irregularly.

DHCP allows the administrator to assign the available IP addresses only as required. A mobile user can connect a laptop to the network when necessary and be assigned an appropriate address automatically. Likewise, a dial-in user doesn't need a permanent IP address; one can be assigned when the connection is made to the network, and when the connection is broken the address is made available for someone else's use. With DHCP, a modest pool of IP addresses can serve a much larger pool of users.

**How DHCP Works** To receive an IP address, the client computer sends out a DHCP discover broadcast, which a DHCP server picks up and responds to by offering the client an IP address for its use. The client responds to the first offer it receives and sends back to the DHCP server a request for the IP address offered. The DHCP server sends an acknowledgment telling the client that it succeeded in leasing the IP address for the amount of time specified by the DHCP server.

DHCP clients attempt to renew their leases at bootup, as well as after 50 percent of the lease time has passed. In this renewal process, the discover stage is skipped and the client simply begins with a request. If the renewal of the lease fails at the 50 percent mark, the client waits until 87.5 percent of the lease has passed and then attempts to acquire a new IP address by sending out a DHCP discover broadcast and starting the IP lease process again.

**Using Multiple DHCP Servers** Because DHCP uses UDP broadcasts, your DHCP servers don't see (and thus don't respond to) client requests on a different subnet unless the router between the two is configured to forward broadcasts. In most large establishments, this means separate DHCP servers for each subnet because broadcast traffic is an unnecessary burden on your routing capacity. In addition, you might want a second DHCP server configured (if not activated) for each subnet to provide for redundancy and to give your network a way to issue addresses if the main DHCP server fails.

If you do opt to allow your routers to pass along broadcasts, they must support RFC 1542 ("BOOTP") and be configured to forward broadcasts. Check the documentation for your router for configuration information; most new routers (and newer versions of router software) support this. If your router doesn't support RFC 1542 and you have clients that don't have access to a local DHCP server, you must configure a DHCP relay agent to forward client broadcasts to a DHCP server on another network segment.

Although you can use DHCP remotely with supported routers, it's best to situate your DHCP servers on-site. WAN failures do occur, and even a brief one can keep clients from being able to acquire or maintain an IP address. Letting a WAN be in a position to put your LAN out of business is a bad idea.

Windows 2000 Server supports integration of DHCP with dynamic DNS to facilitate the updating of a client's DNS record when the client receives a new IP address from a DHCP server. This feature fixes an incompatibility between DHCP and DNS that has existed until this point.

If you're still using static DNS servers on your network, you need to enable WINS lookup for DHCP clients that use NetBIOS to help avoid failed DNS lookups for DHCP clients. Whenever you can, however, replace or upgrade existing static DNS servers with dynamic DNS servers such as the one provided with Windows 2000 Server. If you want to use BIND, we recommend using version 8 or later, although using Windows 2000 DNS servers is the most painless method of providing DNS services to a Windows-based network.

Zone transfers between Windows 2000 and BIND version 9.x DNS servers might not work unless the Windows 2000 server is running Service Pack 3 or later.

Typically, you need one DHCP server for every 10,000 clients, though this number can be higher if you have large disk capacity and a fast CPU, or lower if your IP address class or network layout prevents this kind of server utilization. DHCP is very disk-intensive, so make sure that if your server will be handling a significant number of clients you have sufficient hardware, such as a large and fast redundant array of independent disks (RAID), adequate memory, and one or more fast CPUs. For information on evaluating the performance of your current system, see [Chapter 33](#).

## Real World

### DHCP and Availability

DHCP itself does not support synchronization with other DHCP servers. If your network demands increased reliability, have a backup DHCP server offline with the same scope as the primary server, so if the primary server goes down you can bring the backup online immediately. (You can also use the Windows 2000 Server Cluster service to create a DHCP cluster.)

You might also want to split the address space between two DHCP servers, with the primary server handling 80 percent of the address space and the secondary server handling 20 percent. If the primary server fails, the secondary server handles all client leases from its 20 percent of the address space until the primary server is brought back online. If both servers are down, clients maintain their IP addresses until their leases run out.

If server reliability is a problem on your network, consider increasing the lease time to allow more time to bring servers back online before clients lose their addresses.

## Windows Internet Name Service

NetBIOS is an interface originally developed to allow applications to access network resources in the Microsoft MS-DOS operating system. As such, it was the primary networking API and naming method for Microsoft networks until the release of Windows 2000.

NetBIOS host names are up to 15 characters long and part of a flat namespace, so all names on a given network must be unique. Normally, host names are resolved by broadcast—not the most efficient means in terms of either time or network bandwidth. Routers also usually do not forward NetBIOS broadcasts, eliminating the ability to resolve host names on a different subnet.

WINS was created to provide a solution to this problem by maintaining a dynamic database of IP addresses and their associated NetBIOS names. However, WINS is still limited in many ways by the underlying architecture of NetBIOS and it is now an optional service in a Windows 2000 network.

Although many of us might be eager to do away with WINS, it is still used by many companies to provide NetBIOS name resolution services to downlevel (legacy) Microsoft operating systems, such as Microsoft Windows 98 and Windows NT, that don't function properly in a NetBIOS-free network. (Windows 2000 and Windows XP don't require NetBIOS support.)

WINS is usually deployed in conjunction with DNS to provide optimal support for newer clients. Although BIND 8 and newer versions can be used adequately as a DNS server for Microsoft Windows .NET Server and Windows 2000 Server networks, BIND doesn't support WINS records, which can cause issues with DNS zone transfers. For this reason, stick with Windows 2000 or newer DNS servers if you need to use WINS servers on your network (although there are workarounds, as discussed in [Chapter 14](#)).

When deploying WINS servers on your network, deploy only the minimum number necessary to provide adequate service to your clients. WINS servers can be a pain to replicate, so keeping the number of servers down can be a big plus. (Microsoft itself, for example, used no more than about 12 WINS servers worldwide before moving to Windows 2000.) If you're doing any major restructuring of your network, consider upgrading earlier clients to Windows XP (or at least Windows 2000) and eliminating WINS from your network.

Don't install WINS on a multihomed server. WINS has enough replication problems without complicating the situation by placing the server on two subnets.

To make WINS and Browsing work correctly when you are in an enterprise environment with subnets and multiple domains, keep a few tricks in mind. There are three possible scenarios listed here, and each is discussed in the sections that follow:

- Single domain across a subnet boundary

- Multiple domains within a subnet boundary
- Multiple domains across a subnet boundary

### **Single Domain Across a Subnet Boundary**

To see the resources of a single domain across a subnet boundary, with only TCP/IP as your protocol, you need to set up WINS servers on both sides of the router or mess around with Lmhosts files. Avoid Lmhosts files like the plague: They're a pain to get right in the first place and have to be manually edited every time there is a change anywhere. They also don't deal well with DHCP, under which IP addresses are subject to change. However, if you're setting up a virtual private network with Internet-connected clients, you might not be able to avoid Lmhosts because these clients don't have an available WINS server.

In general, it's a good idea to have a domain on each side of your router. The alternative is much more traffic across the router than you really want, because every authentication request has to cross over. The obvious choice is to put a WINS server in each domain. No special requirements need to be met for this to work because Browsing doesn't need to be told about another domain.

#### **Real World**

##### **Browsing vs. browsing**

A source of possible confusion in any discussion about Microsoft networking is the subtle distinction between the common meaning of the word "browsing" and the very specific meaning that the word has in Microsoft networking. Many texts use "browsing" to mean looking for or at the resources available, which is a reasonable use of the word. However, "Browsing" in the Microsoft networking sense refers to the Computer Browser service used by Windows-based computers to maintain browse lists of all shared resources on the network. It's easy to get confused, and we try to avoid that here by always capitalizing "Browsing" when using it in the Microsoft networking sense.

With the growth of networks and the introduction of directories such as Active Directory in Windows 2000, Browsing has become much less important. Most networks are too large to browse for resources, and Active Directory helps alleviate this issue by permitting you to query Active Directory for the resources you want. This makes finding resources easier, and also reduces the network traffic caused by Browsing.

### **Multiple Domains Within a Subnet Boundary**

If you're running a forest within a single subnet, you might want a WINS server in each domain, but you don't need to do anything special with Browsing. You can set up and explicitly add the other domains to browse, but this step isn't required.

### **Multiple Domains Across a Subnet Boundary**

Now we get to the tricky one. For everything to work in multiple domains across a subnet boundary, you need to set everything up very carefully. Because the Browsing packets don't cross the subnet boundary unless they know where they're going, you need to explicitly set the Computer Browsing service to browse the domain on the far side of the router. Each domain in the forest or tree needs to be configured to browse any domains on the far side of the router.

For the technical details of WINS and Browsing, see the *Microsoft Windows 2000 Server Resource Kit*. Once you have a network free of Microsoft clients earlier than Windows 2000 (Microsoft Windows Me doesn't count), you can happily turn off WINS and make your life a lot easier.

## IP Version 6

As pointed out earlier, the explosive growth of the Internet has pushed it to the very limits of the original design. The number of IP addresses has grown almost exponentially in recent years, leading to the fear that there will soon not be enough addresses to connect all the devices and computers that people want to connect. If that weren't bad enough, routers are being overloaded by the increasing inadequacy of the IPv4 standard.

To find a solution to the limitations of the 32-bit address space and the limits to the routing protocols in the current structure of TCP/IP, the IETF and others began working on a new version of IP several years ago. Different working groups originally proposed different solutions, but over time these groups have arrived at a consensus on the next generation of IP, IP version 6 (often shortened to IPv6). It was formally accepted by the IETF in December 1994, and the current specification is in RFC 2460.

IPv6 defines a 128-bit IP address space compatible with the current implementation of TCP/IP (version 4, or IPv4). The specifications call for packets to include additional information for improved routing and handling of mobile devices. IPv6 will not only enlarge the address space available, but it will also improve network performance, ease configuration issues, and provide enhanced security.

### Real World

#### Unreal Numbers of Addresses

IPv6 addresses have four times the number of bits that IPv4 addresses do (128 vs. 32), but what does that actually mean? The 32-bit address structure can enumerate more than 4 billion hosts on as many as 16.7 million networks, but the number of potential IPv6 addresses totals  $2^{96}$  times the size of the IPv4 address space (4 billion <sup>96</sup>). This works out to 340,282,366,920,938,463,463,374,607,431,768,211,456 possible addresses. Of course, given routing and hierarchical requirements, this theoretical address space is diminished greatly when making practical estimates. The mathematically minded should consult RFC 1715, in which Christian Huitema analyzes other addressing schemes (including the French and U.S. telephone systems) and concludes that 128-bit addressing will suffice for another 25 years of Internet growth.

Despite the benefits, many are not looking forward to the deployment of IPv6. After all, most companies try to minimize the number of protocols they need to support. Supporting yet another protocol is regarded with less enthusiasm than Friday afternoon performance audits. The transition will be gradual, however, and there is an incredible amount of work in progress to ensure that it is painless as well.

Although the impending shortage of IP addresses has been pushed off somewhat by companies that use a small number of Internet-accessible IP addresses to provide Internet access to an internal private network (which is free to use a class A network), the time for IPv6 is approaching. Some companies, such as ISPs and cellular phone networks, are already deploying IPv6, although it will still be some time before IPv6 actually replaces IPv4.

Unfortunately, Windows 2000 doesn't ship with built-in support for IPv6. There are test-quality IPv6 implementations available for download on Microsoft's Web site (which operate side-by-side with the IPv4 stack), but these implementations are currently intended for software developers and testing purposes, not for actual production use. A fully supported IPv6 protocol stack might be available at some point for Windows 2000; otherwise, consider upgrading to Windows .NET Server when it becomes available, which is slated to have built-in support for IPv6.

## **Summary**

Although it's not necessary to become an expert on TCP/IP to run a network, some basic knowledge is required. TCP/IP and DNS in particular are worth studying in some depth because so many network difficulties can be traced to the misconfiguration of one or the other. The next chapter covers the administration of the TCP/IP server programs DNS, DHCP, and WINS.

# Chapter 14

## Administering TCP/IP

Any sizable TCP/IP-based network needs to use DHCP, DNS, and possibly WINS servers, regardless of whether the Active Directory service is deployed (Active Directory is discussed at length in Chapters 11 and 12). DHCP servers dynamically provide clients with IP addresses and network configuration information, while DNS servers translate friendly host names (such as *Srv1.scribes.com*) into IP addresses, or vice versa. If the network is routed and contains previous Microsoft Windows clients (Microsoft Windows 98 clients or other clients earlier than Microsoft Windows 2000), you also probably need WINS servers to translate between NetBIOS names (such as Srv1 in the preceding host name) and IP addresses.

Although Active Directory and Windows clients function with standards-based DHCP and DNS servers, such as those available for UNIX systems (nobody other than Microsoft makes WINS servers), Active Directory works best with the DHCP and DNS servers provided as a part of Microsoft Windows 2000 Server. There are a few additional capabilities available when you deploy Active Directory in conjunction with DHCP and DNS servers running Windows 2000 Server, such as secure dynamic updates for legacy clients, and multiple-master replication between DNS servers.

This chapter shows you how to install and manage DHCP, DNS, and WINS servers running Windows 2000 Server.

### More Info

For basic background information about these services, see [Chapter 13](#). For more in-depth information, pick up a copy of *Microsoft Windows 2000 TCP/IP Protocols and Services Technical Reference* (2000) from Microsoft Press. More information about installing and managing DHCP, DNS, and WINS is available in the Windows 2000 help system, as well as in the *Microsoft Windows 2000 Server Resource Kit* (2001), available from Microsoft Press.

## Using DHCP

DHCP is an essential service for any TCP/IP-based network that has more than a small number of clients. DHCP allows clients to boot up and automatically receive an IP address and other TCP/IP settings such as DNS servers, WINS servers, and the default gateway.

The following sections describe how to use the DHCP server provided with Windows 2000 Server. For more information about how DHCP works, see [Chapter 13](#).

## Designing DHCP Networks

It's important to design the deployment of DHCP servers in a way that fits the network. Small, nonrouted networks can use a single DHCP server. If you have a larger network, you need to consider the subnets and routers in use, and you should also split the address space between two servers to provide fault tolerance. Use the following checklist as part of your planning:

- Draw a map of the network, showing each physical and logical subnet and the routers between the subnets.
- If the network uses routers to subnet the network, determine whether the routers support forwarding DHCP broadcasts (most newer routers do, although this option needs to be turned on).
- Plan on sectioning the IP address range between two servers to provide fault tolerance (DHCP servers can't communicate with each other, so they can't share the same addresses). Give 80 percent of the addresses to one server, and 20 percent to the other server (this is called the 80/20 rule). If one server goes down, clients can still receive IP addresses from the other server. Alternatively, you could set up a DHCP server cluster to handle 100 percent of the addresses in the preceding example.
- If the link between the subnets is fast and reliable and the routers in between can be configured to forward DHCP broadcasts, you can place the second DHCP server on a different physical subnet. Otherwise, deploy a pair of DHCP servers to each physical subnet.

If you're using WINS, you can often make the primary WINS server the secondary (20 percent) DHCP server, and the secondary WINS server the primary (80 percent) DHCP server.

- Don't run a DHCP server on a domain controller if you plan on using the DHCP server to update DNS records for legacy clients. Doing so creates an additional security risk (consult the DNS help topic in the Windows 2000 Server help system for more information—specifically check the Dynamic Updates topics).
- Size the servers appropriately. Microsoft recommends that a single DHCP server service no more than 10,000 clients and 1000 scopes.
- Upgrade any Microsoft Windows NT 4 domain controllers to Windows 2000 Server.
- Use a disk drive with fast access time, or better yet, use a RAID. DHCP servers frequently access the disk drives, and a fast storage subsystem means better DHCP performance.

Another method of protecting against DHCP server failure is to have a hot-backup. To do this, set up a DHCP server identically to the primary DHCP server, except with its own scope that encompasses 20 percent of the address space (or possibly less). Don't activate this server (it could be serving other roles that you don't want to slow down unless it's an emergency). If the primary DHCP server goes down, manually bring the backup server online by activating its scope. However, splitting the address range between two live servers is a superior solution because it provides automatic fault tolerance—no manual intervention is required.

## Plan the IP Address Range and Exclusions

Besides determining how to place the DHCP servers into the network structure, you also need to plan the IP address ranges you'll use, as well as which IP addresses to reserve or exclude from this pool of addresses. Use the following list to help plan the IP address ranges to use and exclude:

- Determine the range of IP addresses that the DHCP server will manage. Most likely, this will be a private address range such as 10.x.x.x or 192.168.x.x.
- Make a list of any IP addresses to exclude to support hosts with static IP addresses. Only DHCP servers and hosts that don't work as DHCP clients need static IP addresses, although you might want to use static addresses for DNS servers as well.

Consider switching all hosts with statically assigned IP addresses to DHCP assigned addresses. If any servers need unchanging addresses, create client reservations for the servers using DHCP (lease reservations are covered later in this chapter). This allows the servers to use an unchanging address and yet still have all TCP/IP options configured automatically through DHCP. It also makes it easier to track and manage IP addresses, and it will make your life much easier if your company ever needs to change its addressing, as might happen after a merger. The fewer static addresses, the better.

- Make a list of servers that need to have unchanging IP addresses, such as DNS and WINS servers.
- If the DHCP server will be using Internet-registered IP addresses (you probably won't), register the IP addresses with the Internet service provider (ISP).

## Installing the DHCP Service

To install the DHCP service on a Windows 2000 Server computer, follow these steps:

1. Use the Network and Dial-Up Connections folder to manually configure a static IP address on any network interfaces for which the DHCP server will provide DHCP services (changing network settings is discussed in [Chapter 6](#)).
2. Open the Add/Remove Programs Control Panel tool, and then click Add/Remove Windows Components to launch the Windows Components Wizard.
3. Select Networking Services from the list of components, and then click Details.
4. Select the check box next to the Dynamic Host Configuration Protocol (DHCP) component, as shown in Figure 14-1, and then click OK. Click Next to install the service. All the necessary files are copied to the hard disk. Click Finish to close the Windows Components Wizard.

You can also use the Configure Your Server Wizard to install the DHCP service and start the Create New Scope Wizard.

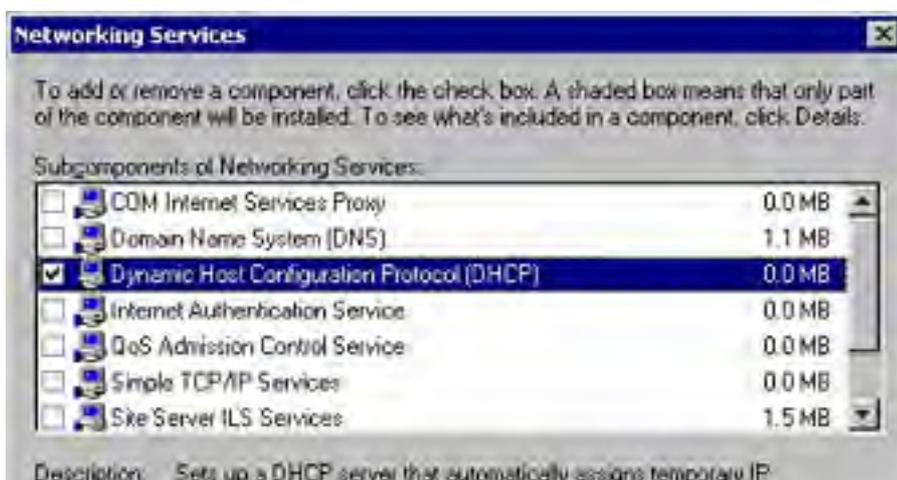

Figure 14-1. Installing the DHCP service.

## Creating a New Scope

Now you're ready to launch the DHCP Manager and create a new scope of IP addresses for the DHCP server to manage (a scope is a range of IP addresses that the DHCP server can manage). Before you do this, make sure you know which range of IP addresses is approved, which IP addresses need to be excluded for systems with static IP addresses, and which IP addresses need to be reserved for DNS or WINS servers.

To open DHCP Manager and create the new scope, follow these steps:

1. Launch DHCP from the Administrative Tools folder on the Programs menu.
2. If the DHCP server you want to administer isn't listed in the DHCP console tree, choose the Add Server command from the Action menu to locate the server you want to administer.
3. Select the appropriate DHCP server in the console tree. Select the Action menu and choose New Scope to launch the New Scope Wizard.

### Real World

#### Scopes, Superscopes, and Multicast Scopes

A scope is simply the range of possible IP addresses on a network. To add more clients to a network where the scope is exhausted, you can add an additional scope as long as the scope doesn't belong to the same subnet as an existing scope. An excellent source of information on the complex subject of choosing subnet masks and other TCP/IP issues is *Microsoft Windows 2000 TCP/IP Protocols and Services Technical Reference* by Thomas Lee and Joseph Davies (Microsoft Press, 2000).

When you create multiple scopes, it's important to understand that clients from one logical subnet aren't able to obtain IP addresses from a different scope than the one they currently belong to, because the other scope is in a different logical subnet. If this is the behavior you want, great. However, if you want clients to be able to use addresses from other scopes, use a superscope.

A superscope is a collection of scopes grouped together into a single administrative whole. There are three primary reasons you might want to use superscopes:

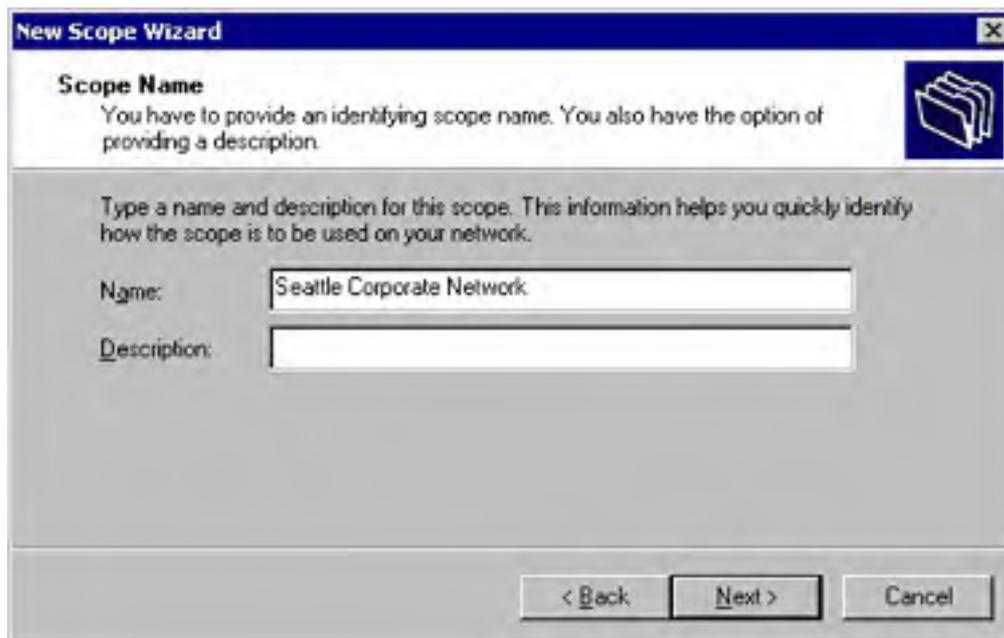

- One scope is running out of IP addresses.
- You need to renumber the IP network, and therefore move clients from one set of addresses to another.
- You want to use two DHCP servers on the same subnet for redundancy.

When you create a superscope, you enable clients to obtain or renew leases from any scope within the superscope, even if they contain addresses from a different logical subnet.

A multicast scope is simply a scope of multicast addresses (class D addresses) that are then shared by many computers (members of the multicast group).

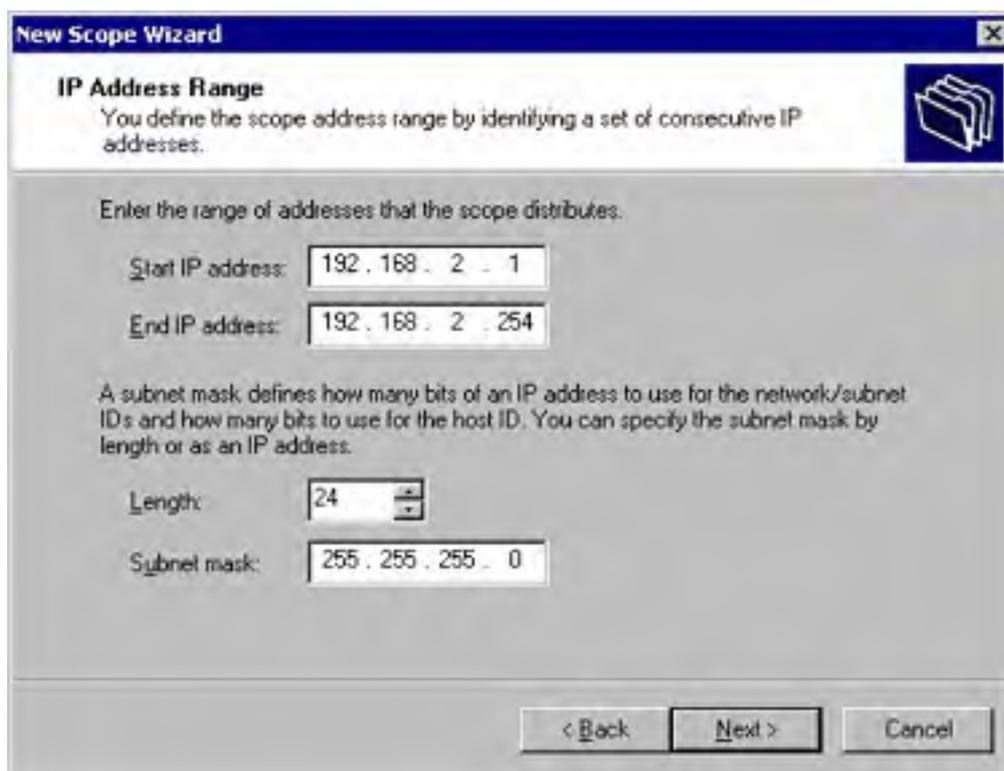

- Click Next, and type a name and description for the scope to use for distinguishing this scope from others (Figure 14-2). Click Next.

**Figure 14-2.** The Scope Name screen of the New Scope Wizard.

- Type the IP address that the scope begins with in the Start IP Address field, and type the IP address that the scope ends with in the End IP Address field, as shown in Figure 14-3.

**Figure 14-3.** The IP Address Range screen of the New Scope Wizard.

- Type the network's subnet mask in the Subnet Mask box, or use the Length box to adjust the length of the subnet mask. Then click Next.
- To exclude a range of addresses from the scope, in the Start IP Address box, type the start IP address for the exclusion range; in the End IP Address box, type the end IP address for the exclusion range (to add a single address, enter it in the Start IP Address box and then click Add). Then click Add. Add as many exclusions as needed, and click Next when you're finished.

8. Specify the lease duration for the clients, and then click Next.

### Real World

#### Setting Lease Durations

Use longer leases for networks without redundant DHCP servers to permit more time to recover an offline DHCP server before clients lose their leases, or to minimize network traffic at the expense of less frequent address turnover. You can also use longer leases if scope addresses are plentiful (at least 20 percent available), the network is stable, and computers are rarely moved.

In contrast, scopes that support dial-up clients or mobile clients such as laptops or PDAs can have shorter leases and therefore function well with fewer addresses.

Lease durations are set in the scope's Properties dialog box. Scopes are listed in the DHCP administration console.

9. To configure DHCP options, choose Yes; otherwise, choose No, and then click Next. If you select No, click Finish to complete the setup of the scope.

### Real World

#### DHCP Options

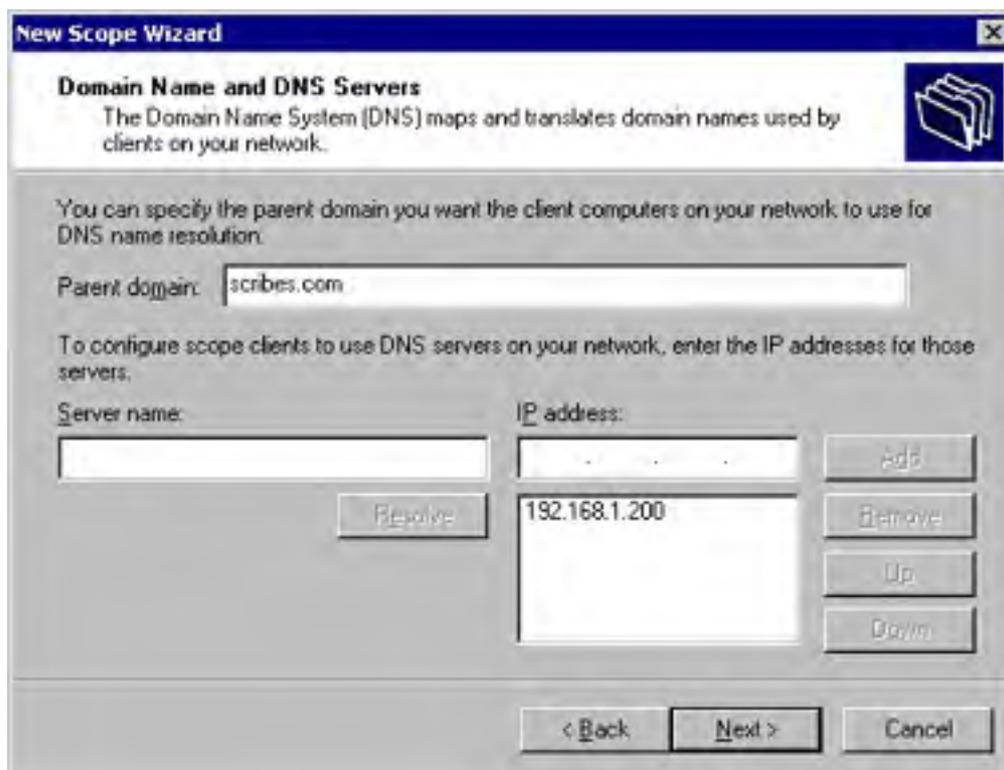

There are four different levels at which you can configure DHCP options in a Windows 2000 DHCP server:

- **Server options** These options apply to all clients of the DHCP server you're managing. Because of this, use server options sparingly—only specify server options for parameters common across all scopes on the server.
- **Scope options** These are the most often used type of options—they apply to all clients within a scope and override any server options set on the DHCP server.
- **Client options** These options are specified for individual clients. This is useful if specific computers need special options. Client options override all other options, including class options.
- **Class options** These options provide DHCP parameters to clients based on the type of client they are—either using vendor classes such as all Microsoft Windows 95/98 clients, or with user classes that specify clients with particular needs, such as RRAS clients, "mobile clients," or any other user-defined class. Class options aren't used very often. For more information about creating and using class options, consult the Help system, or the *Microsoft Windows 2000 Server Resource Kit TCP/IP Core Networking Guide*.

10. If you chose to specify DHCP options for this scope, type the routers (default gateways) you want clients to use in the Router (Default Gateway) screen, clicking Add after typing each one. When you're finished adding gateways, click Next.

Set only the options you know you need. If you're uncertain about an option, leave it alone.

11. Type the domain name of the domain in the Parent Domain box, and add the IP addresses for the DNS servers in the IP Address box, as shown in Figure 14-4, clicking Add after entering each one. Click Next when you're done.

**Figure 14-4.** The Domain Name And DNS Servers screen of the New Scope Wizard.

12. In the WINS Server Address box, type the addresses of any WINS servers you configured on the network for resolving NetBIOS names into IP addresses for downlevel clients. Click Next.
13. To activate the scope immediately, choose Yes; otherwise, choose No to activate the scope later. Click Next, and then click Finish to complete the scope configuration.

## Authorizing the DHCP Server and Activating Scopes

After you set up the DHCP server and create the scopes, you must authorize the server to give leases and activate the scopes. (If installed on a domain controller, the DHCP server is authorized automatically when you add the server to the DHCP Manager console.)

Authorizing a DHCP server is an important step that Windows 2000 Server provides to reduce the occurrence of unauthorized (rogue) servers set up to hand out false IP addresses to clients. Although rogue DHCP servers that use UNIX or a hardware-based DHCP server could still be set up, Windows 2000-based DHCP servers can't be used without authorization (which also means no Windows 2000 DHCP servers in a workgroup).

To authorize the DHCP server after installing the service, follow these steps:

1. In the DHCP Manager, right-click DHCP at the root of the console tree and choose Manage Authorized Servers from the shortcut menu.
2. Click Authorize in the Manage Authorized Servers dialog box.
3. Type the name or IP address for the server in the text box provided and click OK.
4. Verify that the information is correct in the dialog box displayed, and then click Yes. Click OK to close the Manage Authorized Servers dialog box.

To activate a scope, right-click the scope in the console tree, and then choose Activate from the shortcut menu.

Don't activate a scope until you finish selecting all the options you want. Once you activate a scope, the Activate command on the menu changes to Deactivate.

Don't deactivate a scope unless you're permanently retiring the addresses from the network. If you want to temporarily disable a scope, adjust the exclusions for the scope instead. This permits existing clients to keep their addresses while preventing any further leases in the scope.

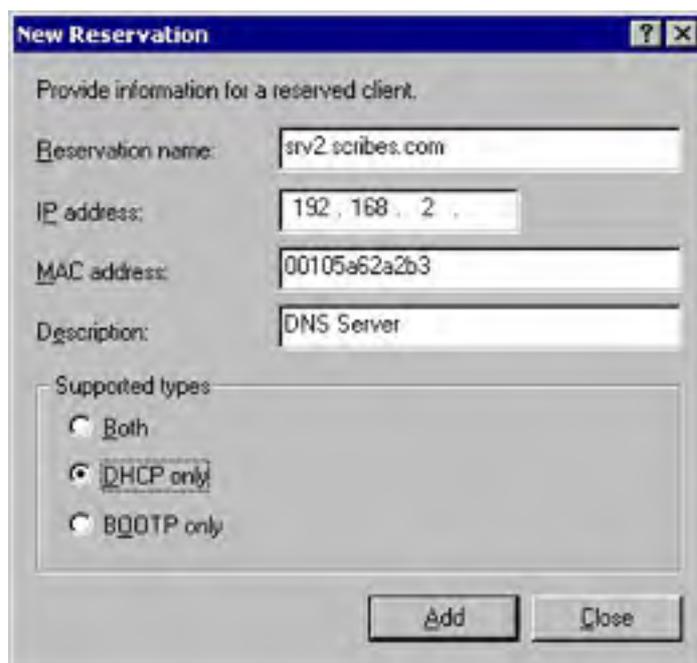

## Adding Address Reservations

Reservations are handy items that you can use instead of static IP addresses (which require you to create exclusions in the DHCP scope) for all hosts that need to maintain a specific IP address, such as DNS and WINS servers (DHCP servers actually do need static IP addresses). Using reservations instead of static addresses guarantees that a server has a consistent IP address, while also providing the ability to recover the IP address in the future if the server is decommissioned or moved.

To add an address reservation to a scope, follow these steps:

1. Right-click the Reservations folder under the desired scope, and choose New Reservation from the shortcut menu.
2. Type a name for the reservation in the Reservation Name box.
3. Type the IP address for the client in the IP Address box, and type the MAC address for the client in the MAC Address box, as shown in Figure 14-5.

When reserving an address for a client, make the reservation on all DHCP servers that potentially service that client.

**Figure 14-5.** The New Reservation dialog box.

4. Type a description for the reservation in the Description box.
5. Determine which type of client you want to allow to use the reservation by selecting DHCP Only, BOOTP Only, or Both. Click Add.

To obtain the MAC address, go to the client computer (or make a remote desktop connection) and type `ipconfig /all` at the command prompt. The MAC address is listed as the physical address. Leave out the dashes when entering the MAC address in step 3 in the preceding procedure.

## Enabling Dynamic Updates to a DNS Server for Earlier Clients

Microsoft Windows XP and Windows 2000 clients automatically update their forward lookup records with the DNS server after obtaining a new IP address from a DHCP server. No DHCP-DNS interaction is required for this behavior. However, Windows XP and Windows 2000 clients explicitly request that the DHCP server update their reverse lookup (PTR) records on the DNS server, which requires communication between the DHCP and DNS servers.

Earlier clients such as Windows Me, Windows 98, and Windows NT clients can't update their resource records themselves, so the DHCP server does it for them—if you turn on this feature (which is recommended). When this feature is enabled, the DHCP server updates an earlier client's forward and reverse lookup records when the client obtains a new IP address.

To enable earlier clients to function properly with DHCP and dynamic DNS, use the following procedure:

1. Select the scope or DHCP server on which you want to permit dynamic DNS updates.
2. From the Action menu, choose Properties, and then click the DNS tab.
3. Make sure that the Automatically Update DHCP Client Information In DNS check box is selected, as shown in Figure 14-6.

**Figure 14-6.** The DNS tab of the Properties dialog box for a DHCP scope.

This enables the DHCP server to update DNS records for clients, based on the following settings (select the Enable Updates For DNS Clients That Do Not Support Dynamic Update check box, which isn't selected by default):

- **Update DNS Only If DHCP Client Requests** This option allows Windows 2000 and other Windows clients to decide whether to update the DNS server themselves or have the DHCP server update their DNS address (A) and reverse lookup (PTR) records (by default, Windows 2000 and other Windows clients update their own A records, but they have the DHCP server update their PTR records).
- **Always Update DNS** This option forces the DHCP server to update the A and

PTR records for all DHCP clients, even if they request permission to update the DNS server themselves.

- **Discard Forward (Name-To-Address) Lookups When Lease Expires** This option forces the DHCP server to delete the A record as well as the PTR record of a client whose lease has expired (the PTR record is always deleted at lease expiration, regardless of this setting).
- **Enable Updates For DNS Clients That Do Not Support Dynamic Update** This option enables the DHCP server to update the forward and reverse lookup records for clients that can't update their own forward lookup records (Windows Me and all other versions of Windows prior to Windows 2000). If you don't select this check box, the DNS records of pre-Windows 2000 clients aren't dynamically updated.

The Windows 2000 DHCP server might not be able to properly update DNS records for legacy clients if the DNS server isn't a Windows 2000 DNS server. However, the specifications are published in the RFC draft document "Interaction Between DHCP and DNS," so it's inevitable that other DNS servers will eventually work this way. Until then, use the all-Microsoft solution if dynamic DNS updates for earlier clients are important on your network.

## Using Multiple DHCP Servers for Redundancy

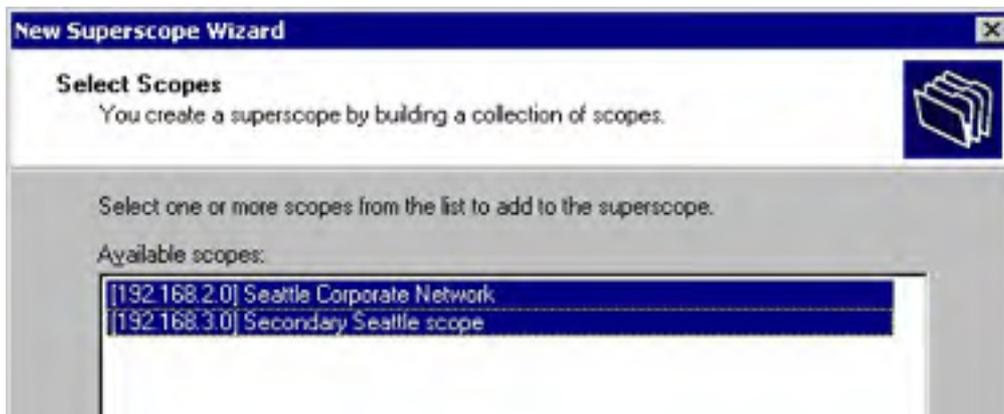

It's vital that computers are able to obtain and keep IP addresses: without an IP address a computer can't communicate on a network or connect to the Internet. Most computers won't lose network connectivity immediately if the DHCP server goes down, but new computers, returning laptops, or little-used systems that haven't recently logged on might not be able to obtain network access until the DHCP server is working properly.

To help prevent these unhappy events, you should use redundant DHCP servers. The following sections show how to set up redundant servers using the traditional method of splitting the addresses between two servers, as well as the more complex, high-performance method of setting up a DHCP server cluster.

### Splitting the Address Space Between Two Servers

To employ two DHCP servers for load balancing and redundancy, use the following procedure:

1. Create scopes for all valid IP addresses that the DHCP servers you're setting up will manage. This might mean creating a single scope (if you have a single subnet), or multiple scopes encompassing a number of subnets.
2. Set up exclusions so that the primary DHCP server handles 80 percent of the address pool and the secondary server handles the other 20 percent of the addresses. Thus, each server excludes the addresses available on the other server so that no address appears in both servers' address pools.
3. Create a superscope on both servers that contains all valid scopes for the physical subnet. To do so, select the appropriate DHCP server from the console tree, choose the New Superscope command from the Action menu, name the superscope, and then select the member scopes to include, as shown in Figure 14-7.

**Figure 14-7.** *Creating a new superscope.*

You can delete a superscope without affecting the member scopes by selecting the superscope and pressing Delete. However, *deactivating* a superscope deactivates all member scopes as well.

If you have a routed network with DHCP relay agents or routers that forward DHCP broadcasts between the physical subnets, you can use DHCP servers on other subnets as secondary servers. However, unless the DHCP server has at least one scope with available addresses from the client's own subnet, the client isn't able to obtain or renew an IP address lease. To make sure this doesn't happen, create two superscopes on each server, one for each logical subnet. Thus, each server owns 80 percent of the address pool for its local subnet, and 20 percent of the address pool for the other DHCP server's local subnet.

## Setting Up a DHCP Server Cluster

Although splitting the address space between two DHCP servers is an adequate way to provide redundancy and load balancing, an even more powerful solution is to set up the DHCP service to run on a Windows 2000 Server cluster. The members of the cluster equally share the DHCP service workload, and if one of the servers fails, the other servers continue to provide addresses to clients as if nothing had happened. Instead of an address space split between servers, each server in the cluster has access to the complete address space.

Using the Windows 2000 Cluster service is discussed in detail in [Chapter 16](#), but the basic steps to get a DHCP server up and running in a cluster are as follows:

1. Install DHCP (as described earlier in this chapter) and set up the server cluster (as described in [Chapter 16](#)).

Microsoft recommends that you postpone creating DHCP scopes until the DHCP service is set up with the cluster, as described in the following steps.

2. Launch Cluster Administrator from the Administrative Tools folder on the Programs menu.
3. Select the cluster you want to use to host the DHCP service.
4. Choose the Configure Application command from the File menu to open the Configure Application Wizard.
5. Click Next in the first page and then choose the Use An Existing Virtual Server option and select the appropriate group. If you haven't already created a virtual server, choose the Create A New Virtual Server option and use the wizard to create a new virtual server (as discussed in [Chapter 16](#)).
6. In the Create Application Cluster Resource page, choose the Yes, Create A Cluster Resource For My Application Now option, choose the DHCP resource type, and then click Next.
7. Type a name and optionally a description for the DHCP resource and then click Next.
8. Click Advanced Properties, click the Dependencies tab, and then click Modify.

9. Double-click the IP address, physical disk, and network name that you want to use for the DHCP server cluster. These resources then appear as dependencies. Click OK when finished, optionally modify the properties of the resource, and then click OK.
10. Click Next in the Application Resource Name And Description page, specify where the DHCP database should be stored (most likely the physical disk you specified in step 9), and then click Next. If you select a different disk, make sure that it belongs to the group and that a dependency has been created for it.
11. Review the settings and click Finish to complete the wizard.
12. Verify that the resource is displayed in the correct group, and then right-click the resource and choose Bring Online from the shortcut menu to enable the DHCP server to begin servicing clients.
13. Authorize the DHCP server in Active Directory (if on an Active Directory network), as discussed earlier in this chapter.

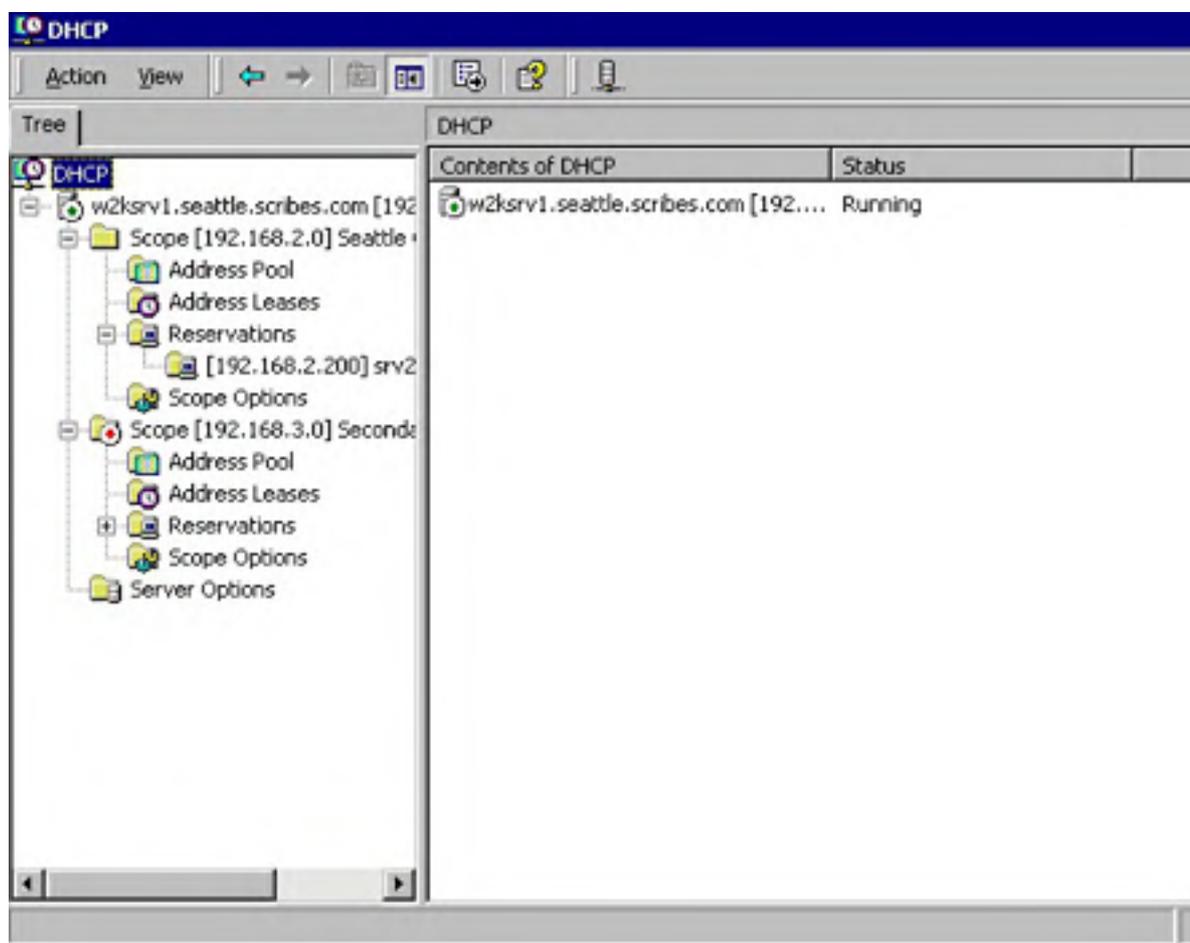

Right-click the group to which the DHCP resource belongs and choose Move Group from the shortcut menu to verify that the resource has been properly created on the cluster. If the group moves properly, the resource setup is fine.

## Other DHCP Functions

The DHCP snap-in, shown in Figure 14-8, provides a single point from which to administer all the properties and functionality of the DHCP servers.

### Adding a DHCP Server

To add a DHCP server to the list of managed servers, right-click DHCP in the console tree and then choose Add Server from the shortcut menu. Select the server you want to add to the console and click OK.

**Figure 14-8.** *The DHCP snap-in.*

## Modifying Scopes

Modify a scope's properties by right-clicking the scope in the console tree and choosing Properties from the shortcut menu. This displays the Scope Properties dialog box shown in Figure 14-9.

**Figure 14-9.** *The General tab of the Properties dialog box for a DHCP scope.*

Deactivate a scope by right-clicking the scope and choosing Deactivate from the shortcut menu. To return the scope to use, right-click the scope again and choose Activate.

To temporarily stop distribution of leases from a scope, adjust the exclusion range so that no new addresses are available rather than deactivating the scope. This avoids forcing clients currently using addresses in the scope to prematurely obtain a new IP address from a different DHCP server or a different scope.

Exclude a range of IP addresses from a scope by right-clicking the Address Pool folder under the appropriate scope and choosing New Exclusion Range from the shortcut menu. Type the range of addresses you want to exclude and then click Add.

## Enabling Server-Based Conflict Detection

To enable server-based conflict detection so that the DHCP server checks an IP address before leasing it, verifying that the address isn't already in use, right-click the DHCP server in the console tree and choose Properties from the shortcut menu. Click the Advanced tab, and then set the Conflict Detection Attempts number to 1. Don't increase this number beyond 2; this results in additional searches and needlessly increases the time it takes a client to obtain an IP address.

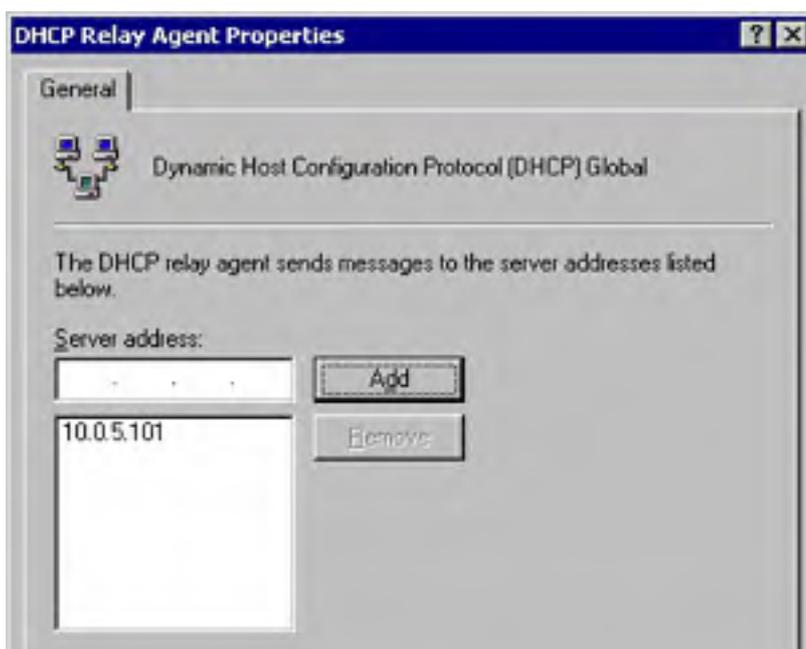

Windows XP and Windows 2000 clients automatically verify that the IP address offered by the DHCP server is available before accepting it, so conflict detection is useful only for earlier clients. In the interest of conserving network bandwidth and reducing client startup times, leave this option disabled unless you're having problems with duplicate IP addresses, as might be the case if you have undocumented static IP addresses on the network.

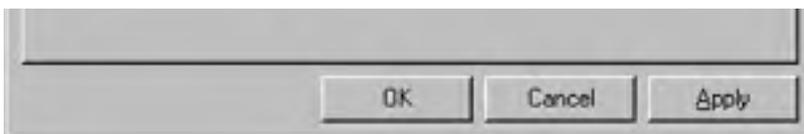

## Setting Up a DHCP Relay Agent

If you have a routed network, deploy DHCP servers on both sides of routers to maximize reliability and minimize bandwidth usage. However, there are instances in which you want to allow DHCP to work across a router; for example, you might want to place a secondary DHCP server on the other side of a router. Or, if the connection is very reliable and fast, as might be the case with a partitioned local network or municipal area network (MAN), you might want to simply allow clients to cross the router to reach a DHCP server.

You can configure most routers manufactured in the last several years to pass DHCP broadcasts (they're BOOTP-compliant), but if the router doesn't support forwarding DHCP broadcasts, you can set up a server running Windows 2000 Server as a DHCP relay agent using the following procedure:

1. Launch Routing and Remote Access from the Administrative Tools folder on the Programs menu.
2. If the server you want to make a DHCP relay agent isn't listed in the console tree, choose the Add Server command from the Action menu to locate the server you want to administer.
3. If the appropriate server isn't already enabled, select it, choose the Configure And Enable Routing And Remote Access command from the Action menu, and then click Next (otherwise skip to step 5).
4. Choose Manually Configured Server in the wizard, click Next, and then click Finish.
5. Open the IP Routing object on the desired server, right-click the DHCP Relay Agent object, and then choose New Interface from the shortcut menu.
6. Select the network adapter connected to the network with the wayward DHCP clients, and then click OK. Click OK in the next screen.
7. Right-click the DHCP Relay object again and choose Properties from the shortcut menu.
8. Type the address of a DHCP server you want to forward DHCP requests to and then click Add, as shown in Figure 14-10.

**Figure 14-10.** Setting up a DHCP relay agent.

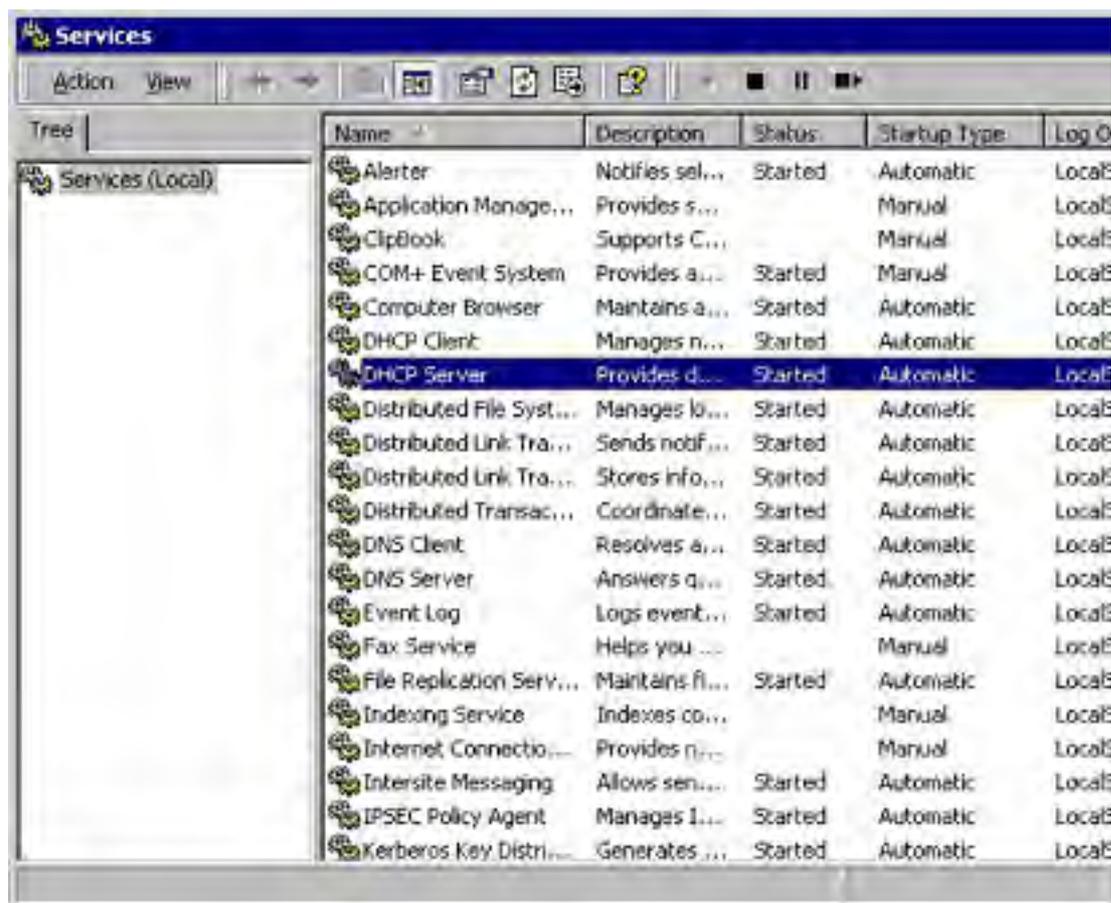

To make a Windows NT 4 system into a DHCP relay agent, open the Network tool in Control Panel, click the Protocols tab, double-click the TCP/IP protocol item, click the DHCP Relay tab, click Add, and then type the IP address for the DHCP server on another subnet. The Windows NT system must be a member of the subnet containing the clients you want to forward to a DHCP server on another subnet and can't actually be a router itself.

## Moving DHCP to Another Server

It occasionally happens that you need to move the DHCP service from one computer to another, perhaps because of a hardware upgrade (or failure) on the existing server. To prevent an interruption in the dispersing of leases, be sure there is a secondary DHCP server available during the transition.

To move a DHCP server database from one computer to another, use the following procedure:

1. If the DHCP console is open, close it.
2. Launch Services from the Administrative Tools folder on the Programs menu.
3. Select the DHCP Server service and click the Stop Service toolbar button, as shown in Figure 14-11.

**Figure 14-11.** Stopping the DHCP Server service.

4. Right-click the DHCP Server service and choose Properties from the shortcut menu.
5. Choose Disabled from the Startup list. This prevents the service from restarting when you open the DHCP console.

6. Copy the contents of the `\%SystemRoot%\System32\Dhcp` folder to a temporary folder on a network share that is accessible from the destination computer.
7. Install the DHCP service on the destination computer and restart the computer, if you haven't already.
8. Launch Services on the destination computer from the Administrative Tools folder on the Programs menu.
9. Select the DHCP Server service and click the Stop Service toolbar button.
10. Delete the contents of the `\%SystemRoot%\System32\Dhcp` folder on the destination computer.
11. Copy the Dhcp.mdb file from the temporary folder (in the System32\Dhcp folder) to the destination computer's `\%SystemRoot%\System32\Dhcp` folder.
12. Select the DHCP Server service in the destination computer's Services window and click Start Service.
13. Launch DHCP on the destination server from the Administrative Tools folder on the Programs menu.
14. Select the destination server in the DHCP console, and then choose the Reconcile All Scopes command from the Action menu.
15. Click Verify. Click Reconcile to reconcile leases as necessary.
16. Select the server and choose the Authorize command from the Action menu to authorize the server in Active Directory.

### **Using Ipconfig to Release, Renew, or Verify a Lease**

On any Windows computer without a static IP address, you can run a command-line utility to release, renew, or verify the client's address lease. At a command prompt (or in the Run window), use one of the following commands:

- To release a client's lease, type `ipconfig /release`.
- To renew a lease, type `ipconfig /renew`.
- To verify the client's lease, type `ipconfig /all`.

The Ipconfig program is useful when troubleshooting problems because it displays every detail of the current TCP/IP configuration. You can find more troubleshooting information in [Chapter 38](#).

## Using DNS Server

In most TCP/IP-based networks, name resolution is provided by one or more DNS servers, which are also required for Windows 2000 Server-based networks using Active Directory.

Although Active Directory works with any DNS server that complies with the appropriate standards, such as BIND version 8.2.2 or later, the DNS server provided with Windows 2000 Server is more than good enough. In fact, unless you already have BIND deployed on the network, you should use Microsoft's DNS server for the network. The DNS server in Windows 2000 Server is easy to set up, integrates well with Active Directory, provides full multimaster zone replication when using Active Directory-integrated zones, and generally works as it's supposed to.

If you're using Active Directory-integrated DNS, you can skip the next section, as DNS is automatically set up during the Active Directory Setup Wizard (see [Chapter 11](#)).

## Installing DNS

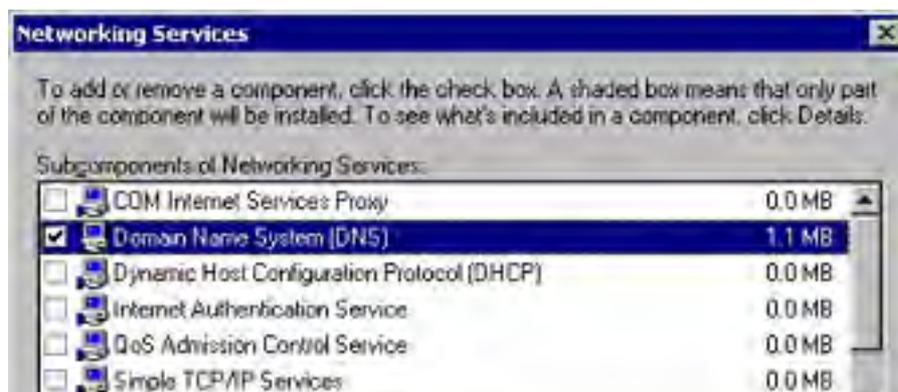

To install DNS, set up Active Directory on the server and let Windows install DNS at the same time. This provides domain controller functionality and also lets DNS benefit from Active Directory integration. To set up the server as a domain controller, see [Chapter 11](#).

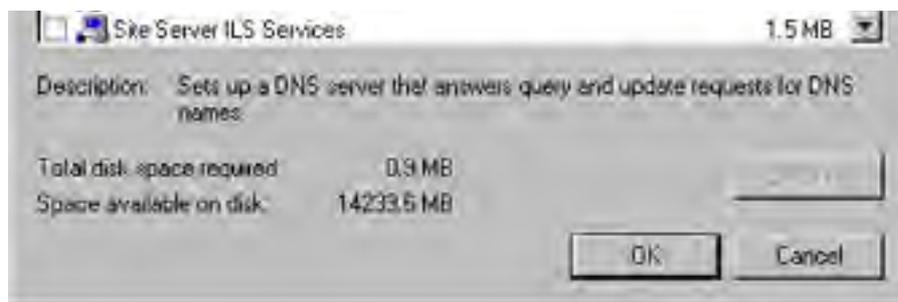

If DNS wasn't installed on the domain controller when you set up Active Directory, or you don't want to use Active Directory integration with DNS Server, follow these steps to install the DNS service, or use the Configure Your Server Wizard, which is discussed in [Chapter 6](#):

1. Click Start and choose Settings, and then select Network And Dial-Up Connections. Right-click the connection you want, and choose Properties from the shortcut menu.
2. Select the Internet Protocol (TCP/IP) entry, and then click Properties. Type the IP address, subnet mask, and default gateway that you're using. Be sure the Use The Following DNS Server Addresses option is selected. In the Preferred DNS Server box, type the computer's assigned IP address.

An alternative to using a static IP address is to make a client reservation with the DHCP server so that the DNS server is always guaranteed the same IP address.

3. Right-click the My Computer icon, and choose Properties from the shortcut menu.
4. In the Computer Name tab, click Change. In the Identification Changes box, click More (you won't be able to perform this procedure on domain controllers).
5. In the DNS Suffix And NetBIOS Computer Name dialog box, type the DNS domain name, and click OK. Reboot the server to implement the DNS suffix changes (if any, otherwise no reboot is necessary).
6. Open the Add/Remove Programs Control Panel tool, and then click Add/Remove Windows Components to launch the Windows Components Wizard.
7. Select Networking Services from the list of components, and then click Details.
8. Select the check box next to the Domain Name System (DNS) component, as shown in Figure 14-12, and then click OK.

**Figure 14-12.** Installing the DNS service.

9. Click Next to install the service. All the necessary files are copied to the hard disk.

## Using the Configure A DNS Server Wizard

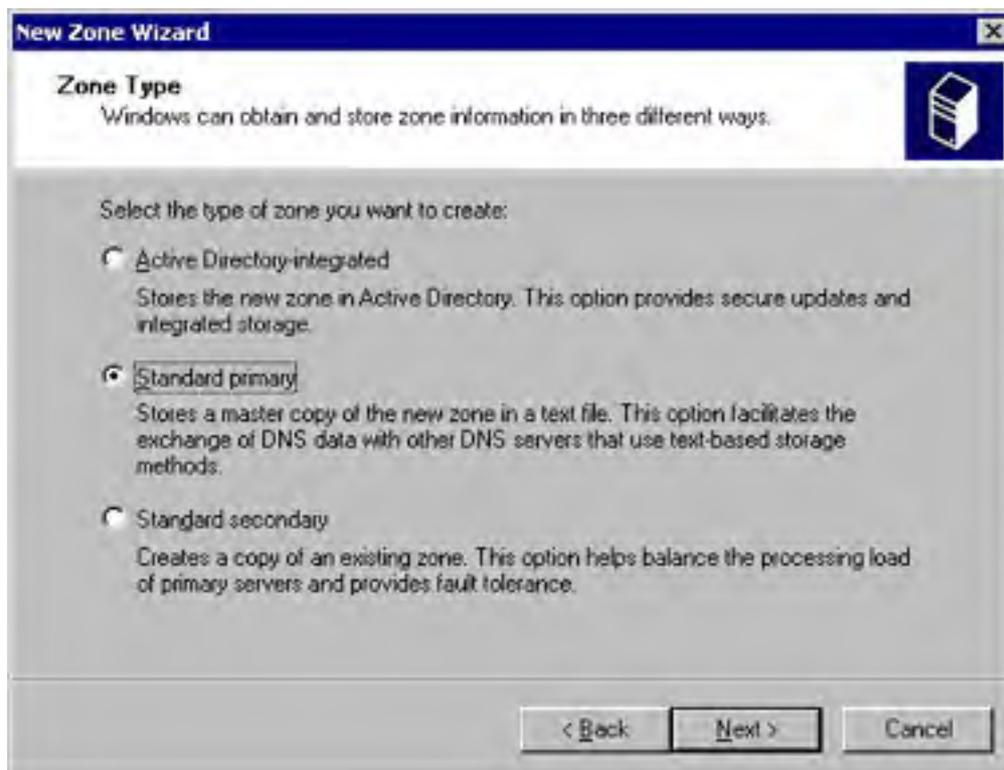

Windows 2000 provides a handy wizard to help you set up a DNS server. The following procedure walks you through the wizard, while later sections delve into more detail on individual tasks that the wizard accomplishes:

1. Launch DNS from the Administrative Tools folder on the Programs menu.
2. Select the DNS server you want to configure (choose the Connect To Server command from the Action menu if the server isn't displayed in the console tree).
3. Choose the Configure The Server command from the Action menu.
4. Click Next in the first page.
5. Choose the Yes, Create A Forward Lookup Zone option in the Forward Lookup Zone page, shown in Figure 14-13, and then click Next.

**Figure 14-13.** Choosing whether to create a forward lookup zone.

- Specify whether the DNS server will maintain the zone (Active Directory-Integrated or Standard Primary), recording and handling DNS records for clients on the network, or whether another DNS server (possibly maintained by your ISP) maintains the zone (Standard Secondary), as shown in Figure 14-14. Click Next to continue.

**Figure 14-14.** Choosing whether to create a primary or secondary forward lookup zone.

### Real World

#### The Need (or Lack Thereof) for Secondary DNS Servers

Because of the pivotal role DNS plays in any TCP/IP-based network, it's vital for it to be reliable. Small networks can often make do with a single DNS server, but medium and large networks must have fault-tolerant DNS service.

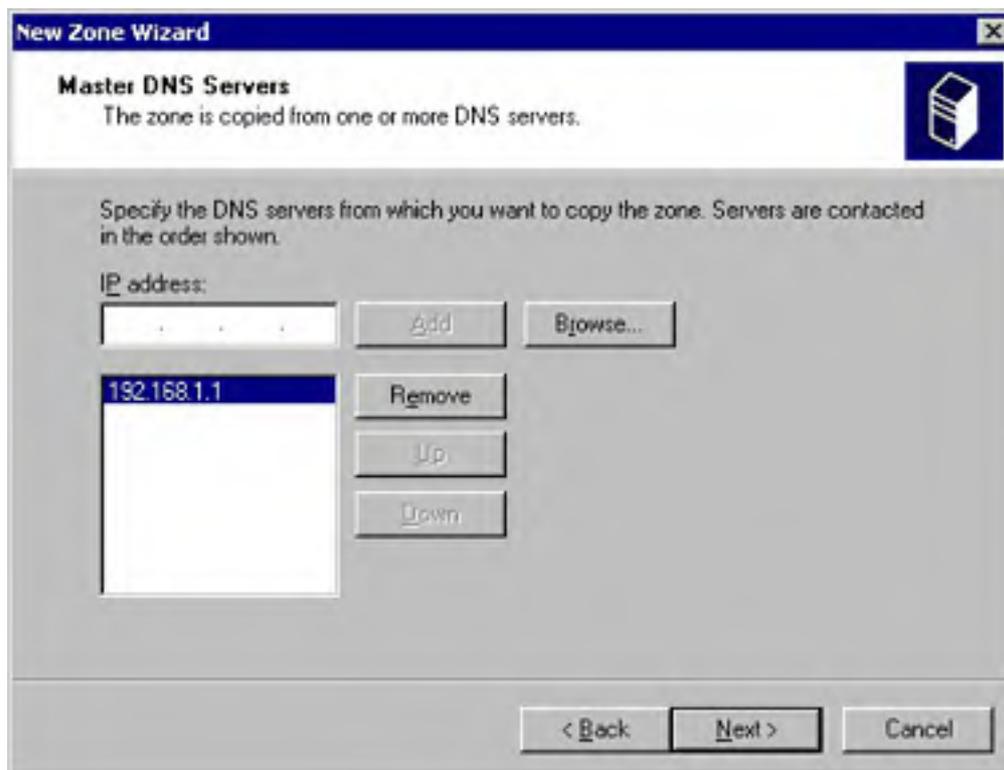

One way of doing this is to set up secondary DNS servers to provide redundancy if the primary DNS server (of which there can be only one) doesn't respond to client queries. Secondary DNS servers can also be useful in reducing network traffic if placed in a location where the zone is heavily queried.

Another way of providing DNS redundancy is to add another Active Directory-integrated DNS server. Because Active Directory uses a full multiple-master model, all DNS servers using Active Directory-integrated zones can be primary servers—no secondary zones are required.

If you are going to use standard primary and secondary DNS servers, set up secondary DNS servers for both forward and reverse lookup zones. Fewer secondary servers are required for reverse lookup zones because of their infrequent use. They are usually placed outside the network and subnet that the reverse zone serves.

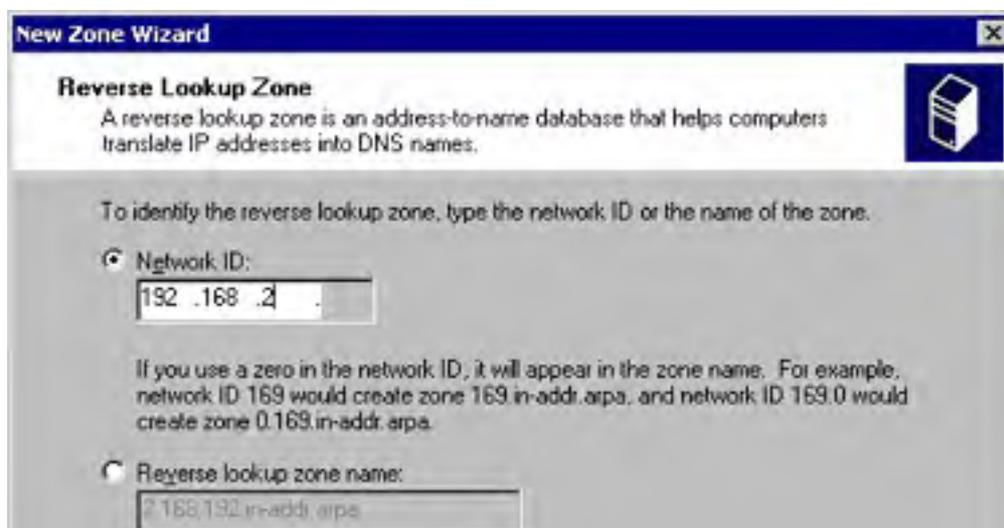

- Enter the zone name and then click Next.

8. If your ISP or another DNS server maintains the zone, enter the IP address of the master DNS server or servers maintaining the zone in the IP Address box, and click Add. The IP address is added to the list box as shown in Figure 14-15. The Windows 2000 Server DNS Server copies the zone information from these DNS servers.

**Figure 14-15.** The Master DNS Servers screen.

9. If you chose to create a standard primary forward lookup zone, the Zone File page appears. Type a filename for the zone file. To use an existing file, copy the file to the `%SystemRoot%\System32\Dns` folder, select the Use This Existing File option, type the filename in the box provided, and then click Next.
10. In the Reverse Lookup Zone page, choose No, Do Not Create A Reverse Lookup Zone to finish the setup process, or click Yes, Create A Reverse Lookup Zone to create a reverse lookup zone.
11. If you chose to create a reverse lookup zone, choose the type of zone to create and then click Next.
12. Enter the address of the network in the Network ID box and then click Next as shown in Figure 14-16. The wizard automatically creates the reverse lookup zone name from this information.

**Figure 14-16.** *Creating a reverse lookup zone.*

13. If you're creating a standard zone, click Next to approve the filename provided.
14. Review the summary of the DNS server configuration, and then click Finish to complete the initial configuration of the DNS server.

Use the Nslookup command from a command prompt to test the functionality of the DNS server. However, the command's functionality is limited without a reverse lookup zone (you won't be able to perform reverse lookups to obtain DNS names from IP addresses). Consult online help for command reference information.

### **Real World**

#### **DHCP and Secure Dynamic Updates**

If multiple DHCP servers are operating in the same DNS zone and you're using secure dynamic updates, you might end up with some stale DNS records if one of the DHCP servers fails. To prevent this, you can use the Active Directory Users and Computers MMC snap-in to add all DHCP servers to the DnsUpdateProxy group, which loosens permissions. Because of these loosened permissions, don't install DHCP on a domain controller in this scenario, unless DNS resource record security is of low importance to you (in which case it's probably easier to use unsecured dynamic updates).

## **Creating Zones**

Zones allow you to store portions of the DNS namespace so that a single DNS server can serve a portion of the namespace.

When setting up the domains, start with the top-level domain. Then create subdomains and delegate control of the domains to other DNS servers as necessary.

The two types of zones concerned are forward lookup zones and reverse lookup zones. Forward lookup zones are the types of zones normally associated with DNS servers; they return an IP address when given a DNS name. Reverse lookups are used less often, but they are still important. They provide the ability to resolve an IP address into a DNS name, something that Internet Information Services (IIS) uses for its log files (troubleshooting tools such as Nslookup rely on reverse lookup zones as well).

### **Creating a New Forward Lookup Zone**

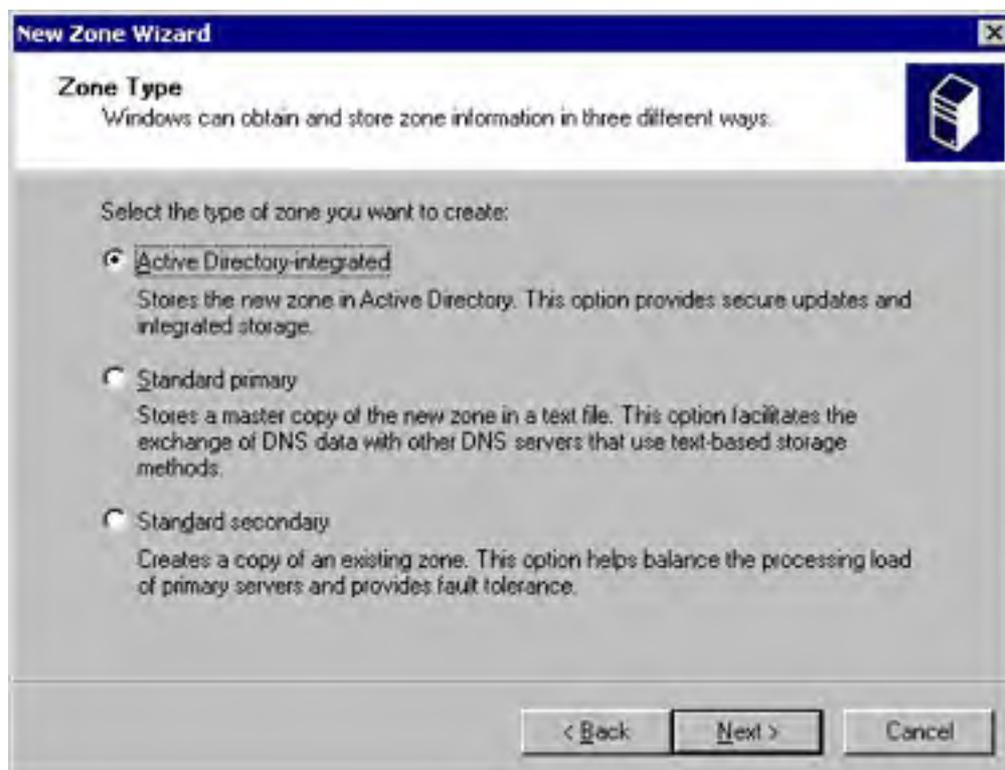

When you first setup a DNS server, you'll probably want to use the Configure A DNS Server Wizard (discussed in the previous section), which walks you through creating the first forward lookup zone. However, if you didn't use the wizard to set up the zones, or you need to create additional forward lookup zones, use the following procedure:

1. Launch DNS from the Administrative Tools folder on the Programs menu.

2. Select the DNS server you want to configure (choose the Connect To Server command from the Action menu if the server isn't displayed in the console tree).

If you select the Forward Lookup Zone container in the console before choosing New Zone from the Action menu, the New Zone Wizard assumes that you intend to create a forward lookup zone and skips step 6.

3. Choose New Zone from the Action menu to start the New Zone Wizard. Click Next to start using the wizard.
4. In the Zone Type page (Figure 14-17) choose one of the following options, and then click Next to continue:
  - **Active Directory-Integrated** Use this option to take advantage of Active Directory-integrated zone storage, which permits multiple-master operation (all servers are primary DNS servers). This option is available only on domain controllers.
  - **Standard Primary** Use this option if the DNS server is to be authoritative for the zone you want to create. Only authoritative servers can update the DNS database.
  - **Standard Secondary** Use this option if the DNS server is hosted on another server. Also use it if this server is to have read-only privileges in the zone with all data obtained from the primary DNS server.

**Figure 14-17.** The Zone Type screen of the New Zone Wizard.

5. Select the Forward Lookup Zone option, and click Next.
6. Type the DNS name for the zone in the Name text box, and then click Next. If you chose an Active Directory-integrated zone, it is created now.
7. If you chose to create a secondary zone, type the IP addresses of the master servers from which you want to copy the zone data, clicking Add after entering each one (shown previously in Figure 14-15). Click Browse to search for servers. Use the Up and Down buttons to arrange the IP addresses in the order in which you want to contact them. Click Next when you're done.

8. To create a new file to store the zone data for a standard primary zone, select the Create A New File With This File Name option and type the name you want to give the zone file, or use the one provided for you.
9. To use an existing zone file to store the zone data, copy the file to the `%SystemRoot%\System32\Dns` folder, select the Use This Existing File option, and type the filename in the box provided. Click Next.
10. Review the summary of the zone, and then click Finish to complete the creation of the zone.

## Creating a New Reverse Lookup Zone

Reverse lookup zones allow clients to resolve a host's DNS name from an IP address, which is useful for troubleshooting tools such as Nslookup. Reverse lookups also permit IIS log files to record DNS names instead of just IP addresses.

To create a new reverse lookup zone, follow these steps:

1. Launch DNS from the Administrative Tools folder on the Programs menu.
2. Select the DNS server from the console tree, and then choose New Zone from the Action menu to start the New Zone Wizard. Click Next to start using the wizard.
3. In the Zone Type screen choose Active Directory-Integrated, Standard Primary, or Standard Secondary, and then click Next to continue.
4. Select the Reverse Lookup Zone option, and click Next in the Select The Zone Type screen.
5. Type the network address in the Network ID box, shown previously in Figure 14-16. (See [Chapter 13](#) for more information about network addresses and TCP/IP addressing.) To type the name of the reverse lookup instead of supplying the network ID, select Reverse Lookup Zone Name, and type the name of the reverse lookup zone. Click Next.
6. If you are creating a lookup zone that is Active Directory-integrated, the wizard creates the zone immediately.
7. If you are making a standard primary zone, type the name you want to give the zone file, or use the name provided for you. To use an existing zone file to store the data, copy the file into the `%SystemRoot%\System32\Dns` folder, choose the Existing File option, and type the filename in the box provided. Click Next to continue.
8. For a secondary zone, type the IP addresses of the master servers from which you want to copy the zone data in the next screen, clicking Add after entering each one. Click Next to continue.
9. Review the summary of the zone, and then click Finish to complete the creation of the zone.

## Creating Subdomains and Delegating Authority

In most large network environments, you need to create subdomains and delegate their management to other DNS zones hosted by other DNS servers. Doing so eliminates the undesirable situation of having a large namespace hosted in a single zone by a single server. Thus, you might have a zone containing the root domain *scribes.com* as well as the subdomain *marketing.scribes.com*; however, you might have the subdomain *tech.scribes.com* and its subdomains delegated to a separate zone managed by another DNS server, as shown in Figure 14-18.

**Figure 14-18.** A domain tree with zones identified.

Be sure that you have a host record created for the DNS server in the forward lookup zone and a pointer record for the DNS server in the reverse lookup zone. DNS might not automatically create these (especially the pointer record) so double-check them—otherwise the server might not work.

Zones must have a contiguous namespace, so it isn't possible to combine subdomains from different branches of the namespace and place them in a single zone. Create separate zones for each noncontiguous part of the domain.

To create a new subdomain in an existing zone and then delegate authority over the domain to another DNS server, perform the following steps:

1. Select the domain in which you want to create a new subdomain, and then choose New Domain from the Action menu.
2. Type the name of the subdomain in the dialog box that appears, and then click OK. This name must not be fully qualified. For example, if you were creating the subdomain *tech.scribes.com* under the domain *scribes.com*, type only *tech* in this dialog box.

Subdomains don't have to be delegated to a different DNS server. Subdomains can even be created in new zone files and still be managed by the same server. This is useful if you want to host the domains on the same computer, yet manage them differently.

3. To delegate authority over the subdomain, select the parent domain of the subdomain, choose New Delegation from the Action menu, and then click Next to start the New Delegation Wizard.
4. Type the name for the subdomain you want to delegate, as shown in Figure 14-19. Check that the fully qualified name of the subdomain displayed is correct and then click Next.

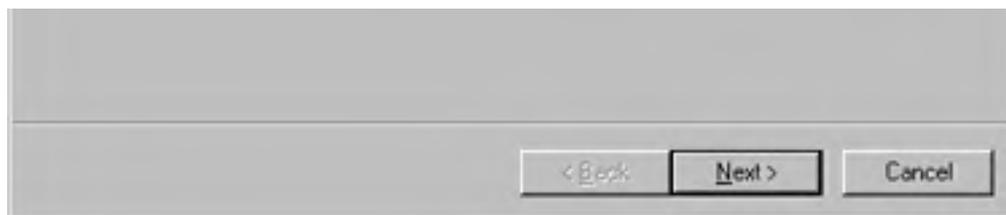

**New Delegation Wizard**

**Delegated Domain Name**  
Specify the name of the domain you want to create.

Authority for the domain you create will be delegated to a different zone.

Delegated domain:

Fully qualified domain name:

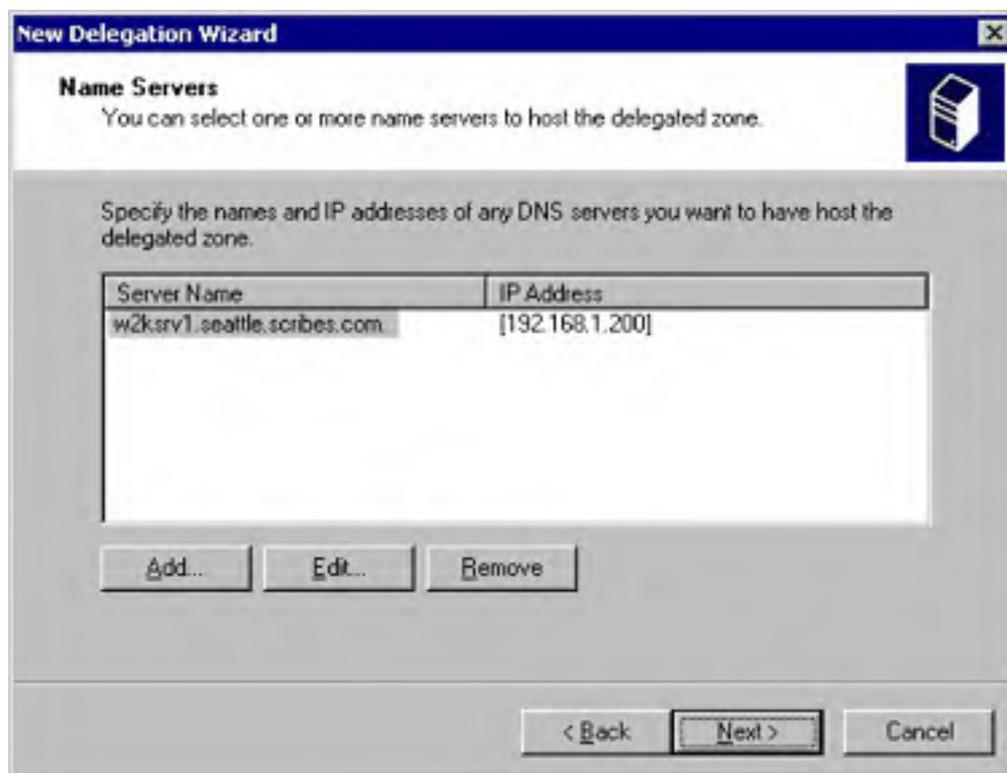

**Figure 14-19.** Delegating a subdomain.

5. Click Add to specify the servers to which you want to delegate the subdomain.
6. Type the name of the server to which you want to delegate authority and then click Resolve, or click Browse to locate its resource record in the DNS server's zone files. Alternatively, type the IP address or addresses for the server, clicking Add after typing each one. Click OK when you're done.
7. Add any other DNS servers that will host the delegated subdomain, as shown in Figure 14-20. Click Next to continue.

When you delegate control over a subdomain to multiple DNS servers, Windows 2000 Server automatically monitors the round-trip times to the servers and selects the closest (fastest) one.

8. Review the summary window, and click Finish to complete the delegation process.

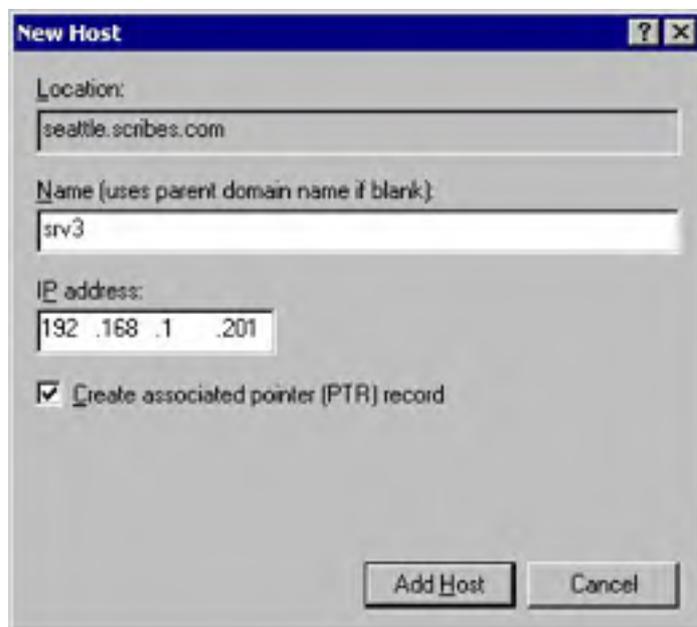

**Figure 14-20.** The Name Servers screen of the New Delegation Wizard.

## Adding Resource Records

After creating zones and subdomains, add resource records (RRs) for the domain server and any other servers with static IP addresses or IP reservations (DHCP servers, WINS servers, routers, and so on). The steps that follow are for adding new host RRs, but the process to add new pointer RRs, Alias (CNAME) RRs, mail exchangers, or other RRs is similar (note that the DNS server doesn't work properly without a host record and a pointer record, which might not be created automatically for you):

1. Select the zone and domain or subdomain to which the host belongs, and then choose New Host from the Action menu. Alternatively choose New Alias, New Mail Exchanger, or another type of record from the Action menu. Table 14-1 lists the records supported by Windows 2000 DNS server.
2. In the Name box, type the host name (and only the host name—the name must not contain any periods), or leave the Name box blank to use the name of the parent domain (Figure 14-21). Type the host's IP address.

**Figure 14-21.** The New Host dialog box.

3. Select the Create Associated Pointer (PTR) Record to create an RR for the host in the reverse lookup zone.
4. Click Add Host, and then fill out the fields for any additional host records you want to create, or click Done.

### Real World

#### Changing DNS Records

When you make a change to the DNS records, make sure you choose the Update Server Data Files command from the Action menu after making the changes. This option increments the serial number, letting other DNS servers know that you made a change and that they need to update their information.

If you're using conventional DNS zones, add or change DNS records only from the primary DNS server for a zone. If you're using Active Directory-integrated DNS, you can make the changes to any Active Directory-based DNS and it propagates correctly to the other Active Directory DNS servers and notifies secondary servers that there are updated records.

**Table 14-1.** Supported DNS record types

Record Type	Common Name	Function	RFC
A	Address record	Maps a fully qualified domain name (FQDN) to a 32-bit IPv4 address	1035
AAAA	IPv6 Host	Maps an FQDN to a 128-bit IPv6 address	1886
AFSDB	Andrews file system	Maps a DNS domain name to a server subtype	1183

	(AFS) or distributed computing environment (DCE) record	that is either an AFS version 3 volume or an authenticated name server (NS) using DCE or network computing architecture (NCA)	
ATMA	Asynchronous Transfer Mode (ATM) Address	Maps a host name to an ATM address	"ATM Name System Specification Version 1.0"
CNAME	Canonical name or alias record	Maps a virtual domain name (alias) to a real domain name	1035
HINFO	Host information record	Specifies the CPU and operating system type for the host	1700
ISDN record	ISDN information	Maps an FQDN to an ISDN telephone number	1183
Key	Public key resource record	Contains a public key for a DNS zone	2535
MB	Mailbox name record	Maps a domain mail server name to the actual host name of the mail server	1035
MG	Mail group record	Maps a domain mailing group to the actual mailbox (MB) resource records of its members	1035
MINFO	Mailbox information record	Specifies a mailbox for the person who maintains the mailbox or list, and can also specify a mailbox for related errors	1035
MR	Mailbox renamed record	Maps an old mailbox name to a new mailbox name for forwarding purposes	1035
MX	Mail exchange record	Provides routing information to reach a given mailbox	974
NS	Name server record	Specifies that the name server listed has a zone starting with the owner name	1035
NXT	Next record	Specifies the nonexistence of the specified name	2035
OPT	Option resource record	Specifies optional data with a DNS request or reply	2671
PTR	Pointer resource record	Points to another DNS resource record, most often used in reverse lookup to point to the A record	1035
RP	Responsible person information record	Provides information about the person responsible for a server	1183
RT	Route-through record	Provides routing information for hosts lacking a direct WAN address	1183
SIG	Signature resource record	Digitally signs a host name	2535
SOA	Start of authority	Specifies the beginning of a zone and indicates the authoritative server	1034
SRV	Service locator record	Provides a way of locating multiple servers providing similar TCP/IP services	2052
TXT	Text record	Maps a DNS name to a string of descriptive text	1035
WKS	Well-known services record	Describes the most popular TCP/IP services supported by a protocol on a specific IP address	1035
X25	X.25 information	Maps a DNS address to a public switched data network (PSDN) address number	1083

### More Info

For more information about each of these record types and what they mean, refer to the related RFC or see *Microsoft Windows 2000 Server Resource Kit (2001)*, available from Microsoft Press.

## Configuring Zone Transfers

Because the DNS service is so important to a modern TCP/IP-based network, and because it's essential to the operation of Active Directory, always configure multiple DNS servers in each zone to provide fault tolerance.

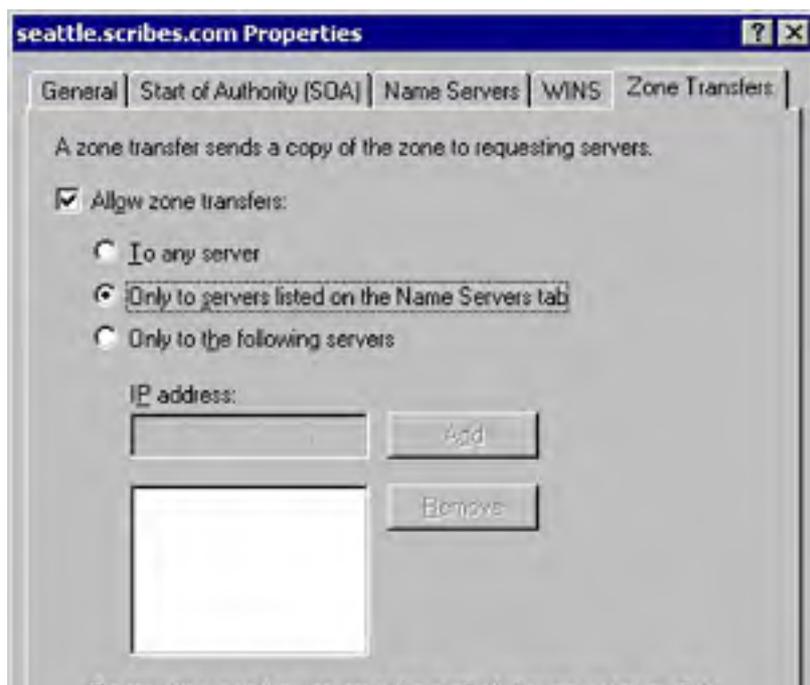

Windows 2000 Server supports several ways of achieving zone transfers between DNS servers managing a zone. If the DNS servers are using Active Directory to store their zone data, Active Directory handles the zone replication, allowing for a full multimaster model in which all servers are peers and any can make changes to the DNS database. Additionally, zone transfers are incremental so that only changed records are synchronized.

Windows 2000 Server also supports RFC 1995-compliant incremental zone transfers when using standard zone files. This incremental zone transfer method permits a secondary DNS server to pull only the zone changes that it needs to synchronize its copy of the zone data with the primary server's. If the serial number of the primary DNS server's zone file matches that of the secondary DNS server's serial number, no changes were made, so no zone transfer need take place.

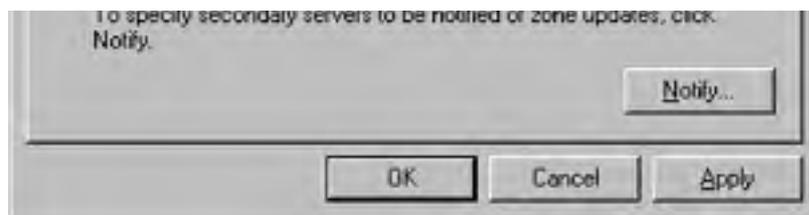

Incremental zone transfers occur only if both servers support this feature. When performing zone transfers with Windows NT 4 DNS servers or other DNS servers that don't support this feature, a full zone transfer occurs. In a full zone transfer, the entire contents of the zone file are pulled from the primary DNS server by the secondary server.

If the DNS server is a secondary DNS server on a zone, the server is already configured to perform zone transfers with the master server in the zone. If the server is a primary server in the zone, the server is configured to perform zone transfers with any DNS servers that request them. This situation can be a potential security problem if someone wants to create a rogue DNS server and pull the zone data, so you might want to allow only certain DNS servers to perform zone transfers with the server. To modify the way zone transfers occur on the DNS server, follow these steps:

1. Select the zone in which you want to enable zone transfers, go to the Action menu, and choose Properties.
2. Click the Zone Transfers tab, shown in Figure 14-22.

**Figure 14-22.** The Zone Transfers tab of the Properties dialog box.

3. To disable zone transfers entirely on the DNS server, clear the Allow Zone Transfers check box.
4. To allow any DNS server to perform zone transfers with the DNS server, select To Any Server (note that this is a potential security risk).
5. To set up the server to allow only servers that have NS records in the zone file to perform zone transfers with the server, choose Only To Servers Listed On The Name Servers Tab.
6. To create a list of approved servers with which the DNS server can perform zone transfers, select Only To The Following Servers. Then type each secondary server's IP address in the box provided, clicking Add after typing each one.
7. To change whether secondary servers in the zone are notified when the zone file has been updated, click Notify.
8. To disable the notification of secondary servers when changes to the zone file take place, clear the Automatically Notify check box, shown in Figure 14-23.

**Figure 14-23.** The Notify dialog box.

9. To notify only DNS servers with name server records in the zone file, select Servers Listed On The Name Servers Tab.
10. To create a list of servers that you want to notify about changes to the zone file, select the The Following Servers option. Then type each server's IP address in the box provided, clicking Add after typing each one.

## Interoperating with Other DNS Servers

Windows 2000 DNS servers perform fast zone transfers with data compression and multiple resource records sent in each message when transferring zones to other Windows DNS servers. This zone transfer method works with all Windows DNS servers, and BIND DNS servers version 4.9.4 or later (although Windows 2000 DNS servers should run Service Pack 3 or newer if receiving zone information from BIND 9.x servers).

If you are using BIND DNS servers, check whether Windows has fast transfers enabled. To perform zone transfers with BIND servers earlier than version 4.9.4, you need to disable this fast zone transfer method.

Although you can use Windows 2000 DNS servers and Active Directory in conjunction with Windows NT 4 Service Pack 4 DNS servers and BIND servers later than version 4.9.4, for best compatibility use Windows 2000 or BIND 8.2 or newer DNS servers. BIND versions 8.2 and later support incremental zone transfers, and BIND versions 8.1.2 and later support dynamic updates.

To toggle support for fast transfers, turn off the BIND Secondaries option. To do so, use the following procedure:

1. Select the DNS server from the console tree and choose Properties from the Action menu.
2. Click the Advanced tab, and clear the Bind Secondaries check box.

## Enabling Dynamic DNS Updates

The DNS servers in Windows NT 4 and BIND 4.9.x are somewhat of a management headache because of the lack of dynamic updates. Every time a host is given a new IP address, an administrator has to manually update the DNS zone file with the new IP address.

Fortunately, the Windows 2000 DNS server implements RFC 2136-compliant dynamic updates. These dynamic updates allow Windows XP and Windows 2000 clients to update their own forward lookup DNS records, and they allow DHCP servers to update the forward and reverse lookup records of all legacy clients (if this option is enabled in DHCP). They also allow you to scavenge records that haven't been refreshed in a long time, reducing the gradual bloat that happens with DNS databases. (See [Chapter 13](#) for more information about setting up aging and scavenging parameters.)

If you didn't turn on dynamic updates when you configured the DNS server, follow these steps to do so:

1. Select the zone in which you want to enable dynamic updates.
2. Choose Properties from the Action menu and click the General tab.
3. In the Allow Dynamic Updates box, select Yes.

For dynamic DNS to work properly, DHCP servers must be configured to update the DNS server when a client's IP address changes. Windows 2000 Server-based DHCP servers are set up to dynamically update DNS for Windows XP and Windows 2000 clients by default. Dynamic updates for legacy systems must be specifically enabled on the DHCP server.

## Enabling WINS Resolution

WINS allows NetBIOS names to be resolved into IP addresses. This capability is important for networks that support large numbers of pre-Windows 2000 Microsoft clients. DNS can work with WINS to search the entire combined DNS and NetBIOS namespace, if necessary, when a client attempts to resolve a host name.

In Windows NT 4, enabling WINS resolution within DNS is essential to successfully resolving hosts that might have recently changed IP addresses—the dynamic WINS database provides an up-to-date IP address when the static DNS zone file can't. However, with Windows XP and the Windows 2000 family, dynamic updates to the DNS server eliminate the need to use WINS servers to keep the namespace up to date, and WINS is gradually phased out.

To enable WINS resolution in a zone, follow these steps:

1. Select the zone in which you want to enable WINS resolution, and then choose Properties from the Action menu.
2. Click the WINS tab and select the Use WINS Forward Lookup check box.
3. If you're not using Microsoft DNS servers as secondary servers, select the Do Not Replicate This Record check box to prevent compatibility problems (only Windows DNS servers support WINS records).
4. Type the IP address of each WINS server you want to query, clicking Add after typing each one.

You will find more about setting up WINS in the section [Setting Up a WINS Server](#), later in this chapter.

## Setting Up a Forwarder

No name server is able to answer the queries of all clients; sometimes clients request a DNS name that isn't in a zone managed by the DNS server, let's say *example.microsoft.com*. The DNS server goes to the Internet to the top level of the DNS domain tree. The top-level DNS servers then provide the address of the DNS server for the first level (.com). This server in turn provides the address of the *microsoft.com* DNS server, which then provides the address of *example.microsoft.com*'s DNS server.

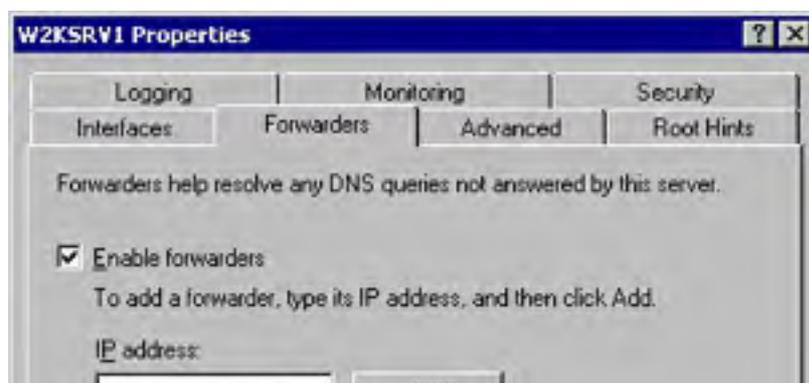

This process is called recursion, and it takes time and a number of trips out to the Internet by the DNS server. In a network with multiple DNS servers and domains, it can be advantageous to have DNS servers forward their unresolved queries to another DNS server. This server then either replies with the desired record from its own DNS zone, or hunts down the unresolved query and reports back to the DNS server that forwarded the request. This can reduce WAN link usage in two ways:

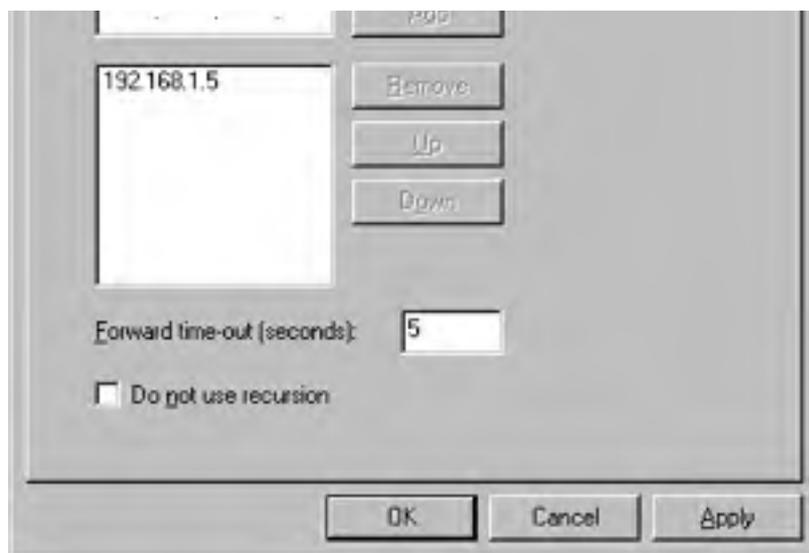

- If the server is authoritative for the zone containing the requested DNS record, the DNS server can reply directly without having to hunt for the appropriate DNS server.
- If the server isn't hosting the zone with the requested record, it still might be able to answer the query from its cache of recent DNS queries.

To configure the DNS server to forward unresolved queries to another DNS server, follow these steps:

For security reasons, a single DNS server typically forwards queries from the internal network to a DNS server on the other side of the firewall. All other internal DNS servers forward their queries to the designated forwarder to be passed on to the external name server (or resolved from the forwarder's cache file).

1. In the console tree, select the DNS server on which you want to enable forwarding, and then choose Properties from the Action menu.
2. Click the Forwarders tab and select the Enable Forwarders check box.
3. To forward all unresolved queries to another DNS server, type the IP addresses of the DNS server or servers to which you want to forward unresolved queries, clicking Add after typing each one, as shown in Figure 14-24.

**Figure 14-24.** Setting up DNS forwarders.

4. Before moving on to the next server in the list of servers to forward queries to, type the amount of time you want to spend attempting to contact a DNS server.
5. To disable recursion for a particular domain, select the domain and then select the Do Not Use Recursion check box. If the DNS server that is the target of the forwarded queries doesn't respond and the Do Not Use Recursion check box is selected, the DNS server fails the query, and the client fails over to a secondary DNS server, if configured to do so. A DNS server that's configured to use forwarders and not perform recursion is called a slave server.

## Updating Root Hints

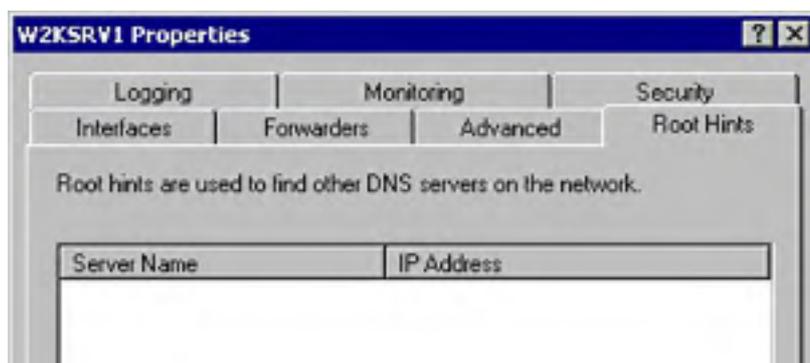

Root hints tell a DNS server where to look to find the DNS servers authoritative for the top level of the domain structure. Root hints for the Internet's root servers are automatically installed in the Cache.dns file located in the %SystemRoot%\System32\Dns folder.

If the DNS server only needs to resolve names in the private network, you must provide the locations of the top-level DNS servers for the network, either through the DNS console (as described next) or by manually editing the Cache.dns file. Alternatively, you can import root hints from another server.

If the server is the root of the network's namespace and doesn't resolve Internet host names, you can delete the Cache.dns file.

To update root hints on the server, use the following procedure:

1. In the console tree, select the DNS server on which you want to update the root hints, and then choose Properties from the Action menu.
2. Click Add in the Properties dialog box, as shown in Figure 14-25, to manually add a name server record for a root DNS server.

**Figure 14-25.** Updating root hints.

## Setting Up a Caching-Only DNS Server

Caching-only servers are DNS servers that don't host any zones and that aren't authoritative for any domains—they simply cache the queries that they perform on behalf of the clients that use the server. Caching-only servers are useful for sites that use a slow WAN link to other DNS servers. By simply caching queries instead of holding its own zone files, a caching-only server reduces network traffic because it never performs any zone transfers. To set up a caching-only server, follow these steps:

1. Install the DNS service, as described earlier in this chapter.
2. Configure the caching server with a static IP address.
3. Launch DNS from the Administrative Tools folder on the Programs menu, and then choose Connect To Computer from the Action menu (don't configure any zones).
4. In the Select Target Computer dialog box, select The Following Computer, type the name of the DNS server from which you want to cache (Figure 14-26), and click OK.

**Figure 14-26.** The Select Target Computer dialog box.

The DNS server is added to the DNS console on the caching server. The caching server performs recursive queries on behalf of its clients and over time accumulates resource records for answering future queries. You can clear the cache on a caching server by right-clicking the server's name in the DNS console and selecting Clear Cache from the shortcut menu.

## Setting Up a WINS Server

Although networks consisting exclusively of servers and clients running Windows XP and Windows 2000 can safely do away with WINS (DNS replaces it), not many networks have this luxury yet.

WINS is an essential part of any large network with earlier Windows clients. It provides the equivalent of a DNS server for the NetBIOS namespace: WINS servers resolve NetBIOS names into IP addresses by using the WINS dynamic database to call up the appropriate name records.

## Determining Whether You Need WINS

If you're asking yourself whether you need WINS at this point, the answer is probably yes. Most large networks need WINS to provide NetBIOS name resolution for their earlier Windows clients. However, here are some instances in which you don't need WINS servers:

- All clients on the network support name resolution through another method (for example, DNS). Windows XP, Windows 2000, and the upcoming Windows .NET Server family are currently the only Microsoft operating systems that can rely exclusively on DNS for name resolution, so unless all Windows clients are running one of these operating systems, you need WINS. If you have a mixed environment with other clients such as UNIX clients, make sure they're all configured to properly use DNS.
- The network is small (fewer than 50 clients) and not subnetted. If the entire network consists of a single network segment, clients that require NetBIOS name resolution can effectively resolve NetBIOS names by broadcast—a technique that doesn't work across routers or on large networks where the NetBIOS broadcasts would generate too much network traffic.

Also, before you implement WINS on your network, you must be aware of the WINS clients that are supported by WINS in Windows 2000 Server:

- Windows XP
- Windows 2000
- Microsoft Windows NT 3.5 or later
- Windows 95
- Windows 98
- Microsoft Windows Me
- Microsoft Windows for Workgroups 3.11
- MS-DOS with Microsoft Network Client version 3
- MS-DOS with LAN Manager version 2.2c
- Linux and UNIX clients running Samba
- OS/2 with Microsoft LAN Manager version 2.2c

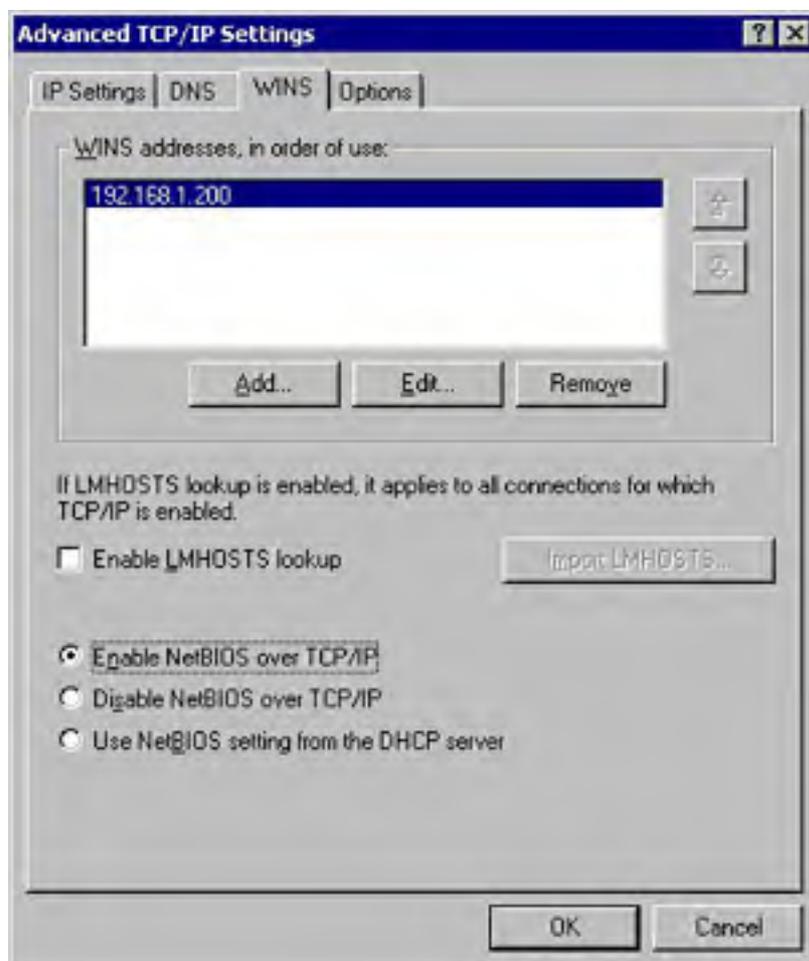

Non-WINS clients aren't resolvable by WINS unless static entries are added for them. This practice is strongly discouraged; don't use it unless absolutely necessary because static entries are extremely difficult to eliminate from the WINS database after replication takes place. Instead, clients should be configured to use DNS to resolve names that aren't in the WINS database.

## Configuring the Server to Prepare for WINS

After you determine that you need WINS on your network, it's time to configure the server. The most common cause of WINS problems is improper TCP/IP configuration on the server. Follow these steps to properly configure the TCP/IP settings for the WINS server before you install the service:

1. Right-click the Local Area Connection icon in the Network and Dial-Up Connections folder, and choose Properties from the shortcut menu.

2. Select the Internet Protocol (TCP/IP) component, and click Properties.
3. Configure the server to use a static IP address, or make sure that an address reservation for the server is configured on the DHCP server.
4. Click Advanced, and then click WINS.
5. Select any WINS servers listed in the tab and click Remove, as shown in Figure 14-27. Failure to do this can cause the WINS server to register its own address with another WINS server instead of with itself, which you don't want.

**Figure 14-27.** The WINS tab of the Advanced TCP/IP Settings dialog box.

6. Click Add and type the IP address of your own server. Then click OK.

## Installing WINS

After the TCP/IP settings are correct, you're ready to install the WINS component. Use the Windows Component Wizard, accessible either from the Configure Your Server tool or from Add/Remove Programs in Control Panel. If you installed WINS during Windows Setup, you can skip this section. Otherwise, use these steps to install WINS:

1. Open the Add/Remove Programs Control Panel tool, and click the Add/Remove Windows Components icon in the frame on the left (the Places bar) to launch the Windows Component Wizard.
2. Click Next, select Networking Services from the list of components, and click Details.
3. Select the Windows Internet Name Service (WINS) component check box, click OK, and then click Next.

Don't install WINS on a multihomed server. You can physically do it, but it often causes dreadful replication problems, especially if the server is on two different subnets.

## Adding Replication Partners

WINS servers are easy to set up and require little management, except for replication partners. WINS replication is an important and somewhat delicate issue that you must examine closely before setting up. Deploy as few WINS servers as possible to minimize management migraines. For example, the entire Microsoft Corporation used only 12 WINS servers worldwide during the height of NetBIOS. Just about every enterprise can get by with a handful of WINS servers at most. Microsoft recommends one WINS server for each 10,000 users, plus one WINS server for redundancy.

Set up replication between WINS servers in a hub (star) pattern, with a single-master WINS server in the center and all other WINS servers replicating only with this server, using the push/pull method. Using a double hub with two master servers in the center can provide additional redundancy, but the replication problems that can arise generally outweigh the added reliability.

[Chapter 13](#) contains a more thorough investigation of WINS deployment and replication planning. You can also refer to the *Windows 2000 Server Resource Kit*. To set up a replication partner and configure its settings after planning your WINS deployment, follow these steps:

1. Launch WINS from the Administrative Tools folder, and in the console tree expand the WINS server that you want to set up for replication.
2. Select the Replication Partners folder, and then choose New Replication Partner from the Action menu.
3. Type the IP address for the WINS server you want to enable replication with, and click OK.
4. To modify the replication parameters for the new replication partner, if necessary, double-click the server in the Replication Partners folder, and then click the Advanced tab.
5. To change the way you replicate with the server, choose an option from the Replication Partner Type drop-down list (Figure 14-28).

**Figure 14-28.** The Advanced tab of the Properties dialog box.

6. To configure a permanent connection for pull or push replication, select the Use Persistent Connection For Replication check box in the Pull Replication section, the Push Replication section, or both.
7. In the Start Time fields, type the time you want pull replication to begin in hours, minutes, and seconds.
8. In the Replication Interval fields, type the frequency—days, hours, and minutes—with which you want to replicate with the replication partner.
9. Use the Number Of Changes In Version ID Before Replication box to type the number of changes to the local copy of the WINS database that you will allow before the server pushes changes to the replication partner.

Use push/pull replication on the entire WINS namespace to make troubleshooting replication problems easier. In addition, primary and backup WINS servers must use push/pull replication.

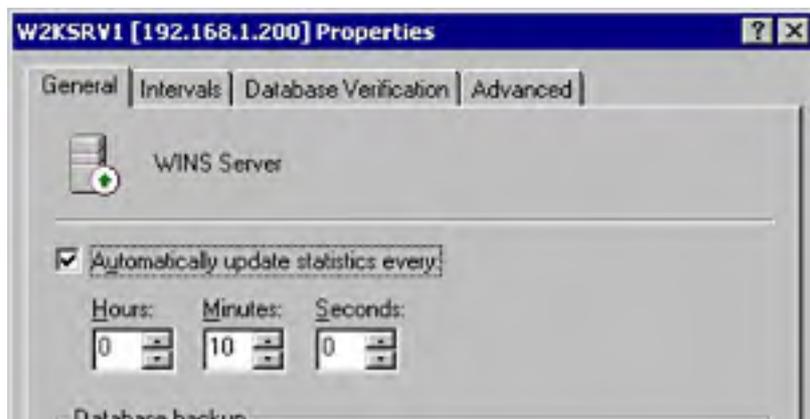

## Miscellaneous WINS Functions

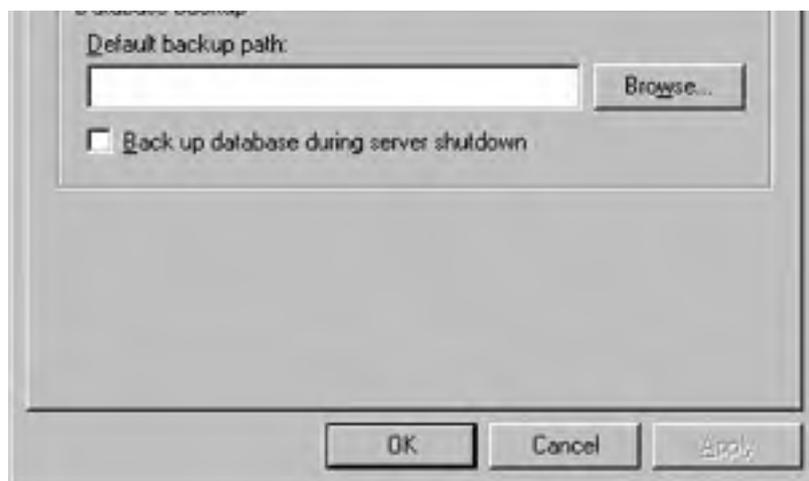

The WINS snap-in lets you manage all the functionality of WINS on multiple servers from the same application. The following are some functions you can perform with the WINS snap-in:

- To view the status of your WINS servers, click Server Status in the console tree. The status of your servers appears in the pane on the right.
- To view records in the WINS database, right-click the Active Registrations folder in the console tree under the desired server. Choose either Find By Name to search for a particular name or Find By Owner from the Action menu to display the Find By Owner dialog box, which shows all the records in the WINS database. When viewing records, you can use the Record Types tab of the Find By Owner dialog box to filter the type of records displayed.
- To add a static entry to the database, right-click the Active Registrations folder and choose New Static Mapping from the shortcut menu.

Add static entries only for computers that do not support WINS and only if absolutely necessary. Static entries are notoriously difficult to eliminate after replication and can be deleted only by the owner.

- To initiate scavenging, which purges the WINS database and does general cleanup on it, select the WINS server you want to scavenge and choose Scavenge Database from the Action menu. When initiating scavenging, don't attempt to alter the scavenging parameters for WINS. These parameters have been extensively tested and optimized by Microsoft. Any change you make will be for the worse.
- To modify the properties for the WINS server, select the server you want to work on, and then choose Properties from the Actions menu. This displays the Properties dialog box shown in Figure 14-29, which you can use to modify the path to the backup copy of the WINS database, change the length of name leases, and modify logging and other options.

**Figure 14-29.** The Properties dialog box for a WINS server.

#### **More Info**

If you're fortunate enough to have outgrown WINS on your network, it's time to decommission the WINS servers. For information about doing so, consult the Windows 2000 Server help system or the *Windows 2000 Server Resource Kit*.

## **Compacting the WINS Database**

Microsoft recommends that you compact the WINS database file monthly or quarterly (at a minimum, whenever the database reaches 30 MB in size) to maximize performance and stability.

To do so, follow these steps:

1. Open a command prompt window.
2. Type the following commands:  

```
cd %systemroot%\system32\wins  
net stop wins  
jetpack wins.mdb tmp.mdb  
net start wins
```

#### **More Info**

For more information about the Jetpack.exe command, see Microsoft Knowledge Base article Q145881.

## **Summary**

DHCP and DNS servers are essential to any TCP/IP-based network with more than a few clients, as are WINS servers for routed TPC/IP networks with legacy Windows clients. Windows 2000 Server provides powerful, easy-to-use, and reliable DHCP, DNS, and WINS servers.

The next chapter covers the configuration of hard disks for maximum security and efficiency.

# Chapter 15

## **Implementing Disk Management**

Under normal circumstances, this would be a combined chapter on disk management and storage. However, with Microsoft Windows 2000 the subject of computer and network storage has become more complex for the administrator while it has become simpler for the user. Windows 2000 Server provides for both local and remote storage and for storage on removable media—all in a way that is completely transparent to the user. After all, the user doesn't really care whether a program or file is stored on disk, on tape, or somewhere on the intranet, as long as it's available when needed. This chapter covers the more traditional disk management tasks that are possible under Windows 2000, and the next chapter takes a look at some of the less traditional methods of storage that are now possible.

## Understanding Disk Terminology

Before going into the details of managing disks and storage, let's review some definitions:

- **Physical drive** The actual hard disk itself, including case, electronics, platters, and all that stuff. Not terribly important to the disk administrator.
- **Partition** A portion of the hard disk. In many cases, this is the entire hard disk space, but it needn't be.
- **Allocation unit** The smallest unit of managed disk space on a hard disk or logical volume. Also called a cluster.
- **Primary partition** A portion of the hard disk that's been marked as a potentially bootable logical drive by an operating system. MS-DOS can support only a single primary partition, but Microsoft Windows NT and Windows 2000 can support multiple ones. There can be only four primary partitions on any hard disk.
- **Extended partition** A nonbootable portion of the hard disk that can be subdivided into logical drives. There can be only a single extended partition per hard disk, but it can be divided into multiple logical drives.
- **Extended volume** Similar to, and sometimes synonymous with, a spanned volume, this is any dynamic volume that has been extended to make it larger than its original size. When it uses portions of more than one physical disk, it is more properly referred to as a spanned volume.
- **Logical drive** A section or partition of a hard disk that acts as a single unit. An extended partition can be divided, for example, into multiple logical drives.
- **Logical volume** Another name for a logical drive.
- **Basic disk** A traditional disk drive that is divided into one or more partitions, with a logical drive in the primary partition, if present, and one or more logical drives in any extended partitions. Basic disks do not support the more advanced functions of Disk Management, but they can be converted to dynamic disks in many cases.
- **Dynamic disk** A managed hard disk that can be used to create various volumes.
- **Volume** A unit of disk space composed of one or more sections of one or more dynamic disks.
- **Simple volume** The Disk Management equivalent of a partition. A portion of a single dynamic disk, it can be assigned either a single drive letter or no drive letter and can be attached (mounted) on zero or more mount points.
- **RAID (redundant array of independent [formerly "inexpensive"] disks)** The use of multiple hard disks in an array to provide for larger volume size, fault tolerance, and increased performance. RAID comes in different levels, such as RAID-0, RAID-1, RAID-5, and so forth. Higher numbers don't necessarily indicate greater performance or fault tolerance, just different methods of doing the job.
- **Spanned volume** A collection of portions of hard disks combined into a single addressable unit. A spanned volume is formatted like a single drive and can have a drive letter assigned to it, but it spans multiple physical drives. A spanned volume—occasionally referred to as an extended volume—provides no fault tolerance and increases your exposure to failure but does permit you to make more efficient use of the available hard disk space.
- **Striped volume** Like a spanned volume, a striped volume combines multiple hard disk portions into a single entity. A striped volume uses special formatting to write to each of the portions equally in a stripe to increase performance. A striped volume provides no fault tolerance and actually increases your exposure to failure, but it is faster than either a spanned volume or a single drive. A stripe set is often referred to as RAID-0, although this is a misnomer because plain striping includes no redundancy.
- **Mirror volume** A pair of dynamic volumes that contain identical data and appear to the world as a single entity. Disk mirroring can use two drives on the same hard disk controller or use separate controllers, in which case it is sometimes referred to as *duplexing*. In case of failure on the part of either drive, the other hard disk can be split off

so that it continues to provide complete access to the data stored on the drive, providing a high degree of fault tolerance. This technique is called RAID-1.

- **RAID-5 volume** Like a striped volume, this combines portions of multiple hard disks into a single entity with data written across all portions equally. However, it also writes parity information for each stripe onto a different portion, providing the ability to recover in the case of a single drive failure. A RAID-5 volume provides excellent throughput for read operations but is substantially slower than all other available options for write operations.
- **SLED (single large expensive disk)** Now rarely used, this strategy is the opposite of the RAID strategy. Rather than using several inexpensive hard disks and providing fault tolerance through redundancy, you buy the best hard disk you can and bet your entire network on it. If this doesn't sound like a good idea to you, you're right. It's not.

## Overview of Disk Management

Hard disk storage has been the usual long-term storage method for modern computers, from the mainframe to the desktop, and that's not likely to change, even considering the richer storage options that have been added to Windows 2000. This section looks at each of the new facilities.

### RAID

RAID (redundant array of independent disks) is a term used to describe a technique that has gone from an esoteric high-end solution to a normal assumption on most servers. Seven or eight years ago, RAID was mostly unheard of, although the original paper defining RAID was written in 1988. Until recently, most server systems relied on expensive, higher quality hard disks—backed up frequently. Backups are still crucial, but now you can use one form or another of RAID to provide substantial protection from hard disk failure. Moreover, this protection costs much less than those big server drives did.

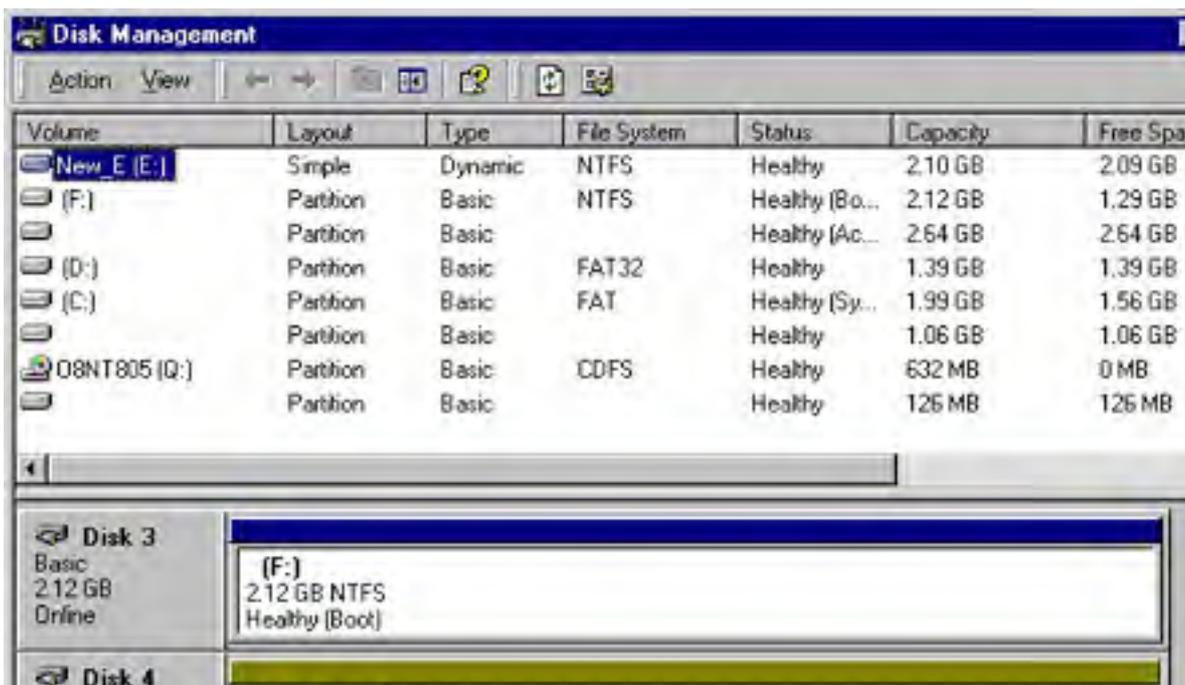

RAID can be implemented at a software or hardware level. When it is implemented at the hardware level, the hardware vendor provides an interface to administer the arrays and the drivers to support the various operating systems it might need to work with. Although there are advantages to using a hardware RAID solution, it's not cheap.

Windows 2000 includes an excellent and flexible implementation of RAID levels 0, 1, and 5 in software. It doesn't cover all of the possibilities by any means, but it is certainly sufficient for many purposes.

## Disk Administration Enhancements

The task of disk management in Windows 2000 brings not only a brand new interface, based on the Microsoft Management Console (MMC), but also a whole new set of capabilities (Figure 15-1). Anyone who has spent much time with Windows NT will probably not miss the old Disk Administrator at all.

The MMC's Disk Management snap-in for managing your physical disks is divided into two panes. By default, the top pane shows the drive letters (volumes) associated with the local disks and gives their properties and status, and the bottom pane has a graphical representation organized by physical drive. It can be used as a stand-alone snap-in or as part of the Computer Management console, shown in Figure 15-2.

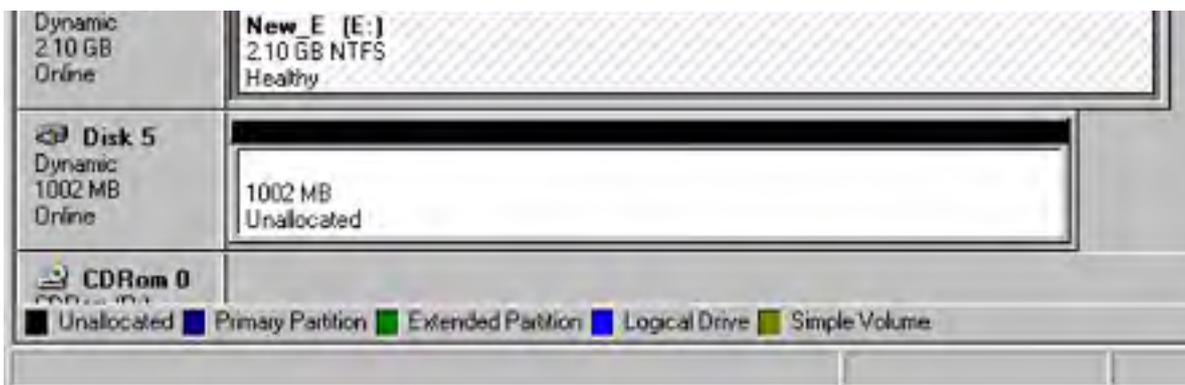

Figure 15-1. Disk Management with an MMC interface.

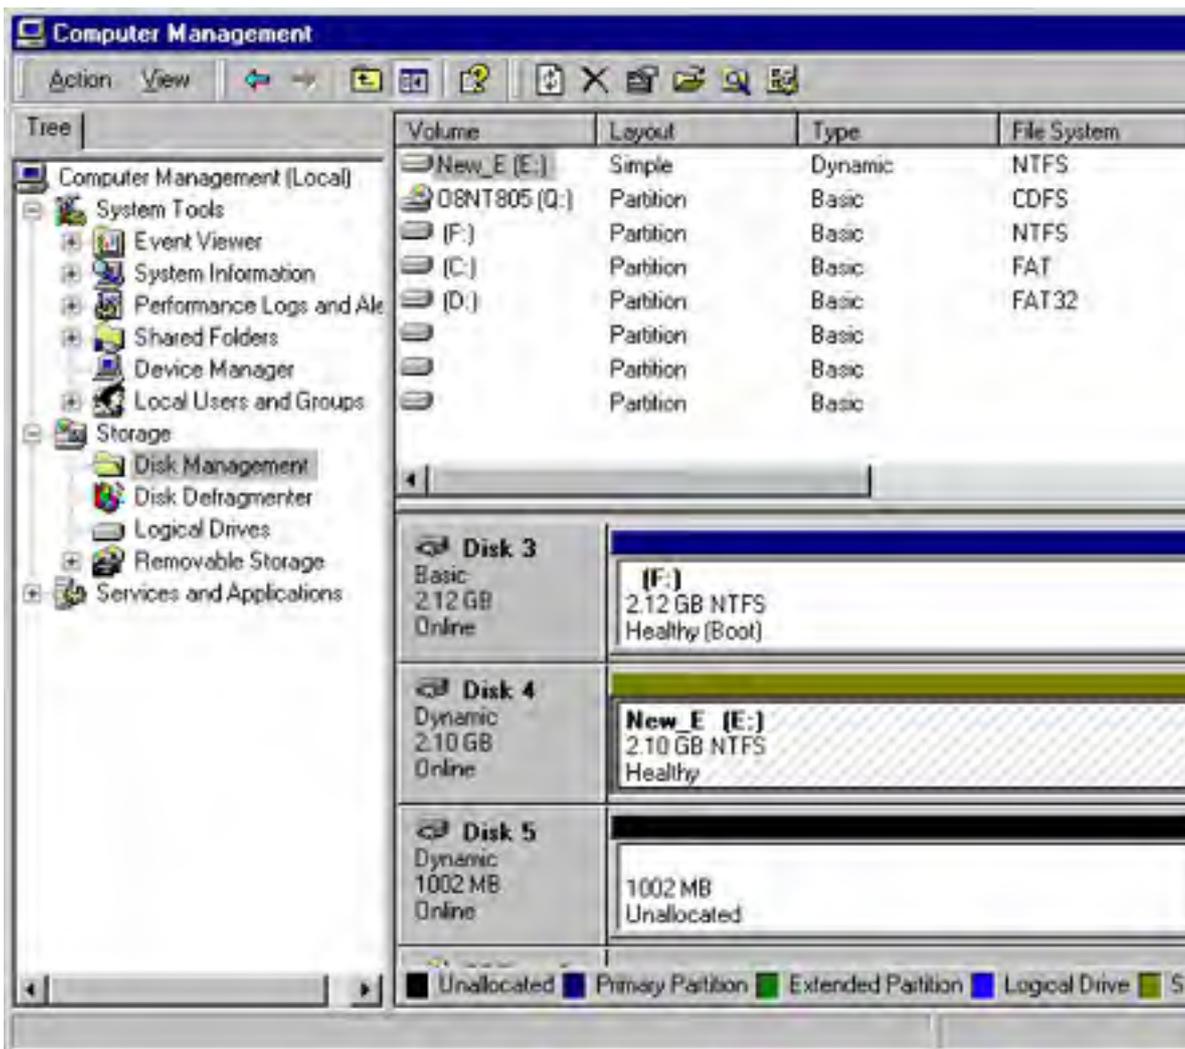

Figure 15-2. The Computer Management console and the Disk Management snap-in.

### Hardware RAID

Disk Management provides an excellent software RAID solution, but hardware RAID is also now widely available, from either the original server vendor or from third parties, and it provides substantial advantages over software RAID. Hardware RAID solutions range from a simple RAID controller to fully integrated, stand-alone subsystems. Their features vary, as does their cost, but all claim to provide superior performance and reliability over a simple software RAID solution such as that included in Windows 2000. In general, they do. Some of the advantages that they can offer include the following:

- Hot-swap and hot-spare drives, allowing for virtually instantaneous replacement of failed drives
- Integrated disk caching for improved disk performance
- A separate, dedicated system that handles all processing, for improved overall performance
- Increased flexibility and additional RAID levels, such as RAID-10 (also called RAID 0+1), a combination of striping (RAID-0) and mirroring (RAID-1) that provides for fast read and write disk access with full redundancy

Not all hardware RAID systems provide all of these features, but all have the potential to improve the overall reliability and performance of your hard disk subsystem. As such, they should definitely be considered for any mission-critical server.

## Remote Management

The new Disk Management snap-in in Windows 2000 Server lets you manage not only the local hard disks but also drives on other computers running Windows 2000 or Microsoft Windows XP, enabling the administrator to manage disk tasks and space allocations from a workstation without having to sit at the machine that is being administered. This capability is a boon for remote site management and—using the MMC—makes it easy to delegate authority and administrative responsibilities for a group of computers to others without having to give them full administrative privileges.

## Dynamic Disks

The other major feature that Disk Management adds in Windows 2000 and later versions is the concept of dynamic disks. By converting a disk to a dynamic disk, you give Disk Management the ability to manage it in new ways, *without requiring a reboot* in most cases. You can extend a disk volume, span a volume across multiple physical disks, stripe the volume for improved performance, mirror it, or add it to a RAID-5 array—all from the MMC and all without a reboot, once the disk is converted to a dynamic disk. The initial creation or conversion of the first of your basic disks to a dynamic disk requires a reboot, unfortunately, but once you've gotten over that hurdle, you'll breeze through the remaining tasks. When combined with the new remote management functionality, dynamic disks give the system administrator powerful tools for managing the type and configuration of hard disk storage across the enterprise.

## Disk Management Tasks

Like all MMC snap-ins, the Disk Management snap-in can be opened in a number of ways. One of the most direct ways is to right-click the My Computer icon in the upper left corner of your desktop and choose Manage from the shortcut menu. This opens a local version of the Computer Management snap-in, containing the System Tools, Storage, and Services and Applications snap-ins. Click Storage to access the Removable Storage (if you have removable storage drives installed), Disk Defragmenter, Logical Drives, and Disk Management snap-ins, and then click Disk Management to open the Disk Management window. To open the Disk Management snap-in only, double-click the file Diskmgmt.msc in the %WinDir%\System32 directory. Note that the .MSC extension is probably hidden unless you've changed the default options in Windows Explorer.

When you open the Computer Management snap-in, you have the ability to manage not only the resources of the local computer but also those of remote computers. This makes it easy to manage the disks on a remote computer. If you run the Disk Management snap-in only, you'll be limited to managing disks on your local computer, unless you create a custom MMC. See [Chapter 10](#) for information on creating and customizing MMCs.

## Adding a Partition or Volume

Adding a new drive or partition to a Windows 2000 server is straightforward. First, obviously, you need to physically install and connect the drive. If you have a hot-swappable backplane and array, you don't even have to shut the system down to accomplish this task. If you're using conventional drives, however, you'll need to shut down and power off the system.

Once the drive is installed and the system is powered up again, Windows 2000 automatically recognizes the new hardware and makes it available. If the disk is a basic disk that is already partitioned and formatted, you'll be able to use it immediately. If it's a brand new disk that has never been partitioned or formatted, you'll need to prepare it first. If it's a dynamic disk or disks but is from another machine, you'll be able to use it as soon as you import it. If the disk is a basic disk that has already been formatted, you won't get prompted to upgrade it to a dynamic disk, but you should do it anyway. If the disk has never been used, you'll be prompted by the Write Signature and Upgrade Disk Wizard.

## Adding a New Disk Using the Write Signature and Upgrade Disk Wizard

If you install a new hard drive it is recognized automatically and the Write Signature and Upgrade Disk Wizard starts automatically when you open Disk Management. To add a new disk when the logon is complete, follow these steps:

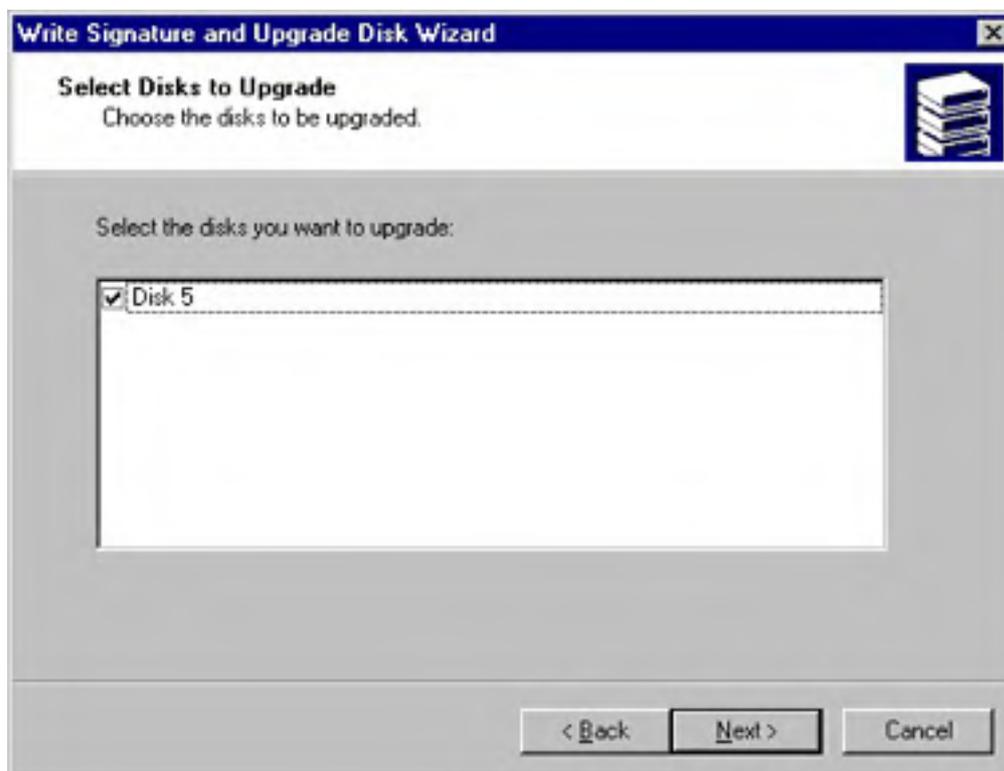

1. Open the Computer Management console by right-clicking the My Computer icon on your desktop and choosing Manage from the shortcut menu.
2. On the Storage menu, choose Disk Management. If the disk is new, you'll see the first screen of the Write Signature and Upgrade Disk Wizard, shown in Figure 15-3. This wizard allows you to upgrade the new disk to a dynamic disk. Click Next.

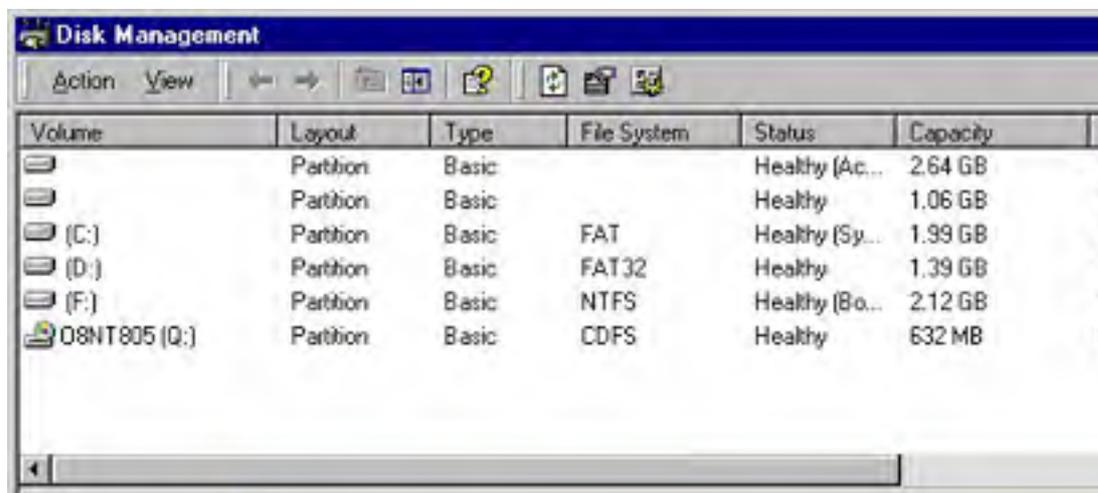

**Figure 15-3.** The first screen of the Write Signature and Upgrade Disk Wizard.

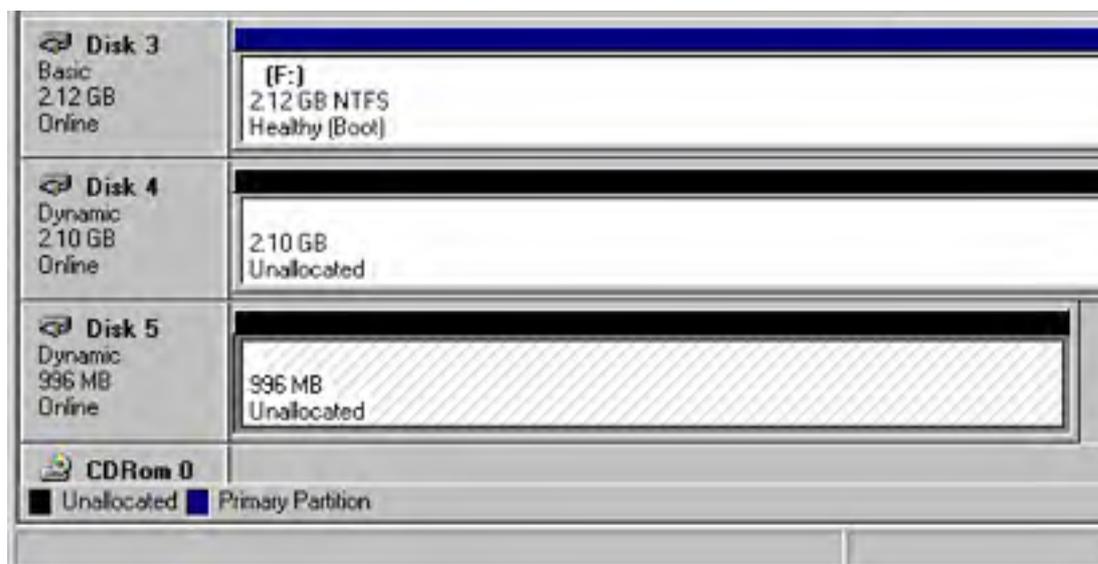

3. You'll see a confirmation of the disk (or disks, if you've added more than one) that can be selected for upgrading, shown in Figure 15-4.

**Figure 15-4.** The Select Disks To Upgrade screen of the Write Signature and Upgrade Disk Wizard.

4. Make sure that there is a check mark to the left of the disk or disks to be upgraded and then click Next again. You'll get a confirmation message. If all the options are correct, click Finish and the disk is upgraded to a dynamic disk.
5. After the wizard finishes, you'll be at the main Disk Management console, shown in Figure 15-5. Notice that the disk is still not formatted or allocated and is highlighted in black (if you haven't changed the default color settings for the Disk Management console).

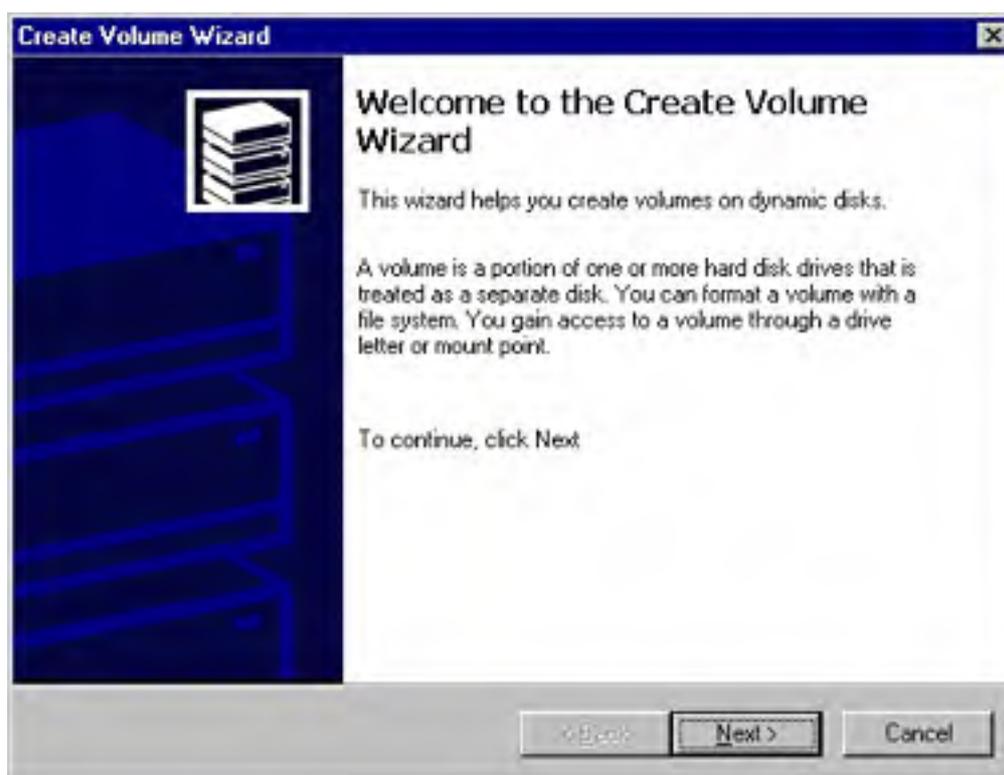

**Figure 15-5.** The main Disk Management console, showing the new disk (Disk 5).

## Creating a Volume

To create a new volume (the dynamic disk equivalent of a partition), complete these steps:

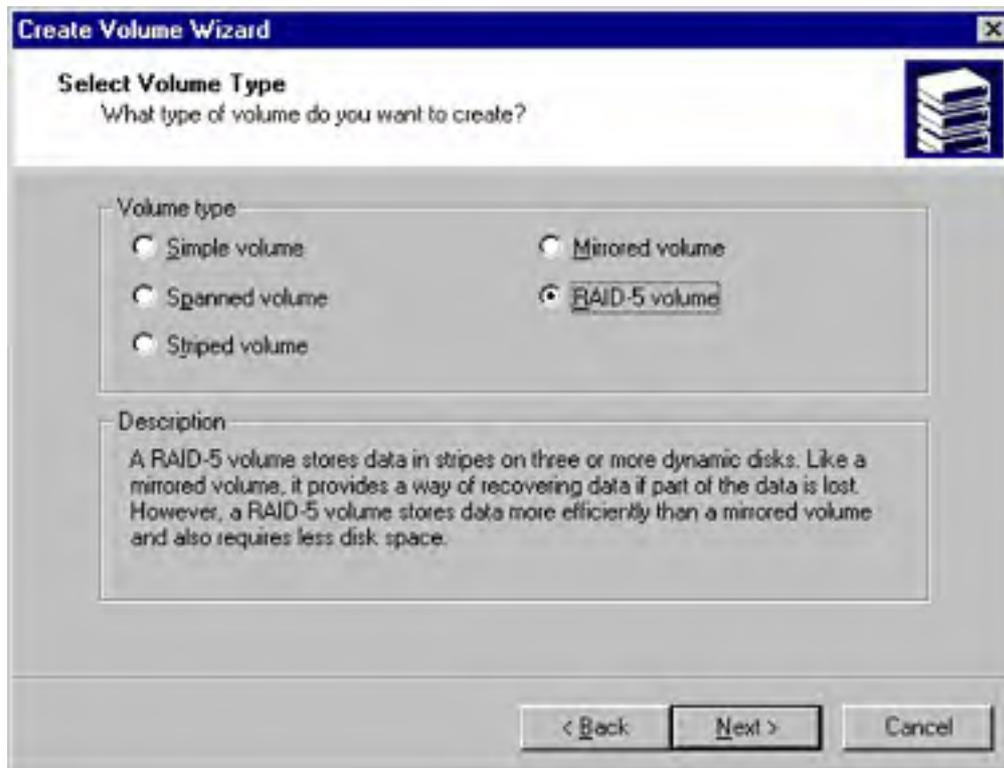

1. In the Disk Management console, right-click the unallocated disk and choose Create Volume from the shortcut menu. The Create Volume Wizard opens to guide you through the process of creating the new volume on the dynamic disk (Figure 15-6). Click Next.

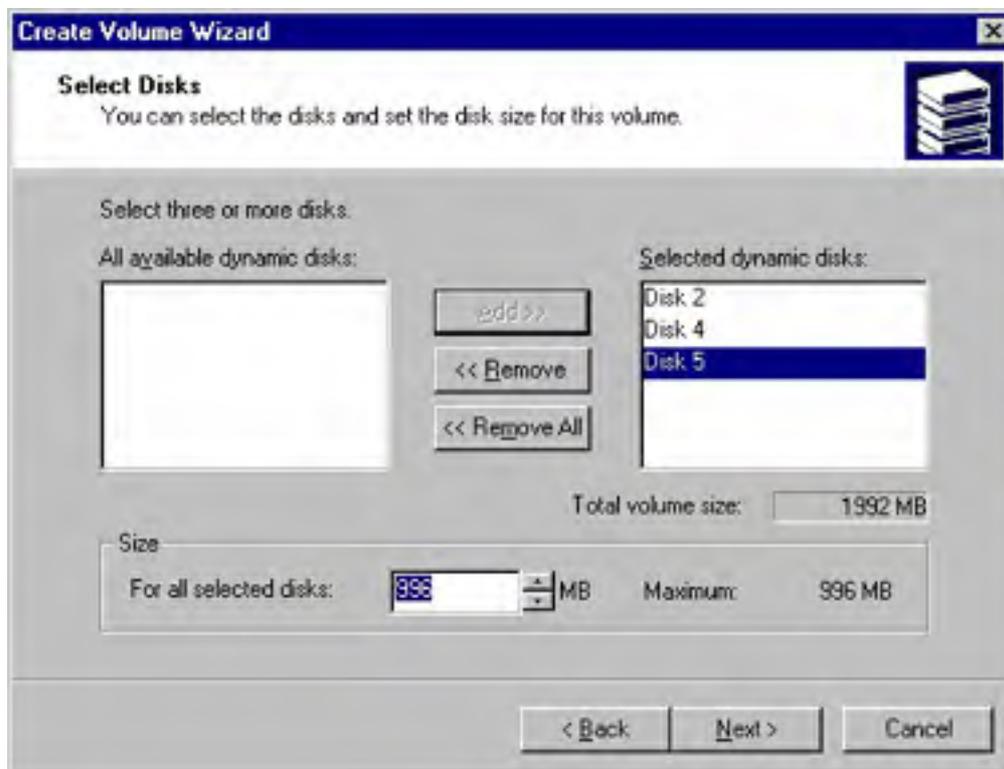

**Figure 15-6.** The first screen of the Create Volume Wizard.

2. Select the type of volume you'll be creating (Figure 15-7). Depending on the number of available unallocated volumes, you'll see one or more options for the type of volume. These options include Simple, Spanned (the Windows NT 4 Volume Set), Striped (RAID-0), Mirrored (RAID1), and RAID-5. Click Next.
3. Select the dynamic disks to use for the new volume. The choices available and the selections you'll need to make depend on the type of volume you're creating and the number of available unallocated disks. Figure 15-8 shows a RAID-5 volume being created.

4. In the same screen, adjust the size of the new volume. By default, the new volume uses the maximum available space from each of the selected disks. For spanned volumes, this is the sum of the free space on the selected disks; for other types of volumes, it is the number of disks times the available space on the smallest of the selected disks. Click Next.

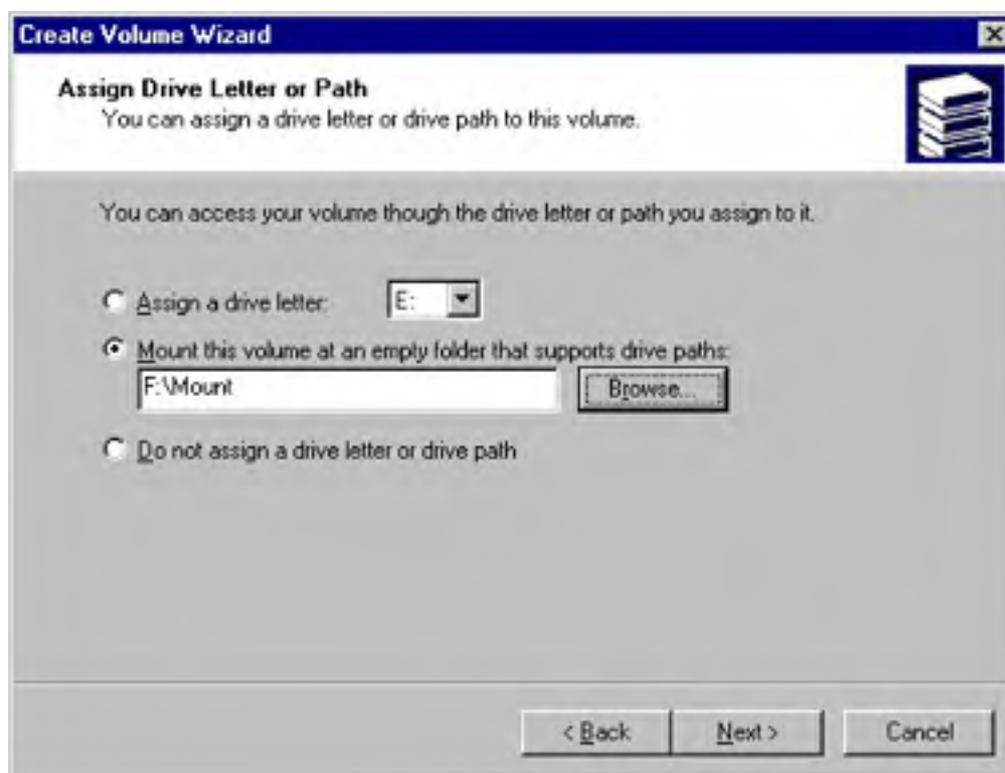

**Figure 15-7.** Select the type of dynamic volume you want to create.

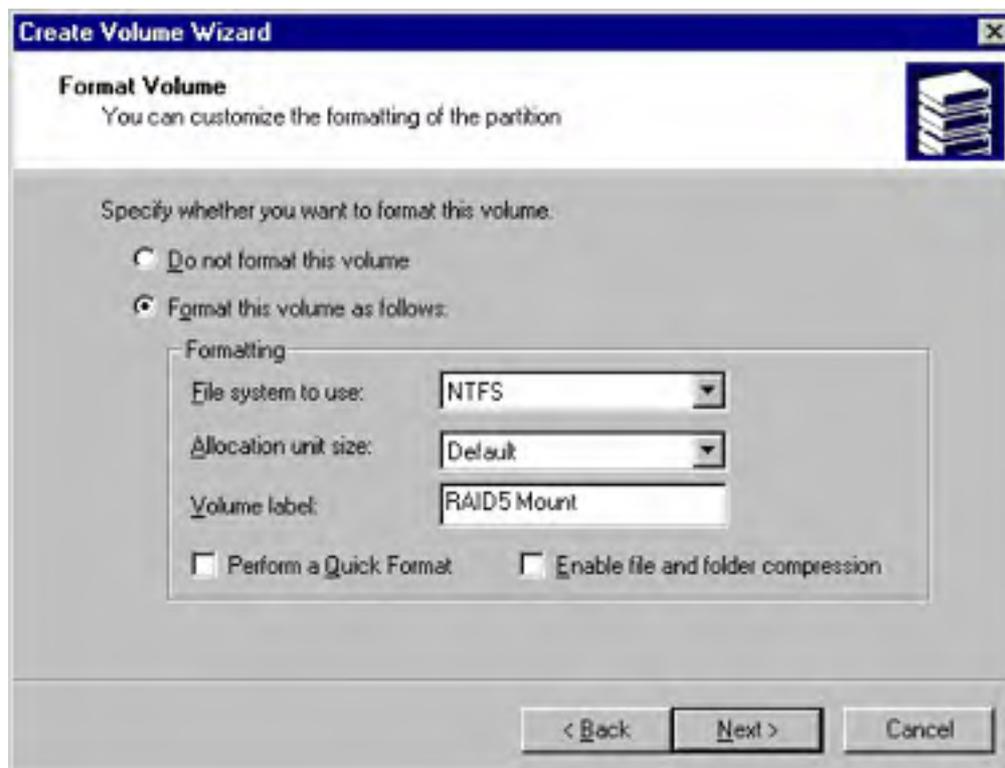

**Figure 15-8.** Select the dynamic disks that will be part of this volume.

5. Select either a drive letter or a mount point for the new volume (Figure 15-9), or opt not to assign a drive letter or path at this time. With Windows 2000, you can "mount" a volume on an empty sub-directory, minimizing the number of drive letters and reducing the complexity of the storage that is displayed to the user. If you want to take advantage of this feature, click Browse to locate the directory where you will mount the new volume. See the sidebar "Mounted Volumes" for more on this subject. Click Next.

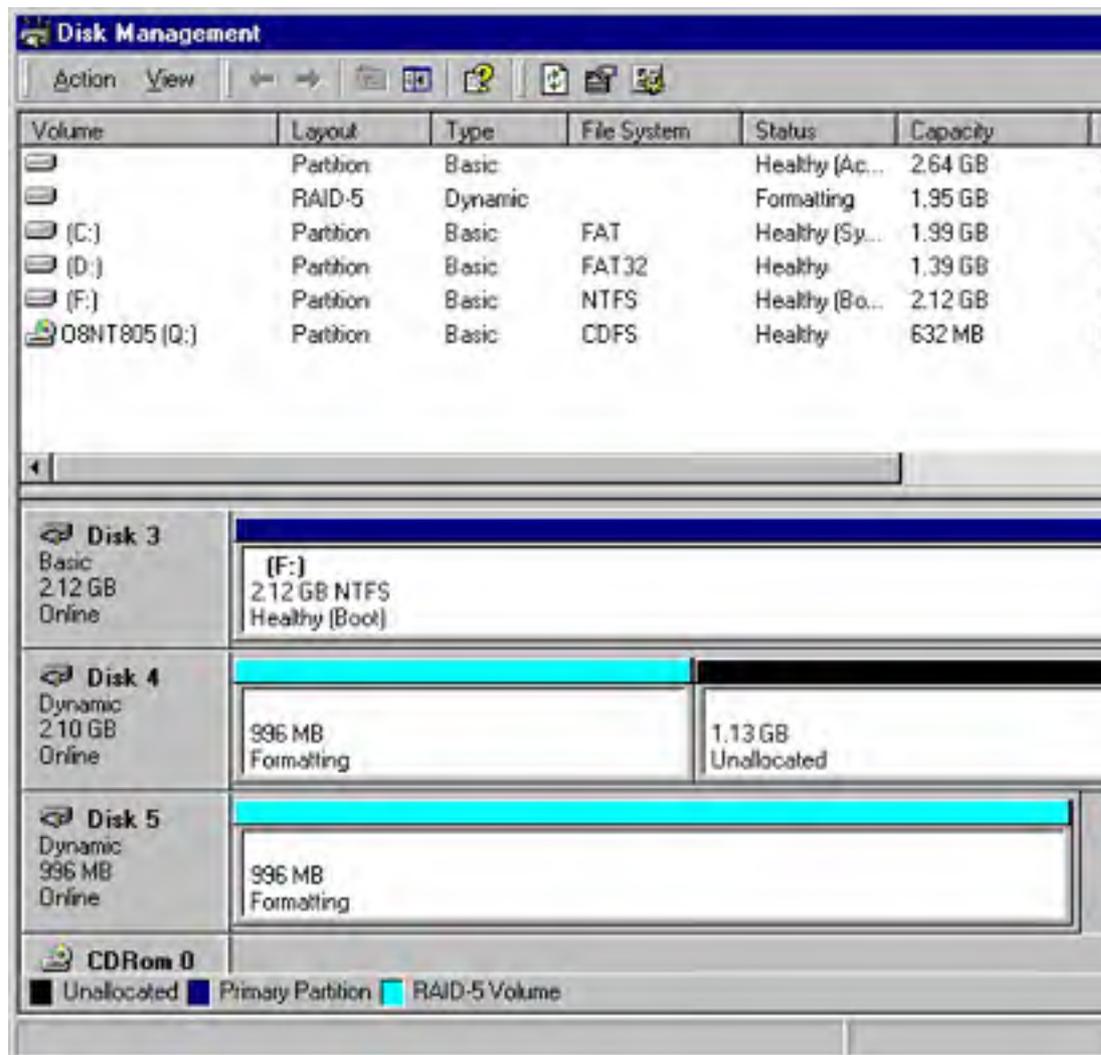

**Figure 15-9.** Select a drive letter or mount point for the new volume.

6. Select the formatting options you want (Figure 15-10). Even when mounting the volume rather than creating a new drive, you can choose your format type without regard to the underlying format of the mount point. Click Next.

**Figure 15-10.** Set the formatting options for the new volume.

7. You'll see a confirmation screen. If all of the options are correct, click Finish to create and format the volume. You return to the Disk Management console, where you'll see the new volume (Figure 15-11).

**Figure 15-11.** The new RAID volume being generated and formatted.

## Real World

### Mounted Volumes

Windows 2000 borrows a concept from the UNIX world by adding the ability to mount a volume or partition on a subfolder of an existing drive letter. A mounted volume can also have a drive letter associated with it, although it does not need to, and it can be mounted at more than one point, giving multiple entry points into the same storage.

A volume must be mounted on an empty subfolder of an existing NTFS volume or drive. FAT and FAT32 drives do not support mounted volumes. You can, however, mount a FAT or FAT32 volume at any mount point. You can mount only a single volume at a given mount point, but you can then mount further volumes on top of an existing mounted volume, with the same rules and restrictions as any other mount. The properties of a drive do not show all of the available disk space for that drive, as they will not reflect any volumes mounted on the drive.

Mounted volumes can be used to provide a mix of redundant and nonredundant storage in a logical structure that meets the business needs of the enterprise while hiding the complexities of the physical structure from the users.

## Creating a Partition

You can create partitions only on basic disks, not on dynamic disks. To create a new partition, follow these steps:

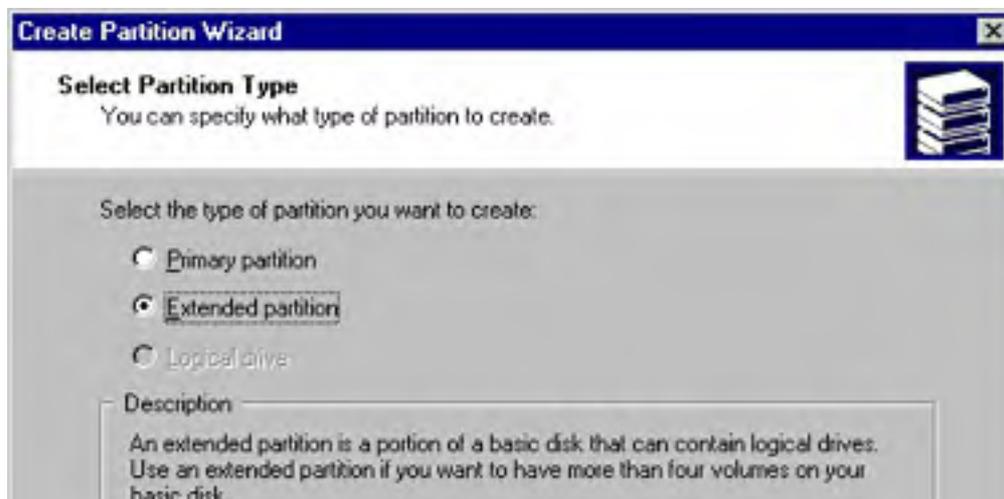

1. In the Disk Management console, right-click the unallocated basic disk and select Create Partition. The Create Partition Wizard, shown in Figure 15-12, opens to guide you through the process of creating the new partition on the basic disk. Click Next.

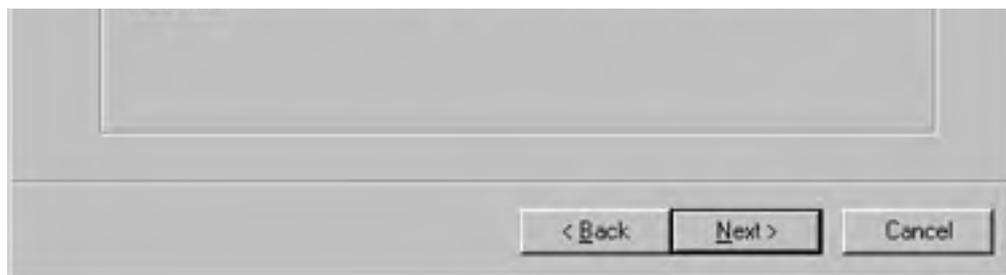

**Figure 15-12.** The first screen of the Create Partition Wizard.

For security and performance reasons, data files should not be on the same partition as Windows. In particular, make sure the Internet Information Services (IIS) publishing folder (\Inetpub) is not in the same partition.

2. Select the type of partition you'll be creating (Figure 15-13). If this is a removable drive, you'll see only an option for a primary partition, but with a nonremovable disk you'll be able to choose either a primary or an extended partition. A basic disk can hold up to four primary partitions or three primary partitions and one extended partition. Click Next.

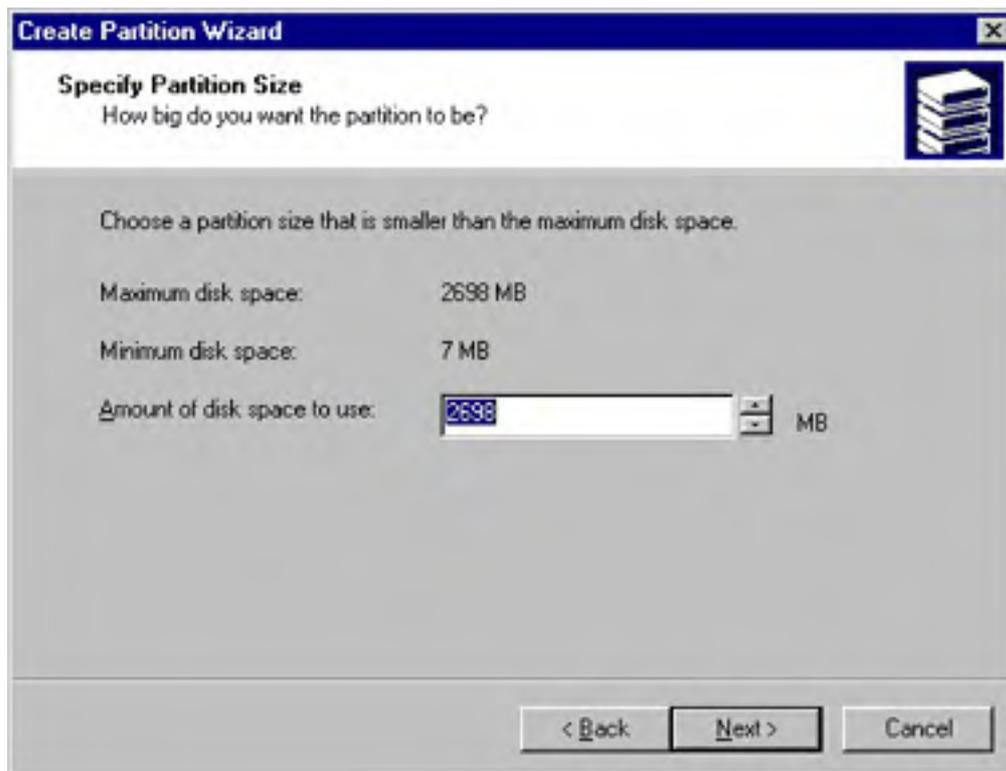

**Figure 15-13.** Select the type of partition you want to create.

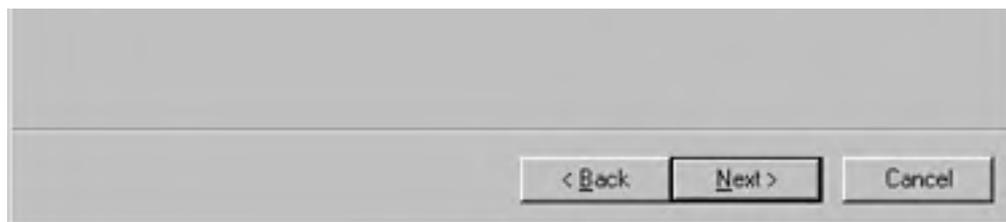

3. Specify how much of the available space on the disk you want to use for this partition (Figure 15-14). Click Next.

**Figure 15-14.** Specify how much of the disk will be used by this partition.

4. If you're creating an extended partition, continue with step 6. If you're creating a primary partition, select either a drive letter, as shown in Figure 15-15, or a mount point for the new partition. You can also choose to defer giving the new partition a mount point or drive letter. However, it will be unavailable to your users until you do. Click Next.

**Figure 15-15.** Select a drive letter or a mount point for the new partition.

5. Select the formatting options you want, or opt to defer formatting until later. Click Next.
6. You'll see a confirmation screen. If all the options are correct, click Finish to create the partition. If it is a primary partition, it is formatted and the drive letter or mount point assigned. If it is an extended partition, you'll need to format it and choose the drive letters and mount points for it, as discussed in the next section, "Creating Logical Drives in an Extended Partition."

### **Real World**

#### **Formatting Options**

Windows 2000 supports three different file system formats: FAT, FAT32, and NTFS. Before any disk or volume can be used, it must be formatted. For disks larger than 510 MB, you will probably find that FAT32 or NTFS use space most efficiently. However, only NTFS supports the more advanced features of Windows 2000.

You can choose to quick-format a drive to make it available more quickly, but this option simply removes the file entries from the disk and does no checking for bad sectors. You should select this choice only when recycling a disk that has already been formatted and when you are confident that it hasn't been damaged.

On an NTFS volume or partition, you can specify the allocation unit size. This option lets you tune the disk for a particular purpose, depending on the disk's size and intended function. A database storage volume that will contain large database files that are managed by the database program might lend itself to large allocation units (also called clusters), whereas a disk that must hold many small files is a candidate for smaller clusters. However, the default sizes are an excellent compromise for most situations and should be modified only with caution and a clear understanding of the consequences for your environment.

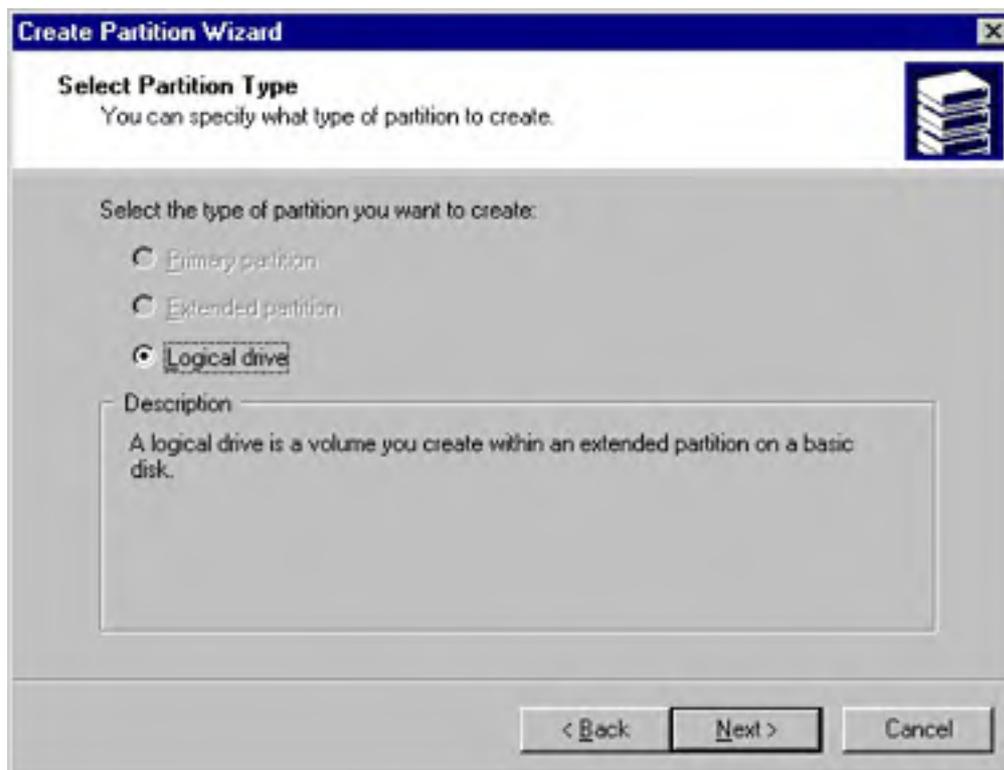

You can also choose to enable disk and folder compression on NTFS volumes and partitions. This causes all files and folders on the volume to be compressed, as opposed to individual files or folders that you select. Compression can minimize the amount of hard disk space used by files but can have a negative impact on performance, especially on busy file servers. Given the cost of hard drive space today, using compression is a false economy, particularly for frequently updated data.

### **Creating Logical Drives in an Extended Partition**

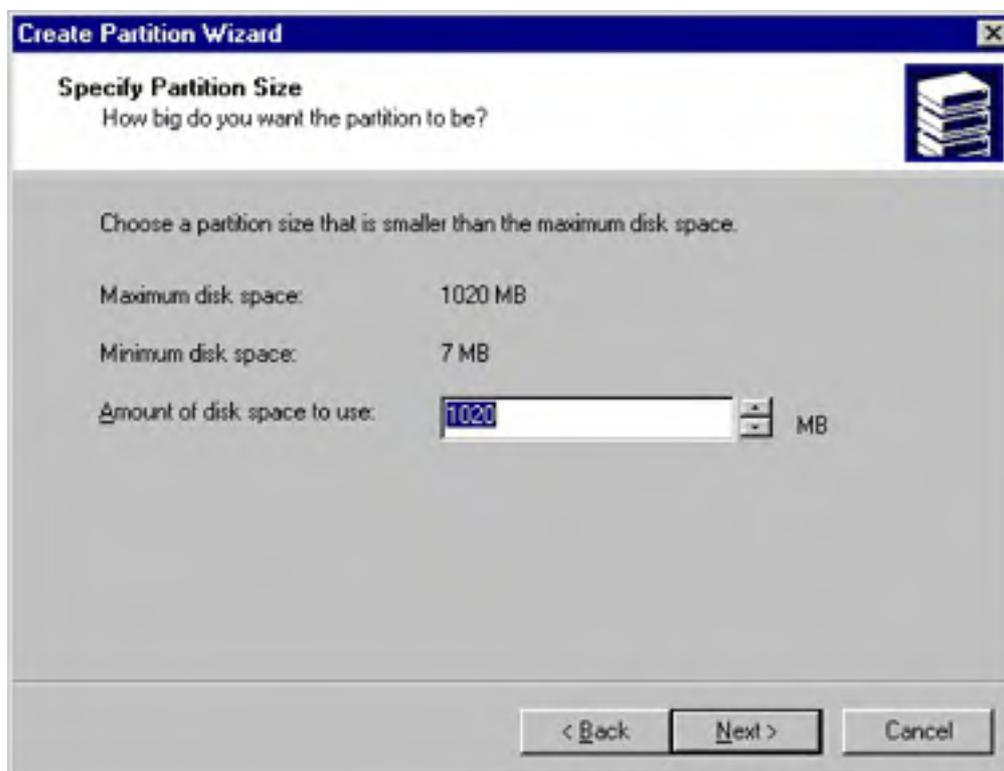

If you've created a new extended partition, the next step is to create logical drives in the partition. You can assign one or more logical drives in an extended partition, and each of those logical drives can be assigned a drive letter and/or one or more mount points. Each of the logical drives can be formatted with any of the supported file systems, regardless of the format of other logical drives. To create a logical drive, follow these steps:

1. In the Disk Management console, right-click on the Free Space portion of the extended partition and select Create Logical Drive from the shortcut menu to open the Create Partition Wizard (shown earlier in Figure 15-12). Click Next.

2. You'll see the Select Partition Type screen, shown in Figure 15-16, with the Logical Drive option selected and the only choice active. Click Next and specify the size of the logical drive you'll be creating, as shown in Figure 15-17. You can specify the entire partition for a single drive, or you can divide the partition into multiple logical drives. Click Next.

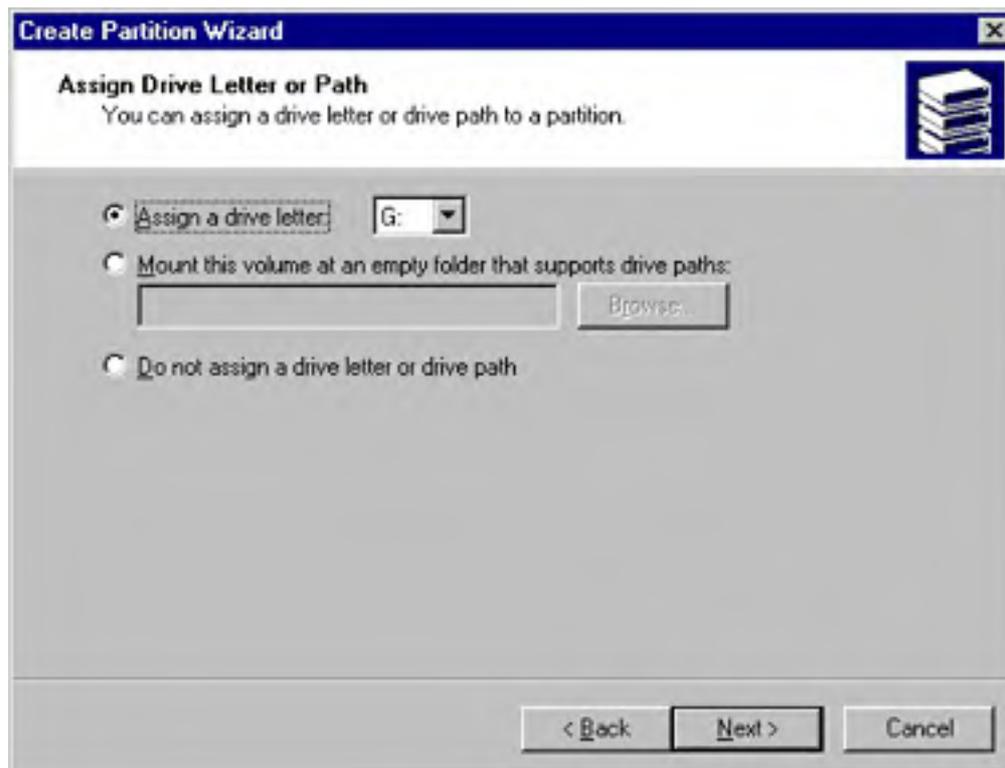

**Figure 15-16.** The Select Partition Type screen of the Create Partition Wizard.

**Figure 15-17.** Adjusting the size of the logical drive.

3. Select the drive letter or mount point for the new logical drive, as shown in Figure 15-18. You can also choose not to assign a letter or mount point at this time. Click Next.

**Figure 15-18.** Assigning a drive letter or mount point for the logical drive.

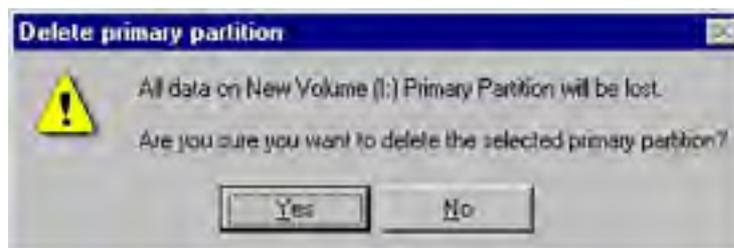

4. Select the formatting options you want. Click Next again, and you'll see the final confirmation screen. If all of the options are correct, click Finish to create and format the new logical drive. If you need to create additional logical drives on the partition, you can repeat these steps as many times as required to create the number of logical drives desired.

## Deleting a Partition, Volume, or Logical Drive

Deleting a partition, deleting a logical drive, and deleting a volume are essentially the same task, with one important exception. When you delete a logical drive, you end up with free space on the partition, but other logical drives on the partition are untouched. When you delete a partition or volume, the entire volume or partition is deleted. You cannot, however, delete an extended partition until all of the logical drives in the partition have first been deleted. You can directly delete a primary partition or a volume.

In all cases, when you delete a volume, logical drive, or partition, you'll end up with free or unallocated space and no data on the volume, drive, or partition when you're done, so make sure you've got a good backup if there's a chance you might later need any of the data. To delete a partition, logical drive, or volume, follow these steps:

1. Right-click the partition, logical drive, or volume and choose Delete Partition, Delete Logical Drive, or Delete Volume.
2. If you're deleting a volume or partition, you'll see a warning message similar to the one shown in Figure 15-19. Deleting an extended partition involves extra steps, as you must first delete the logical drives in the partition before you can delete the partition itself.

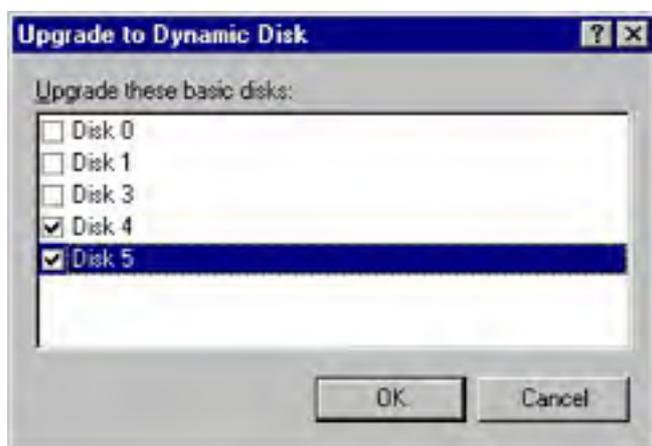

**Figure 15-19.** Confirmation message for deleting a volume.

Once the volume or partition has been completely deleted, the space it occupied is unallocated. Space that is unallocated on dynamic disks can be used to create mirrors, extend an existing volume, create a RAID array, or otherwise manage the storage on your server. Space that is unallocated on basic disks can be partitioned.

## Converting a Disk to a Dynamic Disk

The advantages of dynamic disks are substantial. Even if you use hardware RAID controllers and hot-swappable disks to manage your hard disks, you'll probably find it a good idea to use dynamic disks. There is a caveat, however. Because you can't boot from or even see a dynamic disk from another operating system, and even Windows Setup doesn't have complete support for dynamic volumes, you might want to consider leaving at least your boot drive as a basic drive. Doing so makes working with it somewhat easier. If you need to provide for redundancy on that drive, and if hardware RAID is an option, use RAID level 1 to make recovery from a failed hard disk or other disaster as painless as possible. To convert a basic disk to a dynamic disk, follow these steps:

1. Right-click the disk's icon on the left side of the Disk Management console, and choose Upgrade To Dynamic Disk from the shortcut menu.
2. You'll see a dialog box like the one shown in Figure 15-20, listing the available basic disks on your machine. The disk you clicked is checked, and you can select other disks to upgrade at the same time. Click OK to continue with the upgrade.

**Figure 15-20.** You can select more than one disk to upgrade.

3. You'll get a warning message stating that no other version of Windows can use these disks. Click Next.
4. If there are no file systems on the disks you've chosen to upgrade, that's all there is to it. However, if there are file systems on any of the disks, you'll get a warning message stating that the file systems will be force dismounted. Click Yes and the upgrade proceeds. You can now manage the disks dynamically, and they can be part of mirrors, RAID-5 arrays, or other enhanced disk configurations that aren't supported by basic disks.

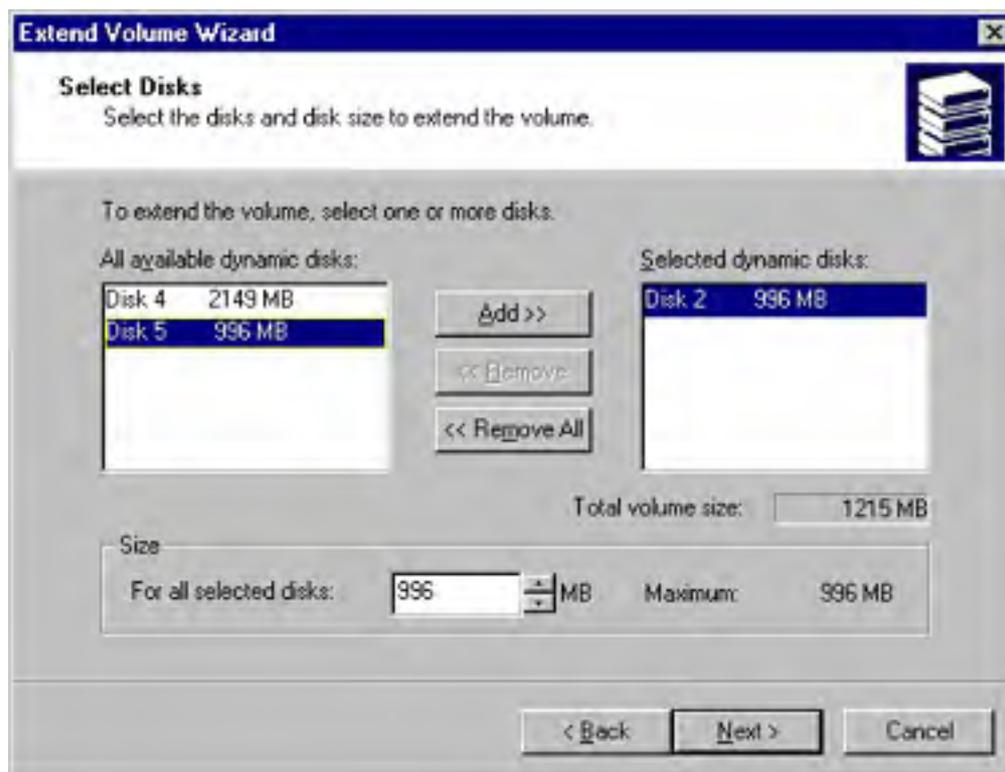

If there are any open files on the disk to be upgraded, you might experience data loss. You should only perform disk upgrades during quiet times when no users are logged on or using the server.

## Extending a Volume

You can add space to a volume without having to back up, reboot, and restore your files if the volume is on a dynamic disk and if it is a simple volume or a spanned volume. You do this by converting the volume to a spanned or extended volume that incorporates unallocated space on any dynamic disk. Unfortunately, you can't increase the size of a RAID-5 or RAID-0 (striped) volume simply by adding disks to the array, unless you're using a version of hardware RAID that supports this functionality. To extend a volume, follow these steps:

1. In the Disk Management console, right-click on the volume you want to extend. Choose Extend Volume from the shortcut menu to open the Extend Volume Wizard. Click Next.

2. Highlight one or more disks from the list of dynamic disks that are available and have unallocated space. Click Add to add the selected disk or disks, and indicate the amount of space you want to add (Figure 1521). Click Next.

**Figure 15-21.** Selecting the disks to use to extend the volume.

3. The Extend Volume Wizard displays a final confirmation screen before extending the volume. Click Finish to extend the volume, or click Cancel if you change your mind.

It's important to remember that a spanned (extended) volume is actually less reliable than a simple disk. Unlike a mirror or RAID-5 volume, in which there is built-in redundancy, a spanned or striped volume will be lost if any disk in the volume fails.

### Real World

#### Extending—Administrator's Friend or Foe?

Most administrators have wished at some point that they could simply increase the users' home directory space on the fly without having to bring the system offline for several hours while the entire volume is backed up and reformatted to add the other hard disks, the backup is restored, and the share points are re-created. Fun? Hardly. Risky? Certainly. And definitely a job that means coming in on the weekend or staying late at night—in other words, something to be avoided if at all possible.

All this makes Windows 2000's ability to create additional space on a volume without the need to back up the volume, reformat the disks, and re-create the volume a seductive feature. However, if you're using conventional hard disks without hardware RAID, you might want to think twice before jumping in. Only dynamic volumes allow you to add storage on the fly, and only if the volume is either a spanned or striped volume, or a simple volume that was created as a dynamic volume (not upgraded). Because spanned volumes provide no redundancy, using them exposes your users to the risks of a failed drive. Yes, you have a backup, but even under the best of circumstances, you'll lose some data if you need to restore a backup. Further, using spanned volumes actually increases your risk of a hard disk failure. If any disk used as part of the spanned volume fails, the entire volume is lost and must be restored from a backup.

Why, then, would anyone use spanning? Because they have hardware RAID to provide the redundancy. This combination offers the best of both worlds—redundancy provided by the hardware RAID controller and flexibility to expand volumes as needed, using Windows 2000 disk management. This is yet another compelling argument for hardware RAID, if you need one.

Windows 2000 uses the terms "extended" and "spanned" nearly interchangeably when describing volumes. Technically, however, a spanned volume must include more than one physical disk, whereas an extended volume can also refer to a volume that has had more space added to the original simple volume on the same disk.

## Adding a Mirror

When your data is mission-critical and you want to make sure that no matter what happens to one of your hard disks the data is protected and always available, you should consider mirroring the data onto a second drive. Windows 2000 can mirror a dynamic disk onto a second dynamic disk so that the failure of either one does not result in a loss of data. To mirror a volume, you can either select a mirrored volume when you create the volume (see "Creating a Volume," earlier in this chapter) or you can add a mirror to an existing volume. To add a mirror to an existing volume, follow these steps:

1. In the Disk Management console, right-click the volume you want to mirror. If a potential mirror is available, the shortcut menu lists the Add Mirror command.
2. Choose Add Mirror to display the Add Mirror dialog box, shown in Figure 15-22, where you can select the disk to be used for the mirror.

**Figure 15-22.** The Add Mirror dialog box.

3. Select the disk that will be the mirror, and click Add Mirror. The mirror is created immediately and starts duplicating the data from the original disk to the second half of the mirror, as shown in Figure 15-23. This process is called *regeneration*. (The process of regeneration is also used to distribute data across the disks when a RAID-5 volume is created.)

Regeneration is both CPU- and disk-intensive. When possible, you should create mirrors during slack times or during normally scheduled downtime. This goal should be balanced, however, by the equally important goal of providing redundancy and failure protection as expeditiously as possible.

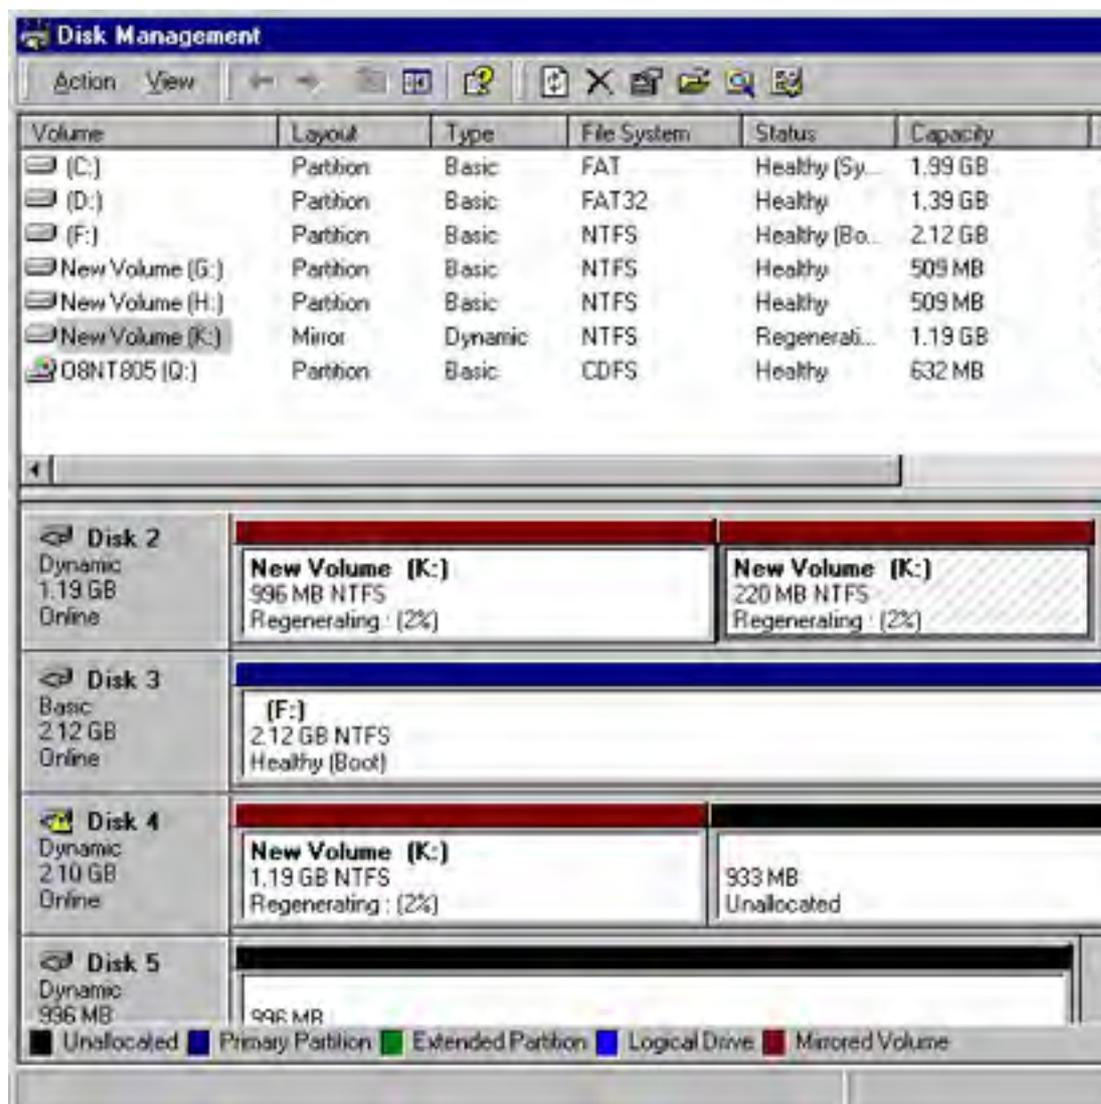

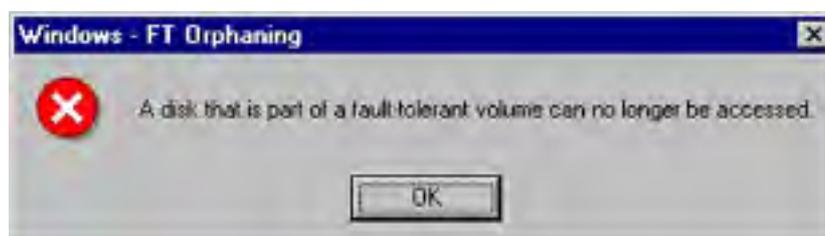

Figure 15-23. A newly created mirrored disk in the process of regeneration.

To improve your overall data security and reliability, you should mirror your volumes onto disks that use separate controllers whenever possible. This process is known as *duplexing*, and it eliminates the disk controller as a single point of failure for the mirror while actually speeding up both reading and writing to the mirror, as the controller and bus are no longer potential bottlenecks.

### Drive Failure in a Mirrored Volume

If one of the disks in a mirrored volume fails, you'll continue to have full access to all of your data without loss. Windows 2000 sends an alert to the console (Figure 15-24), marks the failed disk as missing, and takes it offline, but it continues to read and write from the other half of the mirrored volume as though nothing had happened. Be warned, however: you no longer have any fault tolerance on that volume, and any additional failure will result in catastrophic data loss.

**Figure 15-24.** The warning message that displays when a disk that's part of a mirrored volume fails.

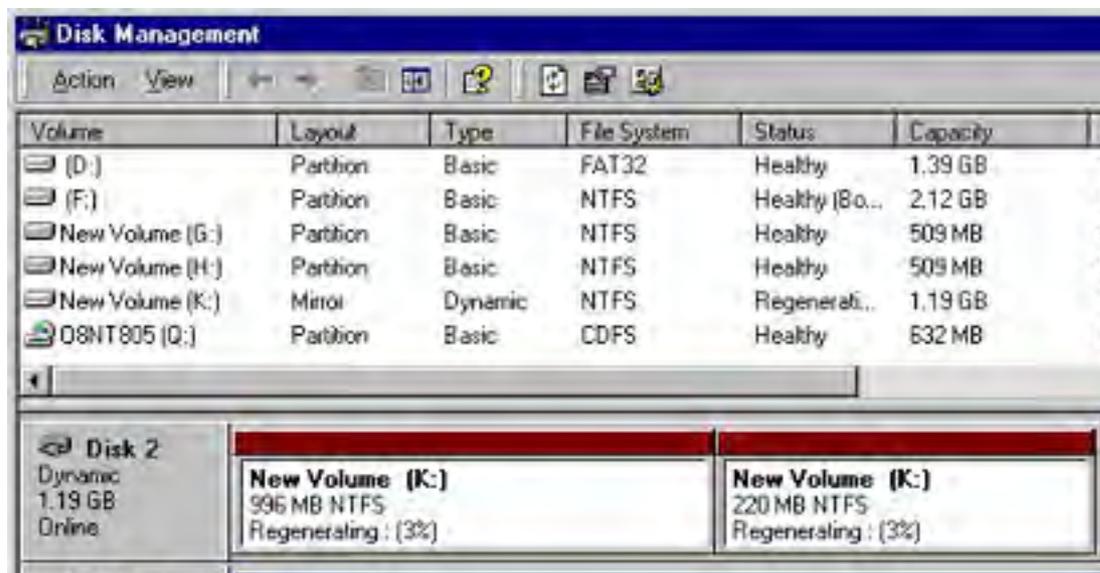

Once you've replaced the failed disk or corrected the problem and reactivated it, the mirror automatically starts regenerating. If the problem can be solved without powering down the system, you can regenerate the mirror on the fly. To reactivate the failed disk, follow these steps:

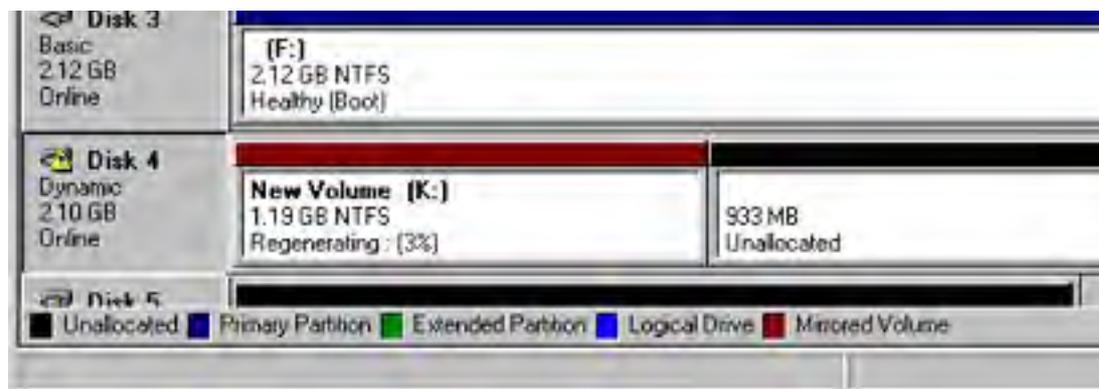

1. Right-click the icon for the failed disk on the left of the Disk Management console, shown in Figure 15-25.

**Figure 15-25.** Reactivating a failed disk that's part of a mirrored volume.

2. Choose Reactivate Disk, and Windows 2000 brings the disk back online and starts regenerating the failed mirror, as shown in Figure 1526. Once the mirror has been regenerated, the disk status changes from Regenerating to Healthy.

**Figure 15-26.** Data being regenerated on a reactivated mirrored disk.

## Removing a Mirror

If you need to make additional disk space available on your system and you have no additional disks available, you can remove the mirror from a mirrored volume. When you remove a mirror, the data on one of the disks is untouched, but the other disk becomes unallocated space. Of course, you will have lost all redundancy and protection for the data, so you'll need to take steps to restore the mirror as soon as possible, and until then you might want to modify your backup schedule for the remaining disk. To remove a mirror, follow these steps:

1. In the Disk Management console, right-click either half of the mirror. Choose Remove Mirror from the shortcut menu, and the Remove Mirror dialog box opens, shown in Figure 15-27.

**Figure 15-27.** The Remove Mirror dialog box.

2. Select the disk that you want to remove from the mirror. Click Remove Mirror. You'll get one last chance to change your mind. Click OK and the disk you selected becomes unallocated space.

## Breaking a Mirror

If a disk fails and you can't replace it with an identical one, you should break the mirror until a replacement becomes available. Breaking a mirror severs the connection between the two disks, allowing the remaining disk to continue to function normally until a replacement disk is available. You might also find it useful to break a mirror even when both disks are still functioning, as you then end up with two identical copies of the same data. One of the halves of the broken mirror continues to have the same drive letter and/or mount point, whereas the second half of the broken mirror is assigned the next available drive letter. To break a mirror, follow these steps:

1. In the Disk Management console, right-click either disk of the mirrored volume.
2. Choose Break Mirror from the shortcut menu. You'll be asked to confirm that you really want to break it.
3. Click Yes, and the mirror is broken. You'll have two disks. One retains the drive letter or mount point of the original mirror, and the other is assigned the next available drive letter. They both contain exact duplicates of the data at the instant of the break but immediately start to diverge as they are modified.

### **Real World**

#### **Backing Up Active Files**

One of the most difficult tasks faced by the system administrator is to get a reliable, sure backup of a file that is in constant active use, such as a data file for a database such as SQL Server or Oracle. The Break Mirror command can be used to get around this problem. You can momentarily stop the database, break the mirror, and restart the database. Now you have a copy of the data file that is no longer in active use and can be safely and effectively backed up. Once the backup has completed, you can delete the broken volume and re-create the mirror. Note, however, that the creation of a mirror involves substantial overhead and might adversely affect system performance until the regeneration is completed.

## **Converting a Volume or Partition from FAT to NTFS**

You can convert a volume or partition from the FAT or FAT32 file system to the NTFS file system without losing data or interrupting the availability of the rest of the server. However, Windows 2000 offers no graphical way to do this—you'll have to run a command-line utility. To convert a volume or partition, open a command window and type

```
convert <volumename | mountpoint | driveletter:> /fs:ntfs [/v].
```

This command converts the volume or drive from either FAT or FAT32 to NTFS. If you use the /v command-line switch, the conversion is fairly noisy, listing the name of each file and directory that's converted. If someone has a file open on the volume and the program cannot gain exclusive access to it, you are offered the opportunity to schedule the conversion for the next time you reboot. This option is acceptable if you have a planned maintenance reboot coming anyway, but otherwise you probably shouldn't schedule the conversion, as it might end up taking a fairly long time if the drive is large and contains a lot of files.

### **Real World**

#### **NTFS Conversion Planning**

If you schedule a conversion to NTFS for the next reboot before you're actually ready to reboot the server and your server needs to be rebooted unexpectedly, you simply have to wait while the conversion happens. There is no way to bypass the conversion once you've committed to it. This can turn a minor downtime into a major headache if it happens in the middle of the production day. Don't commit to a conversion unless you are sure you can afford the downtime if Windows 2000 decides it needs to reboot.

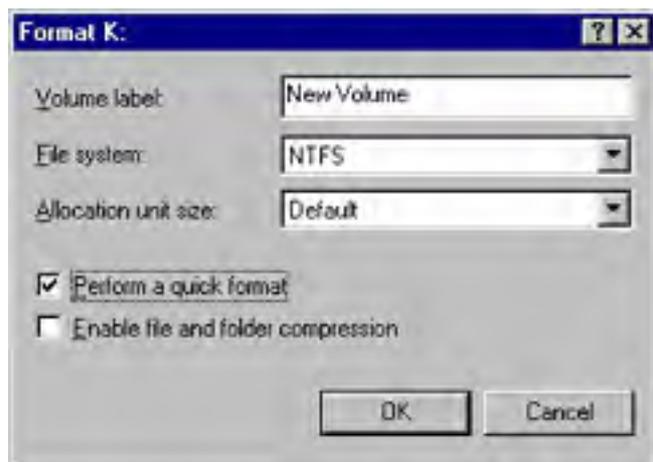

## **Formatting a Partition or Volume**

Before a partition, logical drive, or volume can be used, it must be formatted. Formatting lays down the necessary structure to support the file system you choose for the volume. You must format a volume or drive when it is first created, and at any later point if you want to clear it off. You can also use Format to change the type of file system on a drive, partition, or volume, but all data on the target is deleted during the formatting. (The command-line Convert command—which allows conversion of FAT and FAT32 targets to the NTFS format only—preserves any data on the target.) The file systems that are supported by Windows 2000 are FAT, FAT32, and NTFS.

In general, we recommend that you use NTFS unless you have a compelling reason not to. One case in which you would not use NTFS is when log files will reside on the volume or partition. A FAT or FAT32 volume tends to be faster and more appropriate for large files that grow constantly in small increments, as log files do. However, even with log files, you should use the FAT or FAT32 file system only when security or quotas are not an issue, because these file systems do not support quotas or the security features of NTFS.

Another reason to use FAT or FAT32 is to allow the computer to support dual booting into other operating systems. NTFS is not visible or accessible from other operating systems, whereas FAT can be used by a variety of operating systems and FAT32 can be used by Microsoft Windows 95 and Microsoft Windows 98. To format a logical drive, partition, or volume, follow these steps:

1. In the Disk Management console, right-click the logical drive, partition, or volume you want to format, and choose Format from the menu. You'll see the dialog box shown in Figure 15-28. Select the file system you want to use: FAT, FAT32, or NTFS.

**Figure 15-28.** *The Format dialog box.*

2. Select the allocation unit size (also called the cluster size). Normally, you'll simply accept the default here. See "Optimum Cluster Size" for a discussion of this issue.
3. Type in a name for the volume, logical drive, or partition. The default name is New Volume.

### **Real World**

#### **Assigning Volume Names**

The name you assign to a volume, partition, or drive should tell you something about it rather than simply mimicking the drive letter. A volume name like "120GBSCSI" tells you pretty conclusively that it's that big new SCSI drive you just bought, unless, of course, you already have half a dozen of them on your server, in which case you're going to need to come up with a more effective name. On the other hand, a volume name of C\_DRIVE is just about useless, because the drive letter is available from anywhere that the volume name is.

4. Select the Perform A Quick Format check box if you want to format the drive quickly. We recommend, however, that you not do this unless you have a strong need to make the volume available immediately. The full, long version of the format checks the entire drive for defects. It can take a while on a large drive, and the overall system performance tends to suffer while the format is going on, but the greater sense of confidence in the volume should be worth the wait.
5. If the entire drive will be compressed, check Enable File And Folder Compression. Note, however, that you can choose to compress individual folders and even individual files regardless of whether you check this option now. With the size and cost of drives these days, we think this option is much less useful than it once was.

- Click OK and the formatting begins. Windows 2000 can handle only one format at a time, so you'll be unable to format any other partition or volume until this one finishes.

### Real World

#### Optimum Cluster Size

A discussion of the best cluster size for a particular application or need is beyond the scope of this chapter and can be fairly heated, with an enormous amount of unsubstantiated and generally false statements being bandied about. Suffice it to say that the defaults are good for almost all situations and that decisions to choose something other than the default allocation size should be made only when there is a specific, clearly understood reason and a compelling need to do so. You can choose cluster sizes from 512 bytes up to 256 KB. You cannot enable file and folder compression on NTFS if you go beyond 4 KB for your allocation unit size.

If you seriously think you need to change the cluster size for a particular volume, we suggest you first make the change in a controlled lab environment and perform confidence and performance tests to ensure that the change meets your needs and doesn't cause unintended side effects.

## Changing a Drive Letter

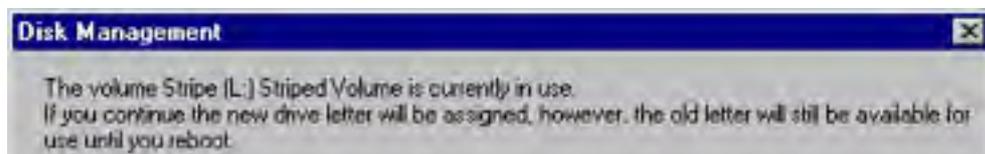

You can change the drive letter of a volume or partition at any time, and you can even have multiple paths to a given drive. In addition, unlike Windows NT, Windows 2000 allows you to change the drive letter of a removable drive, such as a Jaz or Zip drive. To change a drive letter, follow these steps:

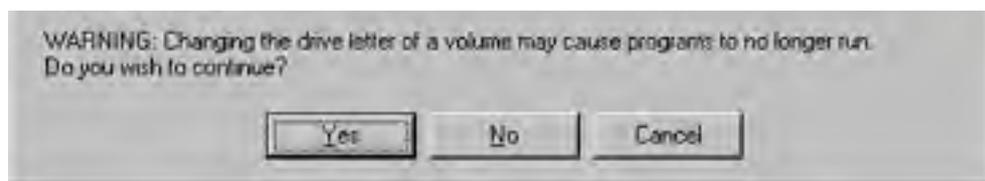

- Right-click on the drive in the Disk Management console, and choose Change Drive Letter And Path from the shortcut menu.
- A dialog box displaying the current drive letter and any mount-point paths for the disk appears, as shown in Figure 15-29. Select the drive letter shown and click Edit. Select the new drive letter from the drop-down list. Click OK.

**Figure 15-29.** Changing the drive letter and path of a logical drive.

- You see a confirmation message warning that the change could affect the ability of some programs to run. Click Yes and the drive letter change takes place immediately, unless there are open files on the drive. If there are open files on the drive, the drive temporarily has two drive letters, the old one and the new one. You'll see the warning shown in Figure 15-30. Click Yes to confirm the change.

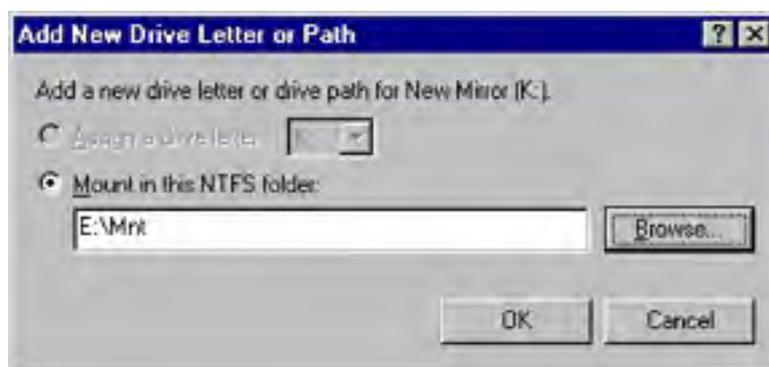

**Figure 15-30.** Message warning that a drive has a dual identity.

## Mounting a Volume

Windows 2000 adds a new feature to the disk and storage management process. You can mount a dynamic volume—or any partition or logical drive in an extended partition—on any empty directory that resides on a drive that is both NTFS formatted and nonremovable. The mounted volume can be formatted as FAT, FAT32, or NTFS and appears to users as a simple directory. This feature makes it possible to create larger file systems that use multiple hard disks without the inherent risks of using spanned volumes, as the failure of any one of the mounted volumes affects only the directories that were part of that volume. You can also easily support multiple formats from a single drive letter. To mount a volume, follow these steps:

1. From the Disk Management console, right-click on a volume or partition. Choose Change Drive Letter And Path from the shortcut menu. The Change Drive Letter And Path dialog box, shown previously in Figure 15-29, opens.
2. Click Add; the Add New Drive Letter Or Path dialog box opens, as shown in Figure 15-31.

**Figure 15-31.** The Add New Drive Letter Or Path dialog box, used to mount a volume.

3. You can type in the mount point or click Browse to select or create a mount point. Any empty directory that resides on a nonremovable NTFS volume or drive can be the mount point.
4. Once you've selected or typed in the mount point, click OK, and the volume or partition is mounted.

It's actually easy to get yourself into trouble with this new feature. Disk Management lets you make multiple levels of mounted volumes, including ones that are recursive. We think you're well advised to mount volumes *only* at the root level of a drive. Trying to mount below that point can lead to confusion and make management and documentation difficult.

## NTFS Version 5

The NTFS file system format has been around, essentially unchanged, since the original version of Windows NT. With Windows 2000, Microsoft has made substantial changes to NTFS to support the new features that administrators and users have been asking for. These new features include disk quotas—finally—and the ability to encrypt files and whole file systems at the physical disk level.

The new version of NTFS, known as NTFS version 5, is a logical extension of the original NTFS but is not completely compatible with it. If you're going to use NTFS in a dual-boot configuration with Windows NT 4 on the same machine as Windows 2000, you must install Windows NT 4 Service Pack 4 or later to permit your Windows 2000 NTFS partitions to be seen when booted into Windows NT 4. Also keep in mind that the quotas and encryption available in NTFS version 5 are not supported under Windows NT 4 and are not enforced or available in it.

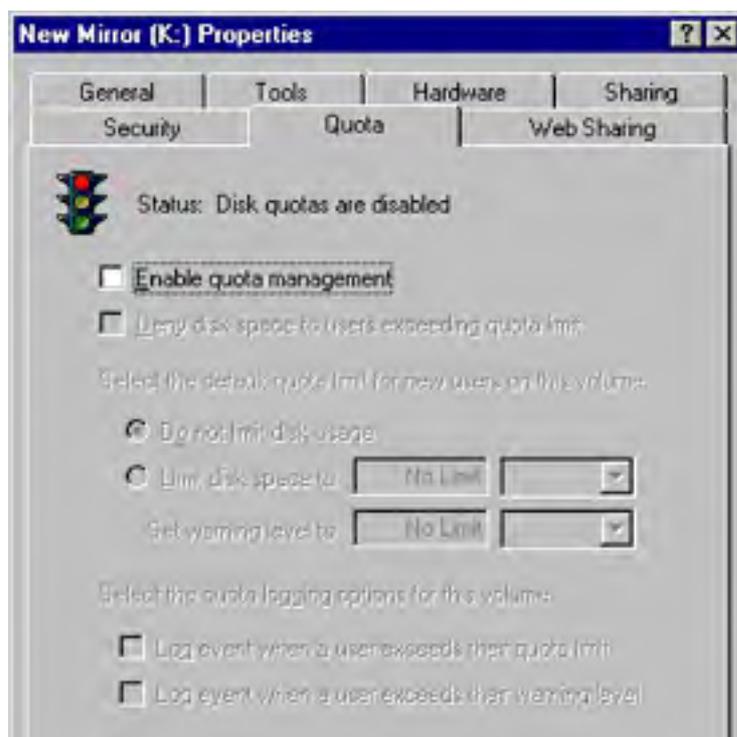

## Disk Quotas

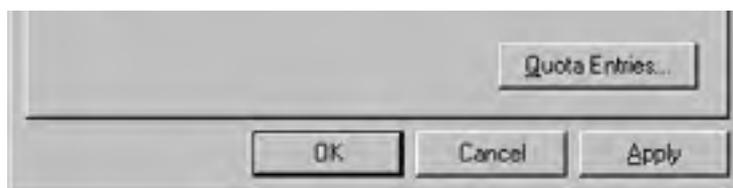

Probably the most annoying missing piece of the disk management equation for most Windows NT administrators has been the inability to manage and limit the disk resources of users without buying an add-on product. Windows 2000 finally addresses this rather glaring omission and provides for either advisory or absolute quotas on disk usage by user or group. However, each volume or partition is treated as a separate entity—there's no way to limit a user or group of users to a total amount of disk usage across the entire server or enterprise. (Sounds like an opportunity for a third-party solution, doesn't it?)

### Enabling Disk Quotas

By default, disk quotas are turned off for all partitions and volumes. You must enable them for each volume on which you want a quota. Quotas are available only for volumes that are assigned a drive letter. You can set different quotas for individual users or for groups of users, or you can set them the same for all users. Follow these steps to enable quotas on each volume where you want them:

1. Right-click the drive letter in Windows Explorer, and choose Properties from the shortcut menu.
2. Click the Quota tab to display the dialog box shown in Figure 15-32.

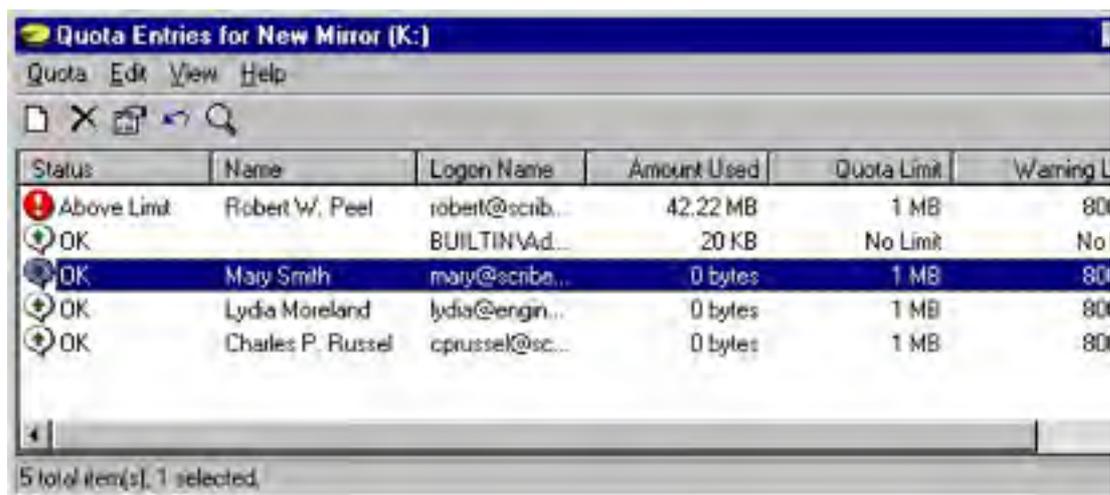

**Figure 15-32.** The Quota tab of the Properties dialog box for a logical drive.

3. Select the Enable Quota Management option.
4. Define the limits on disk usage for this drive letter. The available choices are:
  - **Deny Disk Space To Users Exceeding Quota Limit** When this option is selected, the quotas are enforced on all disk usage. When it is cleared, the limits are advisory only.
  - **Limit Disk Space To** Here you can specify the limits of disk space usage for new users on the volume.
  - **Set Warning Level To** This option indicates the limit at which users receive a warning message.
  - **Logging Options** You can choose to log when users exceed their warning limit or their usage limit, or you can leave these options blank if you don't want logging.
5. You'll see a confirmation message. If everything is correct, click OK to scan the drive and enable quotas.

### Setting Quota Entries for Users

There's one catch with quotas enabled as described in the previous procedure: they apply only to users. Administrators slip by without having quotas enforced unless you explicitly set them in a separate quota entry. To set quotas on administrators, or to tweak the quotas for individual users, you need to perform these additional steps:

1. In Windows Explorer, right-click the drive you want to set quota entries for and choose Properties from the shortcut menu. Click the Quota tab to display the dialog box shown previously in Figure 15-32.
2. Click Quota Entries to display the quota entries for the volume. You'll see the window shown in Figure 15-33. This window contains entries for everyone who has ever stored files on the volume, unless you have explicitly removed the entries for users who no longer store files there.

Status	Name	Logon Name	Amount Used	Quota Limit	Warning L
Above Limit	Robert W. Peel	robert@scrib...	42.22 MB	1 MB	80
OK	BUILTIN\Administrators	BUILTIN\Administrators	20 KB	No Limit	No
OK	Mary Smith	mary@scribe...	0 bytes	1 MB	80
OK	Lydia Moreland	lydia@engin...	0 bytes	1 MB	80
OK	Charles P. Russel	cprussel@sc...	0 bytes	1 MB	80

**Figure 15-33.** The Quota Entries window.

3. You can change the properties for any entry by double-clicking the entry, which displays the dialog box shown in Figure 15-34. The figure shows a user whose quota has been lowered so that he is now exceeding his disk space limit. He is unable to store any additional data on the volume until he is below the limit.

**Figure 15-34.** Quota settings and status for a user.

The Quota Entries window lets you sort by any of the columns to make it easy to quickly identify problem areas or to locate an individual entry. You can also use the Find function to locate a specific entry.

### **Real World**

#### **Avoid Individual Quotas**

Resist the temptation to fine-tune a disk's quotas for each individual. Giving in will lead to an administrative nightmare, especially because you then cannot manage quotas for the all-users audience, only for individual users. Make changes to the quotas for an individual only when there is a compelling reason to do so, and then keep careful records so that all administrators have ready access to the information.

### **Exporting and Importing Quotas**

If you have a complicated quota system set up so that some users get more space than others, implementing that system on a new volume can be a pain. However, Windows 2000 lets you export the quotas from one volume to another. If there isn't an entry for a user on the new volume yet, one is created. If a user already has a quota entry, you'll be asked if you want to overwrite it with the imported quota entry for that user (Figure 15-35). Avoid importing quota settings onto an existing drive unless you're changing your overall quotas across the entire server. Any customizations you've made on the current drive could be lost, and having to acknowledge each change that affects an existing user lends itself to mistakes. In addition, any special limits set for specific users on the source volume are applied to the target volume.

**Figure 15-35.** Confirmation message for overwriting a quota entry with an imported entry.

There are two ways to import quotas from one volume to another. You can open the Quota Entries window for the source volume, click Quota, and then choose Export to save the entry to a file. Next, open the Quota Entries window for the target volume and choose Import from the Quota menu. Or you can simply open both Quota Entries windows and drag the entries you want to import from the source window to the target window.

### Creating Quota Reports

You can use the Quota Entries window to create reports on disk usage. Select the accounts you want to include in the report and drag them into the reporting tool you'll be using. The supported formats include Rich Text Format, Comma Separated Value, CF\_UNICODETEXT, and CF\_TEXT. If you drag the entries into Microsoft Excel, for example, you'll get not only the entries but the column headings as well. This makes whipping out a disk usage report pretty trivial.

### Encrypting on the File System Level

Version 5 of NTFS adds the ability to encrypt individual files or entire subdirectories in a totally transparent way. To their creator, encrypted files look exactly like regular files—no changes to applications are required to use them. However, to anyone except the creator or encryptor, the files are unavailable, and even if someone did manage to gain access to them, they would be gibberish, as they're stored in encrypted form.

Encryption is simply an advanced attribute of the file, as compression is. However, a file cannot be both compressed and encrypted at the same time—the attributes are mutually exclusive. Encrypted files are available only to the encryptor, but the domain or machine recovery agent can recover them if necessary. Encrypted files can be backed up by normal backup procedures if the backup program is Windows 2000-aware. Files remain encrypted when backed up, and restored files retain their encryption.

Under normal circumstances, no user except the actual creator of an encrypted file has access to the file. Even a change of ownership does not remove the encryption. This prevents sensitive data, such as payroll, annual reviews, and so on, from being accessed by the wrong users, even those with administrative rights.

Encryption is available only on the NTFS version 5 file system. If you copy the file to a floppy disk or to any file system other than NTFS version 5, the file is no longer encrypted. This is true even of NTFS file systems on earlier versions of Windows NT.

When you encrypt a folder, all new files created in that folder are encrypted from that point forward. You can also elect to encrypt the current contents when you perform the encryption. Be warned, however: if you choose to encrypt the contents of a folder when it already contains files or subfolders, those files and subfolders are encrypted *for the user performing the encryption only*. This means that even files that are owned by another user are encrypted, and available for your use only.

When new files are created in an encrypted folder, the files are encrypted for use by the creator of the file, not the user who first enabled encryption on the folder. Unencrypted files in an encrypted folder can be used by all users who have security rights to use files in that folder, and the encryption status of the file does not change unless the filename itself is changed. Users can read, modify, and save the file without converting it to an encrypted file, but any change in the name of the file triggers an encryption, and the encryption makes the file available only to the person that triggers the encryption. To encrypt a file or folder, follow these steps:

1. In Windows Explorer, right-click the folder or files you want to encrypt, and choose Properties from the shortcut menu.
2. Click Advanced in the General tab to open the Advanced Attributes dialog box shown in Figure 15-36.

**Figure 15-36.** *The Advanced Attributes dialog box.*

3. Select the Encrypt Contents To Secure Data option, and click OK to return to the main Properties dialog box for the folder or file. Click OK or Apply to enable the encryption. If any files or subfolders are already in the folder, you're presented with the dialog box shown in Figure 1537.
4. If you choose Apply Changes To This Folder Only, all of the current files and subfolders in the folder remain unencrypted, but any new files and folders are encrypted by the creator as they are created. If you choose Apply Changes To This Folder, Subfolders And Files, all of the files and folders below this folder are encrypted so that only you can use them, regardless of the original creator or owner of the file.

**Figure 15-37.** *Choosing whether to encrypt the files already in a folder or just new files.*

5. Click OK and the encryption occurs.

## Summary

Windows 2000 Server provides the system administrator with a much richer set of disk management tools than any previous version of Windows. The addition of dynamic volumes has materially reduced the number of reboots required to manage disk resources. The administrator can now reconfigure arrays on the fly, adding disks and extending volumes to manage disk space without having to reboot for every change. When combined with hardware RAID controllers and hot-swap drives, these tools finally give the administrator the ability to manage a 24-hour, 7-day operation.

The features introduced in the new version of NTFS, including quotas and file system encryption, give administrators additional flexibility and options to control file system abuse and to protect sensitive data so that even administrators don't have inappropriate access to confidential information. And it is all done in a way that is transparent to the user.

The next chapter looks at clustering, a way to use more than one machine to improve the scalability and fault tolerance of your critical applications and services. Windows 2000 supports two distinct types of clustering—network load balancing and server clustering.

# Chapter 16

## **Using Clusters**

Microsoft Windows 2000 supports two clustering technologies: Network Load Balancing clusters and server clusters. These technologies can be used independently or combined to provide a highly available and highly scalable cluster. This chapter describes the two types of clustering supported by Windows 2000, their place in the enterprise, and their configuration and requirements.

## What Is a Cluster?

A *cluster* is a group of two or more computers functioning together to provide a common set of applications or services with a single apparent identity to clients. The computers are physically connected by hardware in the form of either a network or shared storage. The clustering software provides a common interface externally while managing the resources and load internally.

Windows Clustering provides the following benefits:

- **High availability** When a clustered application or service fails or a computer in the cluster fails, the cluster responds by restarting the application or service on another member of the cluster or by distributing the load from the failed server to the rest of the cluster.
- **Scalability** For cluster-aware applications, adding more machines to the cluster adds additional capabilities.
- **Manageability** Administrators can move applications, services, and data from computer to computer within the cluster, allowing them to manually balance loads and to offload machines scheduled for maintenance.

## Network Load Balancing Clusters

Network Load Balancing (NLB)—known as the Windows Load Balancing Service in Microsoft Windows NT 4—gives TCP/IP-based services and applications high availability and scalability by combining up to 32 servers running Windows 2000 Advanced Server in a single cluster. Client requests for applications and services provided by the cluster are distributed across the available servers in the cluster in a way that is transparent to the client.

If a server fails or is taken offline, the cluster is automatically reconfigured and the client connections redistributed across the remaining servers. If additional servers are added to the cluster, they are automatically recognized and the load is reconfigured and distributed.

## Server Clusters

Server clusters distribute the workload among the servers in a cluster, with each server running its own workload. Like other types of clusters, server clusters are scalable and highly available. In the event of a failure, applications and services that can be restarted, such as print queues and file services, are restarted transparently. Ownership of shared resources passes to the remaining servers. When the failed server becomes available again, the workload is automatically rebalanced.

Server clusters use shared disk drives to provide transparent access. They require specially certified hardware, but when properly set up and configured, they provide for extremely high availability with no single point of failure. Windows 2000 Advanced Server supports only two-node server clusters. Windows 2000 Datacenter Server supports up to four-node server clusters. Windows 2000 Server does not natively support clustering.

## **Cluster Scenarios**

In deciding whether and how to implement clustering, you first need to understand what problem is being solved and how best to solve it using the available technologies. Then you can make a business case for the particular solution or combination of solutions that best solves the particular problem. This section describes various scenarios and the type of clustering appropriate for each.

### **Intranet or Internet Functionality**

An intranet or Internet server is a prime candidate for an NLB cluster. By enabling an NLB cluster across multiple servers, you provide your site with both redundancy and increased capacity. If a server should fail, the load is distributed transparently among the remaining servers.

Each Web server in the cluster runs its own Web server and accesses only local Web pages. This version is "shared nothing" clustering—there are no shared disks and no shared applications or data, with the possible exception of a common back-end database. NLB clusters are an appropriate and relatively inexpensive way to achieve both redundancy and high availability for your Web site, whether internal or external. Clients that need access to the Web pages are distributed among the servers in the cluster according to the load at each server. What makes this work is that most Web pages change fairly infrequently, allowing manual updates of all Web servers with the same information when you need to make changes.

### **Mission-Critical Availability**

If your business absolutely, positively can't be run without a certain application, you need a highly reliable server to make sure that the application is always available. A server cluster is a good solution in this scenario, providing both high availability and scalability. With a server cluster, you group your critical applications into two groups, one group to a server. All the resources for each group are self-contained on the server, but if either server in the cluster fails, the other picks up the services and applications from the failed server, allowing for continuous availability of critical services and applications.

Server clusters require a substantially greater investment in hardware than NLB clusters. In addition, they aren't suitable for "shared nothing" clustering, because they use a shared disk array to keep resources in sync. When a server fails, the other server picks up the applications that had been running on the failed server. Because the disks are shared, the remaining server has access to the same set of data as the failed server, and thus there's no loss of functionality.

### **Integrated Windows Clustering**

As you can see from the previous example, Windows 2000's clustering model lends itself well to an integrated approach that can help maximize your investment in hardware and resources. An NLB cluster can distribute the load of an essentially static Web or other TCP/IP load, passing specific applications to another cluster, which in turn uses the resources of the server cluster that runs the mission-critical messaging and database servers.

## Requirements and Planning

Before you attempt to implement any form of clustering, you need to clearly understand the business reason for doing so. You also need to be aware of the costs and benefits of the implementation as well as the resource requirements for a successful implementation. Treat the implementation of a Windows 2000 cluster as you would any other major project. Clearly state the business case for the cluster, and get a commitment from all levels before you expend substantial resources on the project.

## Identifying and Addressing Goals

The first step in planning your cluster is to identify your goals for the implementation and the needs that using clusters will meet. This sounds obvious, but it is actually the part of the process that is most often overlooked. The implementation of any technology should always be first and foremost a business decision, not a technology decision. Creating and maintaining clusters is not a trivial task, and it requires both technological and financial resources. You'll have a hard time selling your project if you haven't clearly identified one or more needs that it will meet.

In identifying the needs to be met and the goals of your project, you need to be as objective as possible. Always keep in mind that what you might view as "cool" technology can look remarkably like scary, unproven gobbledygook to those in the organization who are less technically savvy than you are. This doesn't mean that those individuals won't support your project, but it does mean that you need to make the case for the project on a level that they can understand and identify with.

Start by clearly identifying the business goals that you're trying to accomplish. State the general goals, but provide enough detail to make the success of the project clearly measurable. Identify the specific gains you expect and how those gains will be measured. Be sure to clearly indicate how the needs you've identified are currently being met. This step is critical because it lets you point out both the costs of your suggested method and the risks associated with it.

## Identifying a Solution

Once you know the business needs you're trying to meet, you can identify some solutions. If you've clearly laid out your goals and objectives for the project, the technology that achieves those goals will be driven by those needs, not the other way around. This is also the time to use your best political judgment. You need to identify not only the best way to meet the business needs, but also how much you can realistically sell and implement in a single shot. If you think that ultimately you will need a fully integrated, three-tiered, multiple-cluster solution, you might want to build your plan around a phased approach that allows you to distribute the risks and costs over a broader period.

In addition, if you're proposing a clustering solution to the problem, spend some time and energy identifying methodologies that might be considered alternatives to clustering and clearly laying out the strengths and weaknesses of those alternatives. This effort will short-circuit objections and diversions as you build support for your project.

## Identifying and Addressing Risks

As you plan your schedule, be sure to identify the risks at each step of the process and plan solid fallback positions if problems arise. Selling the project is also much easier if it's clear that you've actually thought about the risks. For example, if your goal is to replace an existing manual methodology, have you left yourself a way to fall back to it if there are problems? Or are the two mutually incompatible? If you're replacing an existing client/server application with a clustered, Web-based, distributed, *n*-tiered application, have you made a clear roadmap for how you will make the transition from one to the other? What are the risks of that transition?

Spend some time identifying failure points in your project. If you're building a server cluster to provide 24-hour, 7-day access to your Microsoft Exchange messaging, have you identified redundant network connections to the cluster? It does little good to create a highly available server if the network connection to it is questionable.

## Making Checklists

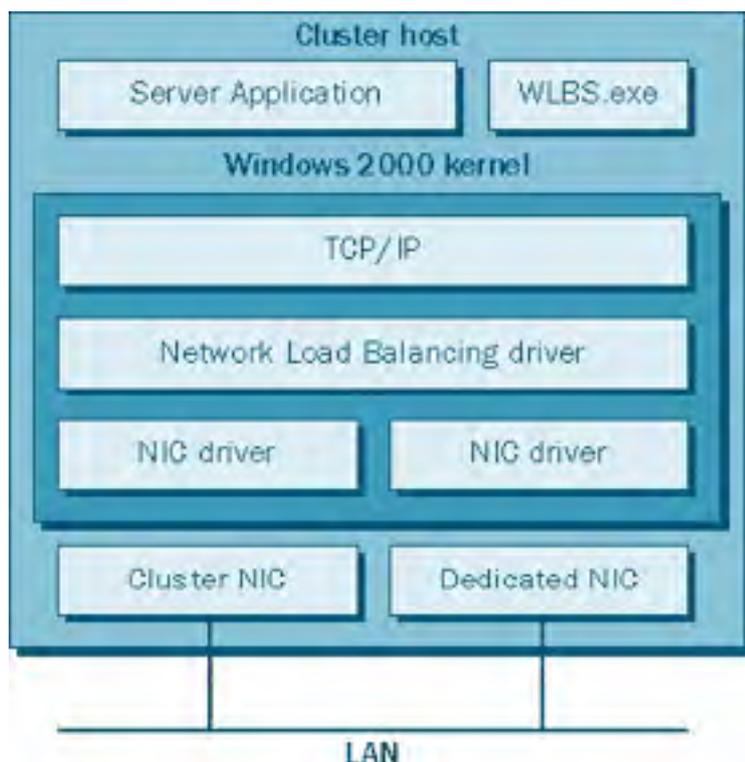

Take the time to identify all the possible pieces of your cluster implementation ahead of time. Use this to build a checklist of steps that you need to take and the dependencies at each point. At each major step, identify the hardware, software, knowledge, and resources required, and create a checklist of the prerequisites for that step. The time you spend planning your clustering implementation will easily be saved in the actual installation and implementation, and greatly reduces your risks of failure.

## Network Load Balancing Clusters

NLB provides a highly available and scalable solution for TCP/IP-based network applications such as a Web server or FTP server. By combining the resources of two or more servers into a single cluster, NLB can provide for redundancy of information and resources while servicing far more clients than a single server alone could handle.

### NLB Concepts

NLB is a Windows 2000 Networking driver. It acts independently of the TCP/IP networking stack and is transparent to that stack. The NLB driver sits between the TCP/IP stack and the network card drivers, with the Windows Load Balancing Service (Wlbs.exe)—the necessary NLB control program—running on top, alongside the actual server application (Figure 16-1).

**Figure 16-1.** NLB as a network driver.

Optimally, each server participating in an NLB cluster should have two network interface cards (NICs), although this is not an absolute requirement. Communications and management are materially improved with two NICs, however, especially in unicast mode. (Unicast mode, as opposed to multicast mode, allows each NIC to present only a single address to the network.) Overall network throughput is also improved, as the second network adapter is used to handle host-to-host traffic within the cluster.

NLB supports up to 32 computers per cluster. Each server application can be balanced across the entire cluster or can be primarily hosted by a single computer in the cluster, with another computer in the cluster providing directed failover redundancy. For fully distributed applications, the failure of any single host causes the load currently being serviced by that host to be transferred to the remaining hosts. When the failed server comes back online, the load among the other hosts is redistributed to include the restored server.

NLB is supported only by Windows 2000 Advanced Server and requires that TCP/IP be installed. It works over Fiber Distributed Data Interface-based or Ethernet-based networks from 10 megabits per second (Mbps) to 1 gigabit per second (Gbps). It uses from 250 KB to 4 MB of RAM and roughly 1 MB of disk space.

### Choosing an NLB Cluster Model

A host in an NLB cluster can use one of four models, each with its own merits and drawbacks. These models are

1. Single network adapter in unicast mode
2. Single network adapter in multicast mode
3. Multiple network adapters in unicast mode
4. Multiple network adapters in multicast mode

The choice of model for a given host and cluster varies depending on the circumstances, requirements, and limitations imposed on the design of the cluster. The sections that follow provide details on each of the models.

NLB in Windows 2000 does not support a mixed unicast mode and multicast mode environment. All hosts in the cluster must be either multicast or unicast. Some hosts, however, can have a single adapter, whereas others have multiple adapters. In addition, NetBIOS cannot be supported in a single-adapter-only configuration.

### **Single Network Adapter in Unicast Mode**

A single network adapter running in unicast mode is in some ways the easiest type of host to set up, and with only a single adapter, is cheaper than one with multiple network adapters. It does, however, impose significant limitations:

- Overall network performance is reduced.
- Ordinary communications among cluster hosts are disabled.
- NetBIOS support is not available within the cluster.

### **Single Network Adapter in Multicast Mode**

Using multicast mode in clusters in which one or more hosts have a single network adapter means that normal communications are possible between hosts within the cluster. This capability overcomes one of the most awkward of the limitations of the single adapter in unicast mode. However, there are still the following significant disadvantages:

- Overall network performance is reduced.
- Some routers do not support multicast MAC addresses.
- NetBIOS support is not available within the cluster.

### **Multiple Network Adapters in Unicast Mode**

Using multiple network adapters in unicast mode is generally the preferred configuration. It does impose the cost of a second network adapter per host, but given the relatively low cost of network adapters, including the per-port cost of hubs, this is a relatively minor price to pay for the resulting advantages:

- No limitations are imposed on ordinary network communications among cluster hosts.
- Ordinary NetBIOS support is available through the first configured adapter.
- No bottlenecks occur due to a single network adapter.
- The model works with all routers.

### **Multiple Network Adapters in Multicast Mode**

If you are forced by circumstances to use some hosts within a cluster that have only a single network adapter and you must be able to maintain normal network communications among the hosts in the cluster, you must run all of the hosts in multicast mode, even those with multiple adapters, because you can't run some hosts in unicast mode and some in multicast mode. This limitation could cause a problem with some routers, but otherwise it is a viable solution.

## Planning the Capacity of an NLB Cluster

In general, an NLB cluster should contain as many hosts as needed to handle the client load for the applications being run in the cluster. The exception to this would be cases in which the sole function of the cluster is to provide failover tolerance for a critical TCP/IP application—that is, when a single server can handle the load and the second server is there simply for fault tolerance.

The maximum number of hosts in a given cluster is 32. If your application requires more than 32 hosts, you can set up multiple clusters, using round-robin DNS to distribute the load among the clusters. The effective limitation, however, is likely to be the network saturation point. If you do run multiple clusters in a subnet, you should host each on its own network switch to minimize the network bottleneck.

Although fewer and more powerful servers may look cost-effective for a given application, you should consider how the failure of a server will affect the application and the remaining servers. If the remaining servers can't handle the resulting load, you could potentially have a cascading failure, bringing down the entire application. Always provide sufficient server capacity within the cluster to handle the expected load when a single server is down. Also consider ways to limit the load to the application when there has been a failure.

When determining the expected cluster capacity, you also need to consider the application being clustered and the type of load it imposes on the cluster. Plan your servers according to where the limitation and stress will be greatest. File serving applications are I/O intensive, e-mail applications such as Microsoft Exchange are very CPU intensive, and database applications tend to be RAM hogs as well as a drain on the disk I/O subsystem.

## Providing Fault Tolerance

Although NLB clusters provide overall fault tolerance for your TCP/IP application, they are not a complete solution for all possible failures. Because they are "shared nothing" clusters, there is always some data lag between servers. For fully fault-tolerant, high-availability clustering that can run any application, you probably want to use server clustering. This provides the greatest level of fault tolerance.

One thing you can do to improve the overall fault tolerance of the cluster is to make the hard drives fault tolerant. Both hardware and software RAID solutions are viable options for improving the fault tolerance of an NLB cluster. For more on RAID and fault tolerance in general, see Chapters 15 and 36.

## Optimizing an NLB Cluster

Optimizing an NLB cluster calls for clearly understanding where the bottleneck in your clustered application is likely to be. An application that is essentially a file and print server, for example, tends to be a heavy user of both disk I/O and network bandwidth. Microsoft Exchange, on the other hand, puts a heavy load on the CPU, and to a somewhat lesser extent, on RAM. Focus your optimization efforts on the bottleneck and you'll get the most gain for your effort.

One area that can be a problem is running an NLB cluster in a switched environment without planning your network load carefully. If each of the servers in your cluster is connected to a different switched port, you can easily end up flooding your switched ports because every client request to the cluster passes through all switched ports to which a member of the cluster is attached. Running in multicast mode can exacerbate the problem. If you're running in a switched environment, we suggest that you follow these guidelines:

1. Use a top-quality hub to connect the servers in the cluster to one another, and uplink the hub to a single switched port.
2. Use unicast mode. If you enabled multicast mode during setup, change it. (You'll need to change this on all servers in the cluster.)
3. Edit the registry on each of the hosts in the cluster, changing the following key from the default parameter of 1 to 0:

```
HKEY_LOCAL_MACHINE\System\CurrentControlSet\Services\WLBS  
\Parameters\MaskSourceMAC
```

This change allows the switch to tell which MAC address is really the source of traffic, helping it to do its switching job properly. You'll need to restart the servers after making this change.

## Server Clusters

A server cluster is a group of independent nodes that work together as a single system. They share a common cluster database that enables recovery in the event of the failure of any node. A server cluster uses a jointly connected resource, generally a disk array on a shared SCSI bus or Fibre Channel, which is available to all nodes in the cluster. Each Windows 2000 Advanced Server node in the cluster must have access to the array, and each node in the cluster must be able to communicate at all times with the other nodes in the cluster.

Windows 2000 supports server clusters only on machines running Advanced Server or Datacenter Server. Additionally, as shipped, Advanced Server supports only two-node clusters using a shared disk resource, through either Fibre Channel or a shared SCSI bus. Both nodes of the cluster must be running TCP/IP for networking and should have at least one dedicated network interconnect available. To avoid a single point of failure, a second network interconnect is highly recommended.

## Server Cluster Concepts

To understand and implement server clusters, it is important to understand several new concepts and their ramifications, as well as specialized meanings for certain terms.

### Networks (Interconnects)

A cluster has two distinct types of networks: the *private network* that's used to maintain communications between nodes in the cluster and the *public network* that clients of the cluster use to connect to the services of the cluster. Each of these networks can share the same network card and physical network cabling, but it is a good practice to keep them separate. Having them separate gives you an alternate path for interconnection between the nodes of the cluster. Because the interconnect between the nodes of a cluster is a potential single point of failure, it should always be redundant. The cluster service uses all available networks, both private and public, to maintain communications between nodes.

#### Real World

##### Always Have at Least Two Interconnects

If you have only a single method of communication in a cluster, the failure of that interconnect has a 50 percent chance of causing the entire cluster to become unavailable to its clients—hardly why you opted for a highly available technology like clustering, certainly. Here's what happens when the two nodes of a cluster can no longer communicate. When the communications fail, each node recognizes that it is no longer able to talk to the other node of the cluster and decides that the other node in the cluster has failed. It therefore attempts to take over the functions of the cluster by itself. The nodes are "partitioned" and as each node attempts to enable itself to take over the functions of the entire cluster, it starts by trying to gain control of the quorum resource (discussed later in the section entitled [Types of Resources](#)) and thus the shared disk on which the quorum resides. Whichever node is unable to gain control of the quorum resource is automatically shut down, while the other node attempts to maintain the processes of the cluster. However, because either node has an equal chance of gaining control of the quorum resource, there's a 50 percent chance that the node with a failed network card wins, leaving all the services of the cluster unavailable.

## Nodes

A *node* is a member of a server cluster. It must be running Windows 2000 Advanced Server and Windows Clustering. It must also be running TCP/IP, must be connected to the shared cluster storage device, and must have at least one network interconnect to the other nodes in the cluster.

## Groups

*Groups* are the units of failover. Each group contains one or more resources. Should any of the

resources within the group fail, all fail over together according to the failover policy defined for the group. A group can be owned by only one node at a time. All resources within the group run on the same node. If a resource within the group fails and must be moved to an alternate node, all other resources in that group must be moved as well. When the cause of failure on the originating node is resolved, the group falls back to its original location, based on the fallback policy for the group.

## Resources

Any physical or logical entity that can be brought online or offline can be a server cluster resource. It must be able to be owned by only one node at a time and will be managed as part of the cluster. The *quorum resource* is a special resource. It is the repository of the configuration data of the cluster and the recovery logs that allow recovery of the cluster in the event of a failure. The quorum resource must be able to be controlled by a single node, it must provide physical storage for the recovery logs and cluster database, and it must use the NTFS file system. The only resource type supported for a quorum resource is the Physical Disk resource as shipped with Windows 2000 (this and other resource types are described in the next section), but it is possible that other quorum resource types will be developed and certified by third parties.

## Types of Resources

Windows 2000 Advanced Server includes several different resource types; the sections that follow examine each of these resource types and the role they play in a server cluster. The available cluster resource types are

- Physical Disk
- DHCP
- WINS
- Print Spooler
- File Share
- Internet Protocol
- Network Name
- Generic Application
- Generic Service

### Physical Disk

The Physical Disk resource type is the central resource type required as a minimum for all server clusters. It is used for the quorum resource that controls what node in the cluster is in control of all other resources. The Physical Disk resource type is used to manage a shared cluster storage device. It has the same drive letter on all cluster servers.

### DHCP and WINS

The DHCP service provides IP addresses and various other TCP/IP settings to clients, and the WINS service provides dynamic resolution of NetBIOS names to IP addresses. Both can be run as a resource of the cluster, providing for high availability of these critical services to network clients. For failover to work correctly, the DHCP and WINS databases must reside on the shared cluster storage.

### Print Spooler

The Print Spooler resource type lets you cluster print services, making them fault tolerant and saving a tremendous number of help desk calls when the print server fails. It also prevents the problem of people simply clicking the Print button over and over when there's a problem, resulting in a very long and repetitious print queue.

To be clustered, a printer must be connected to the server through the network. Obviously, you can't connect the printer to a local port such as a parallel or USB port directly attached to one of the nodes of the cluster. The client can address the printer either by name or by IP address, just as it would a nonclustered printer on the network.

In the event of a failover, all jobs that are currently spooled to the printer are restarted. Jobs that are in the process of spooling from the client are discarded.

## File Share

You can use a server cluster to provide a high-availability file server using the File Share resource type. The File Share resource type lets you manage your shared file systems in three different ways:

- As a standard file share with only the top-level folder visible as a share name.
- As shared subfolders, where the top-level folder and each of its immediate subfolders are shared with separate names. This makes it extremely easy to manage users' home directories, for example.
- As a stand-alone Distributed file system (Dfs) root. You cannot, however, use a cluster server File Share resource as part of a fault-tolerant Dfs root.

## Internet Protocol and Network Name

The Internet Protocol resource type is used to manage the IP addresses of the cluster. When an Internet Protocol resource is combined with a Network Name resource and one or more applications, you can create a *virtual server*. Virtual servers allow clients to continue to use the same name to access the cluster even after a failover has occurred. No client-side management is required, because, from the client perspective, the virtual server is unchanged.

## Generic Application

The Generic Application resource type allows you to manage regular, cluster-unaware applications in the cluster. A cluster-unaware application that is to be used in a cluster must, at a minimum,

- Be able to store its data in a configurable location
- Use TCP/IP to connect to clients
- Have clients that can reconnect in the event of an intermittent network failure

When you install a generic, cluster-unaware application, you have two choices: you can install it onto the shared cluster storage, or you can install it individually on each node of the cluster. The first method is certainly easier because you install the application only once for the whole cluster. However, if you use this method you won't be able to perform a rolling upgrade of the application, because it appears only once. (A rolling upgrade is an upgrade of the application in which the workload is moved to one server while the application on the other server is upgraded and then the roles are reversed to upgrade the first server.)

To give yourself the ability to perform rolling upgrades on the application, you need to install a copy onto each node of the cluster. You need to place it in the same folder and path on each node. This method uses more disk space than installing onto the shared cluster storage, but it permits you to perform rolling upgrades, upgrading each node of the cluster separately.

## Generic Service

Finally, server clusters support one additional type of resource—the Generic Service resource. This is the most basic resource type, but it does allow you to manage your Windows 2000 services as a cluster resource.

## Defining Failover and Failback

Windows 2000 server clusters allow you to define the failover and failback policies for each group or virtual server. This ability enables you to tune the exact behavior of each application or group of applications to balance the need for high availability against the overall resources available to the cluster in a failure situation. Also, when the failed node becomes available again, your failback policy determines whether the failed resource is immediately returned to the restored node, is maintained at the failed-over node, or migrates back to the restored node at some predetermined point in the future. These options allow you to plan for the disruption caused when a shift in node ownership occurs, limiting the impact by timing it for off-hours.

## Configuring a Server Cluster

When planning your server cluster, you'll need to think ahead to what your goal is for the cluster and what you can reasonably expect from it. Server clusters provide for extremely high availability and resource load balancing, but you need to make sure your hardware, applications, and policies are appropriate.

### **High Availability with Load Balancing**

The most common cluster configuration is static load balancing. In this scenario, the cluster is configured so that some applications or resources are normally hosted on one node while others are normally hosted on another node. If one node fails, the applications or resources on the failed node fail over to the other node, providing high availability of your resources in the event of failure and balancing the load across the cluster during normal operation. The limitation of this configuration is that in the event of a failure, your applications will all attempt to run on a single node, and you will need to implement procedures either to limit the load by reducing performance or availability, or to not provide some less-critical services during a failure. Another possibility for managing the reduced load-carrying capacity during a failure scenario is to have "at risk" users and applications that can be shut off or "shed" during periods of reduced capacity, much like power companies do during peak load periods when their capacity is exceeded.

It's important to quickly take steps to manage load during periods of failure when you configure your cluster for static load balancing. Failure to shed load can lead to catastrophic failure, or such extreme slowdown as to simulate it, and then no one will have access to the resources and applications of the cluster.

### **Maximum Availability Without Load Balancing**

The cluster configuration with the highest availability and reliability for critical applications is to run one node of the cluster as a "hot spare." This scenario requires that each server node be sufficiently powerful to run the entire load of the cluster by itself. You then configure all the applications and resources to run on a single node, with the other node sitting idle. In the event of failure on the primary node, the applications fail over to the idle node and continue with full capability. After the primary node is back online it can continue as the new hot spare, or you can force the applications back to the primary node, depending on the needs of your environment.

This scenario provides full and complete fault tolerance in the event of the failure of one of the nodes, but it has the greatest hardware cost. Use this clustering configuration only where your applications or resources are critical and you can afford the extra hardware expense far more than any limits to the load in case of a failure.

### **Partial Failover (Load Shedding)**

Another cluster configuration is called "load shedding" or partial failover. In this configuration, critical applications and resources are designed to fail over to the other node in the cluster in the event of a failure, but noncritical applications and resources will be unavailable until the cluster is back to full functionality. The critical resources and applications are thus protected in a failure situation but noncritical ones simply run as though they were on a stand-alone server.

In this configuration, you might, depending on capacity and load conditions, have to configure the noncritical applications and resources on *both* nodes to be unavailable in the event of a failure on either node. This allows you to maintain a high level of performance and availability of your most critical applications while shedding the load from less critical applications and services when necessary. This strategy can be very effective when you must, for example, service certain critical applications or users under any and all circumstances but can allow other applications and users with a lower priority to temporarily fail.

### **Virtual Server Only**

You can create a server cluster that has only a single node, which allows you to take advantage of the virtual server concept to simplify the management and look of the resources on your network. Having a single node doesn't give you any additional protection against failure or any additional load balancing over that provided by simply running a single stand-alone server, but it allows you to easily manage groups of resources as a virtual server.

This scenario is an effective way to stage an implementation. You create the initial virtual server, putting your most important resources on it in a limited fashion. Then, when you're ready, you add another node to the server cluster and define your failover and failback policies, giving you a high-availability environment with minimal disruption to your user community. In this scenario, you can space hardware purchases over a longer period while providing services in a controlled test environment.

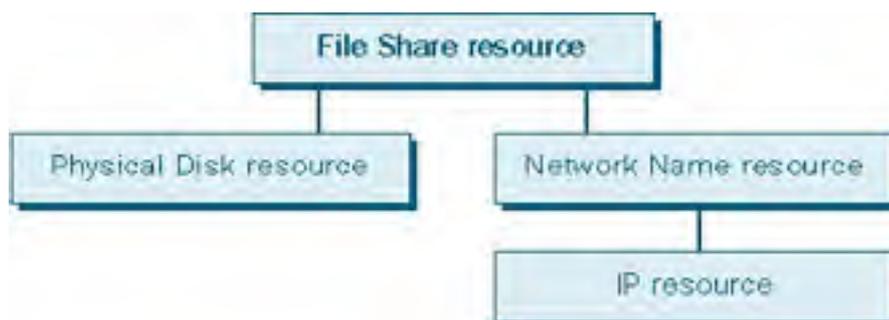

## Planning the Capacity of a Server Cluster

Capacity planning for a server cluster can be a complicated process. You need to thoroughly understand the applications that will be running on your cluster and make some hard decisions about exactly which applications you can live without and which ones must be maintained under all circumstances. You'll also need a clear understanding of the interdependencies of the resources and applications you'll be supporting.

The first step is to quantify your groups or virtual servers. Make a comprehensive list of all applications in your environment, and then determine which ones need to fail over and which ones can be allowed to fail but still should be run on a virtual server.

Next determine the dependencies of these applications and what resources they need to function. This information allows you to group dependent applications and resources in the same group or virtual server. Keep in mind that a resource can't span groups, so if multiple applications depend on a resource, such as a Web server, they must all reside in the same group or on the same virtual server as the Web server and thus share the same failover and fallback policies.

A useful mechanism for getting a handle on your dependencies is to list all your applications and resources and draw a dependency tree for each major application or resource. This helps you visualize not only the resources that your application is directly dependent on, but also the second-hand and third-hand dependencies that might not be obvious at first glance. For example, a cluster that is used as a high-availability file server uses the File Share resource. And it makes perfect sense that this File Share resource is dependent on the Physical Disk resource. It's also dependent on the Network Name resource. However, the Network Name resource is dependent on the IP resource. Thus, although the File Share resource isn't directly dependent on the IP resource, when you draw the dependency tree you will see that they all need to reside in the same group or on the same virtual server. Figure 16-2 illustrates this dependency tree.

**Figure 16-2.** *The dependency tree for a File Share resource.*

Finally, as you're determining your cluster capacity, you need to plan for the effect of a failover. Each server must have sufficient capacity to handle the additional load imposed on it when a node fails and it is required to run the applications or resources that were owned by the failed node.

The disk capacity for the shared cluster storage must be sufficient to handle all the applications that will be running in the cluster as well as to provide the storage that the cluster itself requires for the quorum resource. Be sure to provide enough RAM and CPU capacity on each node of the cluster so that the failure of one node won't overload the other node to the point that it too fails. This possibility can also be managed to some extent by determining your real service requirements for different applications and user communities and reducing the performance or capacity of those that are less essential during a failure. However, such planned load shedding might not be sufficient and frequently takes a significant amount of time to be accomplished, so give yourself some margin to handle that initial surge during failover.

## **Summary**

Windows 2000 Advanced Server provides two clustering models: Network Load Balancing clusters (formerly known as the Windows Load Balancing Service) and server clusters. Clusters provide a highly available and scalable environment. Network Load Balancing clusters use standard hardware to distribute TCP/IP applications across a cluster. Server clusters use specialized shared disk resources to provide failover and static load balancing for a variety of applications. The next chapter covers configuring your storage as well as planning for fault tolerance and flexibility in managing your storage needs.

# Chapter 17

## **Configuring Storage**

Although many books combine file sharing and removable storage with the discussion of local storage management, Microsoft Windows 2000 provides enough new functionality to warrant a whole chapter to cover these subjects separately.

In Windows 2000, both file sharing and removable storage have become simpler for the end user. Although the associated administrative chores have been streamlined, file sharing and removable storage are now more complex to administer because the capabilities of once-simple technologies have grown.

This chapter covers the following advanced storage tools: the Distributed file system, Removable Storage, and Remote Storage. The chapter also explains how to administer shared folders on a corporate network or on the Internet.

## The Distributed File System

One of the problems with file sharing and networks is that users often have difficulty finding the files on the network that they need to access. If you have a single file server on your network, this problem might be inconsequential. However, when you start adding multiple file servers in multiple locations, helping users find the appropriate shares can become a full-time job.

The Distributed file system (Dfs) was designed to help alleviate this dilemma while also providing such benefits as load balancing, additional fault tolerance, and conservation of intrasite network bandwidth. Dfs achieves these goals by hiding the underlying structure of file shares inside a virtual folder structure such that users see a single contiguous folder structure, which in reality might consist of folders residing on a dozen different servers scattered across your organization. To help you make the most of Dfs, the following sections explain its advantages, define its concepts, outline its structure, and then show you how to set up Dfs and administer it.

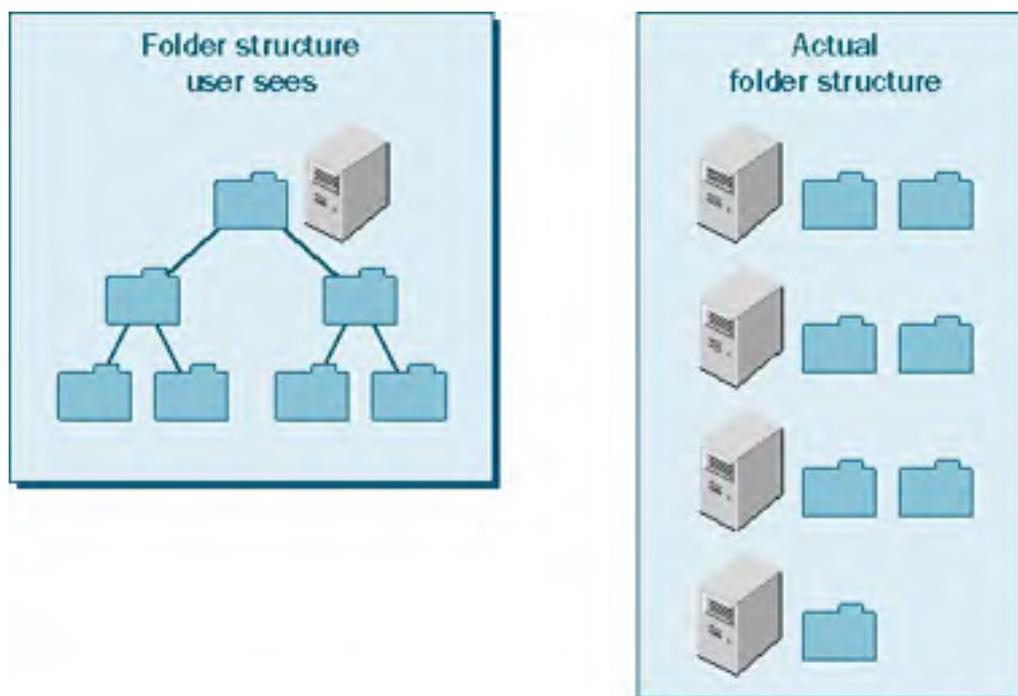

You can download Dfs version 4.x to use in Microsoft Windows NT 4. However, this version is considered beta software. Dfs version 5, which is included with Windows 2000, works much better and has considerably more functionality than earlier versions.

### Advantages

The principal advantage of Dfs is its single point of access to all network shares. Another benefit is that it allows you to organize file shares and to manage increased availability and fault tolerance as well as load-balancing functionality. In addition, security is easy with Dfs. The next sections elaborate on these advantages and why you might want to use Dfs on your network.

#### One Point of Access for All Network Files

Dfs makes it easier for users to find and access the file shares they need. Without Dfs, users often must connect to a number of different shares on multiple file servers to obtain the files they need. Unless the users know which servers and file shares to look in, they might not find the files at all. Dfs permits the creation of a virtual, hierarchically organized collection of file shares so that users can simply connect to a single server (the host server for the Dfs structure) and access all important shared folders, even though the folders are actually stored on multiple servers, as shown in Figure 17-1.

**Figure 17-1.** The folder structure a user sees when using Dfs, and the actual folder structure.

Unfortunately, the current implementation of Dfs in Windows 2000 doesn't provide enough flexibility when creating a virtual folder hierarchy because *midlevel junctions*—Dfs links from a folder other than the Dfs root—are unsupported. See the section entitled [Structure and Topology](#), later in this chapter, for more information on this limitation (Microsoft Windows .NET Server is expected to remove this limitation by allowing multiple Dfs roots per server).

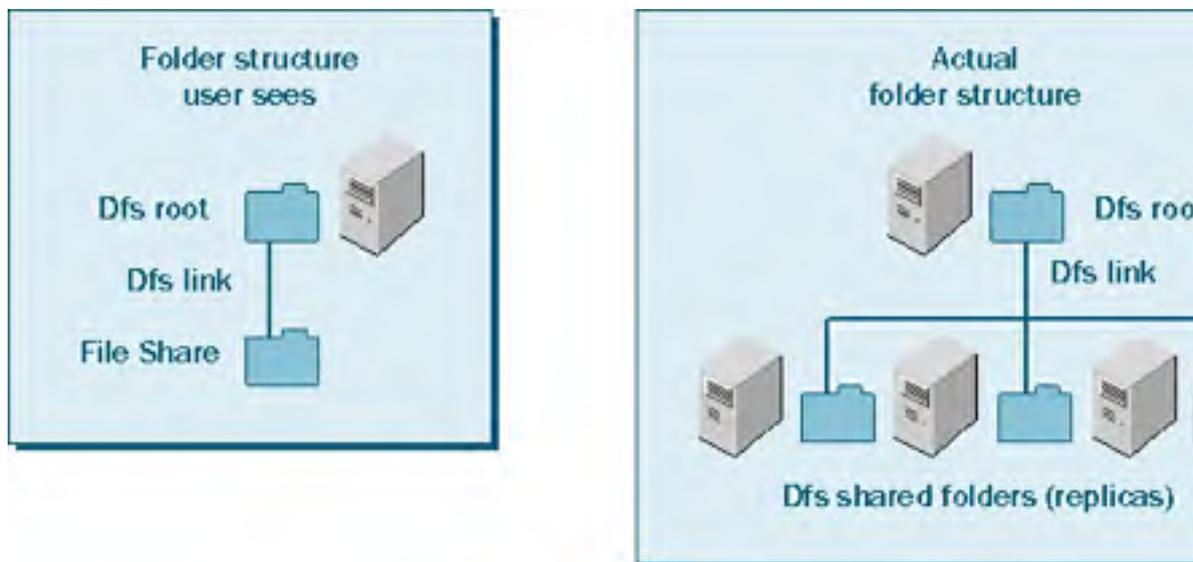

## High Availability and Better Performance

Dfs offers better availability and performance than your garden-variety shared folder. It accomplishes this in three ways: by hiding the underlying folder structure from users, by leveraging Active Directory service for replication and site optimization, and by using replicas for load balancing.

First, Dfs shields the actual file shares from users. Thus, users navigate the Dfs folder structure oblivious to where the files they access are coming from. This permits things like taking a server offline for maintenance without taking any shares offline: simply change the affected Dfs links to point to another server with a copy of the folder shares and no one will be the wiser (except you, of course).

If your intranet Web site makes use of shared folders on the network (instead of residing on the Web server itself), create your Web site in a shared folder, create a Dfs link to the shared folder, and configure Internet Information Services (IIS) to use the Dfs link to the folder for the Web site. If you need to take down the server that is storing the shared folder, just change the Dfs link to point to a copy of the shared folder on another server—no hyperlinks are broken by doing this.

Second, domain-based Dfs roots automatically make use of Active Directory to replicate the Dfs topology and can also use file replication service (FRS) to replicate the actual Dfs root, or individual shared folders, as shown in Figure 17-2. This provides fault tolerance and automatically synchronizes the Dfs root and individual shared folders, permitting access to up-to-date content even if a server goes down.

**Figure 17-2.** The folder structure a user sees when using Dfs and load balancing, and the actual folder structure.

Finally, setting up replication for the Dfs root, shared folders, or both also provides a performance boost to clients by utilizing load balancing and site awareness: clients connect randomly to a root target and shared folder target in their local site, spreading the load over however many servers in the site are set up to replicate the Dfs root or shared folders (targets and root targets are the individual servers set up to replicate shared folders and Dfs roots).

## Security

Another advantage to Dfs is that it doesn't add any complexity to security. You set the permissions for the Dfs root—who can access and modify the Dfs structure—but all other security is handled by the NTFS file system. This arrangement makes sense because Dfs provides only a virtual structure to the existing set of file shares. The same security settings that apply to accessing file shares directly apply to accessing the file shares using the Dfs tree.

## Concepts and Terminology

Because Dfs is such a new technology to Windows, a brief primer on the most important concepts and terms is in order. The next sections cover the Dfs client and server components and consider Dfs on stand-alone servers as well as servers belonging to a Windows 2000 domain. Then you'll learn how a Dfs structure is created and what components make up the Dfs topology.

### Dfs Clients

To access the Dfs folder structure, you need a Dfs client. Table 17-1 shows the type of Dfs client support that is provided by various operating systems. Note that clients that don't have a Dfs client installed can't access the Dfs tree and gain the benefits of Dfs; however, they *can* access the file shares just as they would if Dfs weren't set up on the network. In terms of support for Dfs, if you're running an operating system that doesn't include "Microsoft" in the title, you're out of luck for now.

**Table 17-1.** *Operating system support for Dfs access*

Operating System	DFS Client Support
Non-Microsoft, Macintosh, Unix, OS/2	None
MS-DOS	None
Windows 3.x	None
Windows 95	Downloadable client for Dfs 4.x and 5
Windows 98/98 Second Edition	Dfs 4.x and 5 stand-alone client included, Dfs 5 domain-based client downloadable
Windows NT 4 with Service Pack 3	Dfs 4.x and 5 stand-alone client included, Dfs 5 domain-based client downloadable
Windows 2000, Windows XP	Full support built in

Use Windows 2000 or Microsoft Windows XP for client access to Dfs. Although earlier Microsoft operating systems can work, they have more problems with Dfs than do the newer Microsoft operating systems.

### Dfs Servers

Any Windows 2000 server can host a Dfs root, either in domain-based mode (if the server belongs to a domain) or stand-alone mode (if the server is in a workgroup). Windows NT 4 Server with Service Pack 3 or later and some varieties of UNIX running Samba can also host Dfs roots, but only the stand-alone variety.

Any computer using an operating system that can be resolved by a Windows server using a Universal Naming Convention (UNC) path can contribute file shares to a Dfs tree, including Microsoft Windows 98, Novell NetWare, UNIX, and Mac OS X (keep in mind that users need adequate permissions on a share to be able to use it, and this applies to UNIX and NetWare shares as well).

To use the folder synchronization feature of Dfs to keep two file shares identical, the Dfs root needs to be domain based and the file shares need to be hosted on NTFS partitions on a domain controller (which is fine, because using FAT partitions for file shares is kind of like climbing flagpoles during thunderstorms—not a good idea).

### Dfs In and Out of Domains

Dfs comes in two flavors: stand-alone and domain based. Those astute readers who figured out that these two variations depend on whether the server hosting the Dfs root is a stand-alone server or a server belonging to a Windows domain can take a free coffee break.

Stand-alone Dfs can't use Active Directory, with the net result that stand-alone Dfs roots can't perform automatic replication of targets (shared folders), nor can they replicate Dfs roots (root targets) in any way. Stand-alone Dfs roots can be hosted on any Windows server, and even though they don't make use of Active Directory, they can be hosted on servers belonging to Active Directory domains.

Domain-based Dfs roots differ from stand-alone Dfs in a couple of ways. First, domain-based Dfs roots predictably must be hosted on a member server or domain controller of an Active Directory domain. Second, domain-based Dfs roots automatically publish the Dfs topology in Active Directory. This provides fault tolerance and network performance optimization by directing clients to the nearest target, as discussed in the next section. Active Directory also allows domain-based Dfs to automatically synchronize targets and root targets.

Domain-based Dfs roots are limited to 5000 links, whereas stand-alone Dfs roots can host 10,000 links. To support more than 5000 links, use a stand-alone Dfs root (which can be created even on member servers and domain controllers). To support more than 10,000 links, use multiple stand-alone Dfs servers.

## Using Dfs Without NetBIOS or WINS

Dfs relies on NetBIOS to resolve share names. If your network has NetBIOS over TCP/IP disabled, or has eliminated WINS (you lucky dog), you'll need to enable fully qualified Dfs names in the registry of each Dfs server *before* creating the Dfs namespace (note that you shouldn't perform this procedure unless you don't use NetBIOS addressing on your network).

To do so, follow these steps on every server that will host a Dfs root:

1. Open the Registry Editor by choosing Run from the Start menu, typing *regedit*, and then clicking OK.
2. Open the following registry key:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Services\DFS
```

3. Change the DFSDnsConfig value to have the value data of 1 (0 disables fully qualified name resolution). If the value doesn't exist, create it using the following information:

Value Name: DfsDnsConfig

Data Type: REG\_DWORD

Value Data: 1

## Structure and Topology

Although Dfs mimics a normal file system, the terminology it uses is different, and there are some unique wrinkles to understand. The following sections talk about Dfs roots, which are analogous to drives in a normal file system; Dfs links, which are analogous to folders; targets (picture a RAID volume); and the creation of hierarchies in Dfs, similar to creating a folder tree.

### Dfs Roots

The structure of a Dfs tree begins with a Dfs root, similar to the way the Windows file system starts with a drive. The *Dfs root* is the shared folder that serves as the root for a particular Dfs tree. Because Dfs is only a virtual file system, the Dfs root can be any shared folder, although it really should be on an NTFS partition. The Dfs root can contain normal files and subfolders, although you can't create links from subfolders, so be careful when designing your folder structure (more on this later). The server that stores the Dfs root is called the *host server*.

Windows NT 4 and Windows 2000 servers only support one Dfs root per server, making it difficult to create hierarchies of file shares in Dfs. Windows .NET servers don't have this limitation.

## Links

By itself, a Dfs root is nothing more than just another file share. The beauty of Dfs is its ability to link to other file shares, called *Dfs links*, which appear as subfolders of the Dfs root. When a Dfs client opens a Dfs link (which appears as a normal subfolder), they seamlessly open the linked file share. Whether it's a different folder on the same server or a file share on a server in an entirely different department, users are never aware that the folder they opened is anything but a normal subfolder of the Dfs root.

## Replicas (Targets)

Dfs links have a really cool feature: they don't have to link to just one folder. Instead, a Dfs link can link to a maximum of 32 identical folders, called *replicas* or *shared folders* (or *targets* in Windows .NET Server). The client sees only a single, ordinary folder.

Dfs clients automatically choose a replica in their site, if available, reducing intersite network utilization. If more than one replica is available on the client's site, each client randomly selects a replica, allowing the load to be spread evenly across all available servers. If a replica goes down, the client automatically picks a different replica. In this way, replicas provide fault tolerance, load balancing, and WAN link optimization.

You can create replicas for normal file shares as well as for the Dfs root, and you can set them up to automatically synchronize with all other replicas. The only prerequisites are that the Dfs roots need to be domain-based, and the replicas need to be hosted on Windows servers running the file replication service (which is started automatically on domain controllers but can be started manually on member servers as well; just go into the Services console).

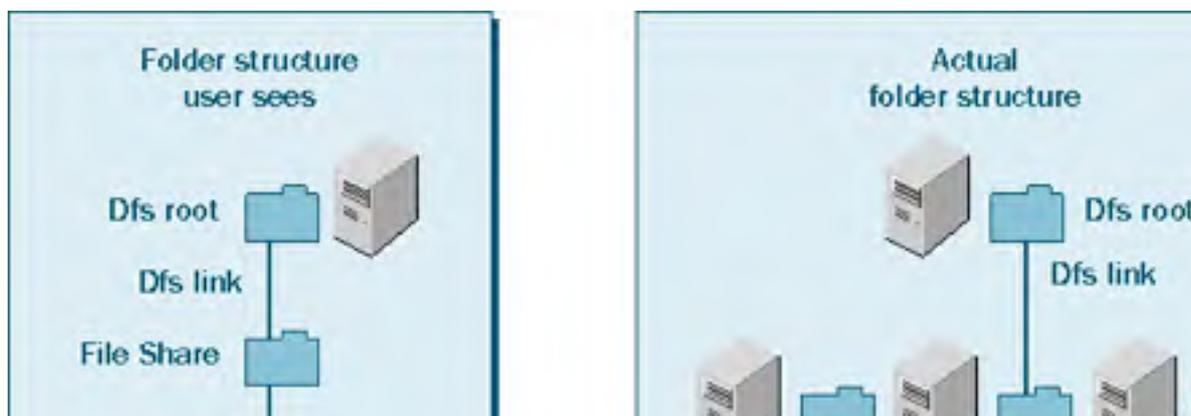

## Creating a Tree Hierarchy

So far, we've covered creating links from the Dfs root, as well as creating Dfs root and Dfs link replicas that are transparent to users. However, this still leaves the Dfs tree only two levels deep: the Dfs root and any linked file shares.

To create deeper layers in Dfs, you might be tempted to use Windows Explorer to create subfolders of the folder that serves as the Dfs root. However, these subfolders won't show up in the Dfs management console, and you can't host additional Dfs links from these subfolders, so this is a bad idea.

To get deeper layers of Dfs structure, create links to other Dfs roots hosted on other servers (or on the same server if running Windows .NET Server). These links are called *inter-dfs links* (Figure 17-3), and currently they are the only way of creating Dfs trees deeper than a single level. Inter-dfs links are also the way to link different DNS namespaces, as all normal Dfs links must be to file shares within the same DNS namespace.

To create an inter-dfs link, create a normal Dfs link but choose a Dfs root as the replica folder instead of a normal file share. Create as many Dfs roots as necessary to support the desired hierarchy.

**Figure 17-3.** The various components of a Dfs tree.

When a user opens a new folder in a Dfs structure, he or she is likely connecting to a new server, which entails some delay. Because of this, it's important to minimize the number of "wrong turns" users make opening folders that don't contain the files they are looking for. To help users find the data they want with as little delay as possible, establish a consistent and intuitive naming structure for Dfs links, and consider creating a site map at key levels of the Dfs tree.

## Setup

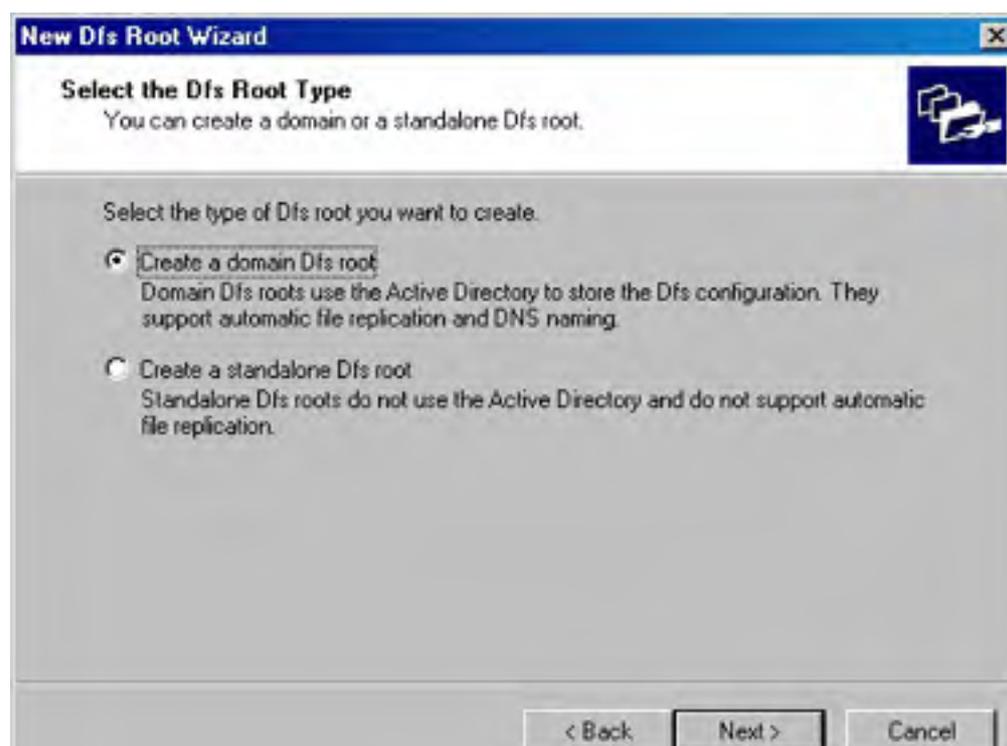

Setting up Dfs is simple. Just create or open a Dfs root and then add Dfs links for any file shares you want to appear in the Dfs root. Of course, before doing this, check with your users and compile a list of network shares to which they need access. Dfs is useless if the right network shares aren't part of the Dfs tree.

### Creating or Opening a Dfs Root

The first step in working with Dfs is to create a Dfs root (or open an existing root). To do so, follow these steps:

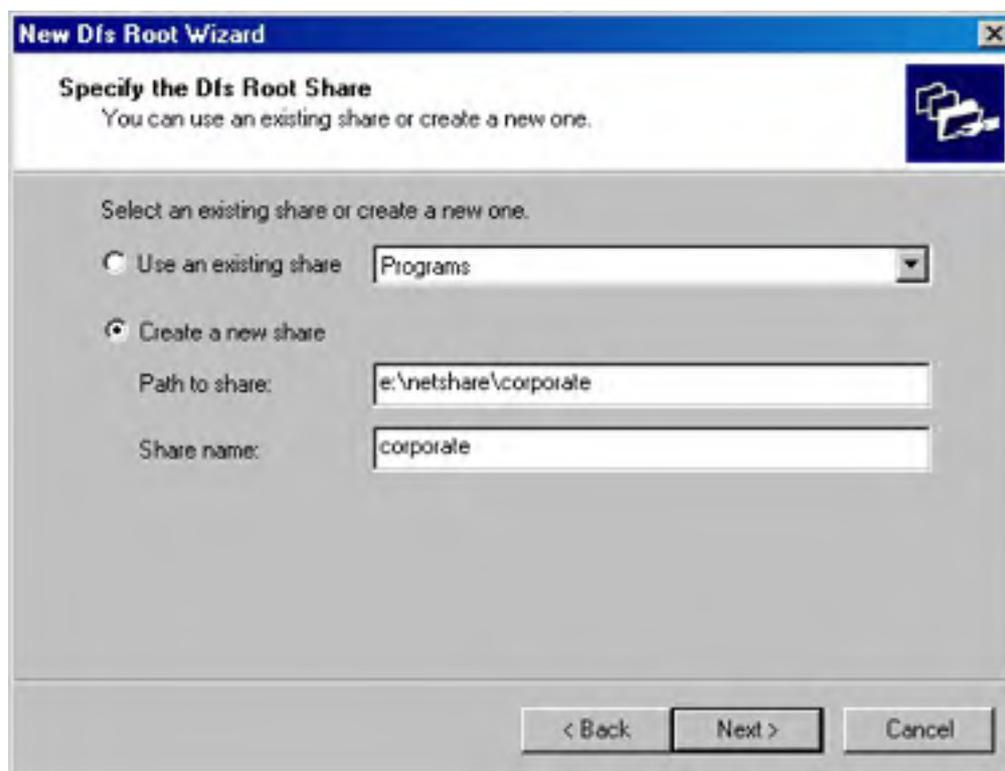

1. Launch the Distributed File System MMC snap-in from the Administrative Tools folder.
2. If a Dfs root exists, open it by choosing Display An Existing Dfs Root from the Action menu. Use the Display An Existing Dfs Root dialog box to enter the host server's name or browse to the Dfs root.

If no Dfs root exists, create one by choosing New Dfs Root from the Action menu and then clicking Next. The New Dfs Root Wizard opens, as shown in Figure 17-4.

**Figure 17-4.** *The New Dfs Root Wizard.*

3. If your server belongs to a Windows 2000 domain, select the Create A Domain Dfs Root option and click Next; otherwise, select the Create A Standalone Dfs Root option, click Next, and skip to step 5.
4. Select the host domain to use for the Dfs root on the next screen, and then click Next.
5. Enter the DNS name of the server to host the Dfs root on the next screen, or click Browse to search the network for the appropriate host. Click Next.
6. Choose an existing file share to use as the Dfs root, or create a new share to host the Dfs root by entering the path to the folder and the share name to use for the folder (Figure 17-5). Click Next.

**Figure 17-5.** *The Specify The Dfs Root Share screen of the New Dfs Root Wizard.*

7. Enter a name for the Dfs root in the Dfs Root Name box, which Dfs users will see when they open the Dfs root. Enter any comments into the Comments box, and then click Next.
8. Review the settings and then click Finish to create the Dfs root.

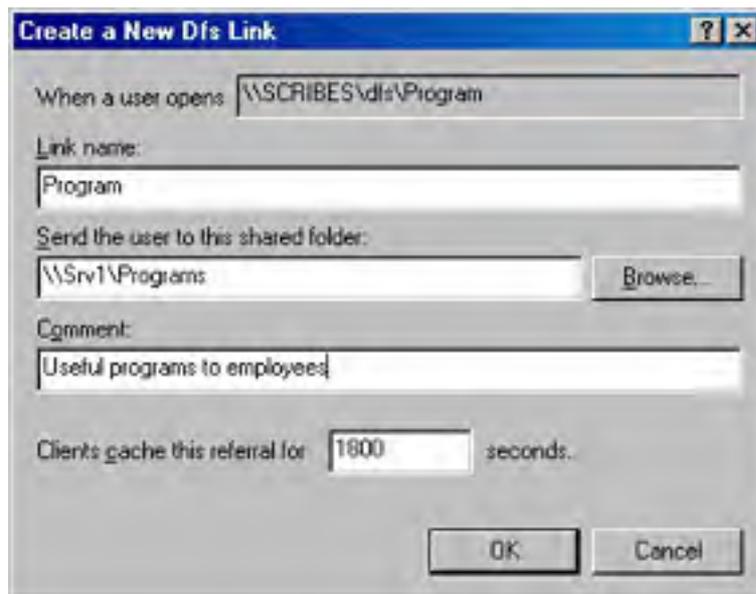

If you frequently administer multiple Dfs roots, open a blank MMC, open the Distributed File System snap-in, open all the roots you want to use, and then save the console file. Then, when you need to access all the Dfs roots, launch the saved console file instead of the standard snap-in.

### Adding Dfs Links

Dfs links are what make a Dfs root special. Without Dfs links, it's just another file share. Dfs links allow users to navigate from the Dfs root to other file shares on the network without leaving the Dfs structure. To create a Dfs link, follow these steps:

1. From the tree pane on the left, select the root to which you'd like to add a link.

2. Choose the New Dfs Link command from the Action menu. This displays the Create A New Dfs Link dialog box, shown in Figure 17-6.

**Figure 17-6.** The Create A New Dfs Link dialog box.

3. In the Link Name box, enter the name users will see for the shared folder you're linking to.
4. Enter the shared folder's UNC or DNS path into the second text box, or click Browse to browse to the shared folder to link to.
5. Enter any comments you want other Dfs administrators to see into the Comment text box (comments aren't visible to clients).
6. Use the Clients Cache This Referral For text box to enter the length of time for clients to cache the referral before checking to see whether the referral is still accurate. Setting a longer time reduces network traffic, but it can lead to inaccurate referrals or interruption of service in the event that the Dfs link is changed—during a failover from one member of a replica set to another, or manually to prepare for maintenance for the server hosting the file share.
7. Click OK when you're finished.

Just as the text in a Web page hyperlink doesn't necessarily reflect the filename of the Web page that it's linking to, a Dfs link name can be completely different from the actual name of the shared folder to which it links.

## Adding Replicas and Configuring Replication

A key feature of domain-based Dfs is the ability to set up Dfs links and the Dfs root with redundant file shares, called replicas or targets. When you create multiple replicas for a link or root, clients only see a single file share, but behind the scenes Dfs selects the proper file share from multiple servers based on which shares are close by and available.

In addition to this redundancy, you can set up replicas to automatically replicate with each other, although we recommend that you only set this up for Dfs links and not the Dfs root itself. (As mentioned before, enable fault tolerance for the Dfs root, but don't set up automatic replication for the root replicas, as this automatically replicates the entire Dfs tree.)

To set up replicas for the Dfs root, see the next section. To set up replicas and configure replication for another shared folder in the Dfs tree, skip to the [Creating Replicas for Dfs Links](#) section later in this chapter.

### Creating Dfs Root Replicas

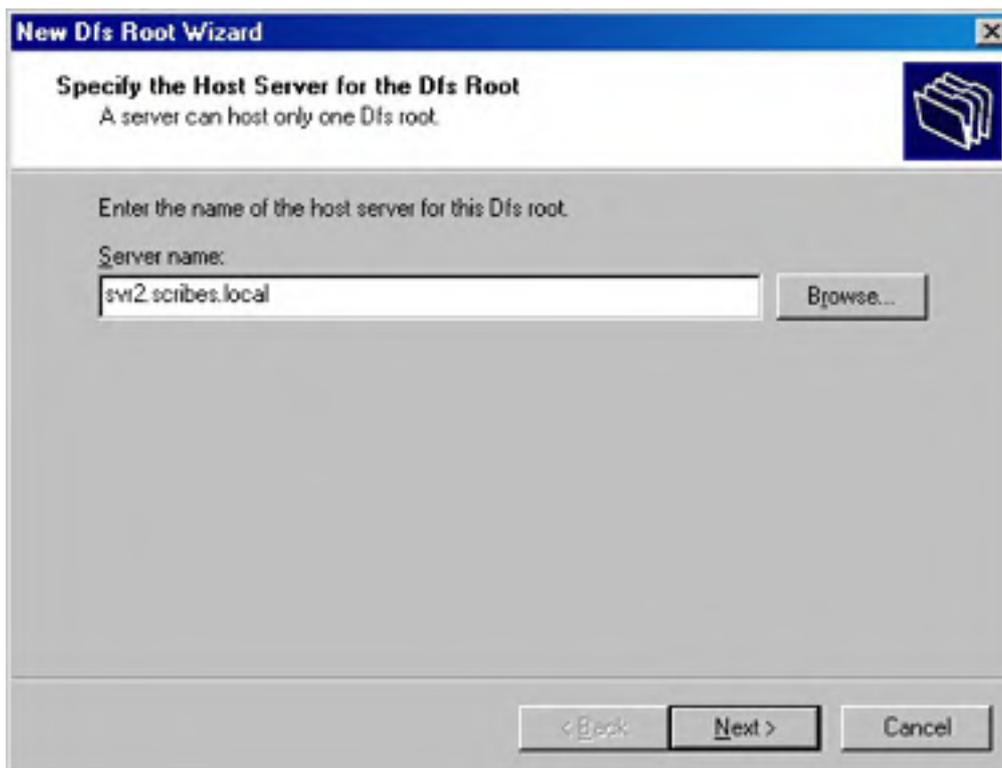

The Dfs root is the most important part of the Dfs tree to replicate because it hosts most of the Dfs links in the tree. Because of this, the first step in creating a more fault-tolerant Dfs tree is to create additional targets for the Dfs root.

To create Dfs root targets, follow these steps:

1. Launch the Distributed File System snap-in and display the Dfs root you want to replicate.
2. Choose New Root Replica from the Action menu.
3. The New Dfs Root Wizard appears, as shown in Figure 17-7. Enter the DNS name of the server you want to use to host the Dfs root replica, or click Browse to search the network for the appropriate host. Click Next.
4. Choose an existing file share to use as the Dfs root replica, or create a new share to host the Dfs root replica by entering the path to the folder and the share name you want to use for the folder. Click Finish.
5. Repeat steps 2 through 4 for any other shared folders you want to use as a replica for this Dfs root.

Microsoft recommends a maximum of 16 Dfs root targets.

Dfs roots can be hosted by server clusters using the Windows 2000 Server cluster service. See [Chapter 16](#) for more information about the cluster service.

**Figure 17-7.** The New Dfs Root Wizard.

#### **Real World**

##### **Don't Replicate Dfs Roots**

Because domain-based Dfs is based on Active Directory, Dfs root targets automatically replicate the Dfs structure (that is, Dfs links), even if you don't set up automatic replication of the Dfs root targets.

You *can* configure replication for the root targets in the Distributed File System console, but doing so replicates the entire Dfs tree and all files within it. This is a somewhat awkward way of configuring replication, and it can consume a good chunk of network bandwidth as well. For these reasons, Microsoft recommends that you not configure replication for Dfs roots, and we agree. Set up replication on individual Dfs links instead; it's more flexible and uses less bandwidth.

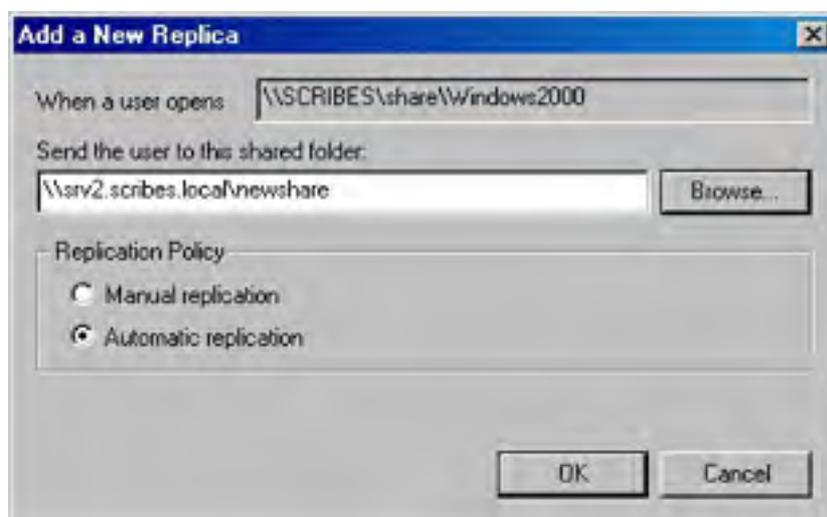

### Creating Replicas for Dfs Links

An easy-to-use, fault-tolerant, and high-performance file system isn't worth much if the data you want to access is unavailable. Creating replicas for the Dfs root ensures that the file system will be available even if one of the root replicas goes down, but that doesn't mean that the files will still be available. To ensure that files will be available to users even if a server goes down, create additional replicas for Dfs links.

To create replicas for Dfs links and set up automatic replication of the shared folder's content, use the following steps:

1. Select the Dfs link in the Dfs tree for which you want to add replicas.
2. Choose New Replica from the Action menu.
3. Enter the UNC path to the network share you want to use as a replica into the box provided, or click Browse to locate the share on the network (Figure 17-8).

Domain-based Dfs leverages Active Directory for full, multimaster file replication; however, when you first create a replica set, you need to specify an initial master that will be used as the initial source folder with which the other targets synchronize.

**Figure 17-8.** The Add A New Replica dialog box.

4. Choose whether you want the shared folder to be replicated automatically (by default, every 15 minutes) or manually. Click OK.
5. Repeat steps 2 through 4 for any other shared folders you want to add to the replica set, and then proceed to step 6.
6. Choose Replication Policy from the Action menu to display the Replication Policy dialog box.
7. Select the shared folder you would like to make the initial master for the replica set, and then click Enable.
8. Select each shared folder you would like to have participate in replication, and click Enable after selecting each one.

9. If you want to change the initial master for the replica set, select the shared folder and click Set Master.
10. Click OK when you're finished.

Don't set some shared folders in a replica set to replicate automatically and others to be replicated manually. You'll cause the shared folders to synchronize poorly.

## Backing Up and Restoring the Dfs Database

The Dfs database for domain-based Dfs is stored in Active Directory and can be backed up and restored using Active Directory-aware backup methods.

To back up the structure of stand-alone Dfs roots to a batch (text) file, enter the following text at a command prompt (replace DomainName and DFSRootName with the name of the appropriate domain and Dfs root):

```
DFSCmd /view \\DomainName\DFSRootName /batch > DFS_backup.bat
```

To back up the Dfs root without validating links and targets, use the following command:

```
DFSCmd /view \\DomainName\DFSRootName /batchrestore > DFS_backup.bat
```

To restore this Dfs structure, use the following command:

```
DFSCmd /view \\DomainName\DFSRootName /restore > DFS.backup.bat
```

In addition to backing up the Dfs topology, you should back up the contents of the actual file shares on a routine basis.

## Dfs Command-Line Administration

Although you can remotely administer any Dfs root using the Distributed File System console, many administrators appreciate command-line administration capabilities, which is where the Dfscmd command comes in.

To use the command line to administer Dfs, open a command prompt and then type *dfscmd*, followed by the appropriate parameters. For example, to create a new Dfs link, you could type the following command:

```
dfscmd /map \\dfs_root_name\dfs_share_name\path  
\\server_name\share_name\path [comment]
```

Here is a brief explanation of the parameters you can use with the Dfscmd command:

- **/?** Displays parameter help for Dfscmd (this works for all commands).
- **/map** Creates a new Dfs link to the specified path. The first path is the Dfs link path and the second is the UNC path to the network share.
- **/unmap** Removes a Dfs link.
- **/add** Adds a target to the Dfs link (or root) you specify.
- **/remove** Removes the specified target.
- **/view** Displays information on the specified Dfs root and share. You can append the */partial* parameter to display comments or the */batch* parameter to create a script that you can use to restore the Dfs root.

For example:

```
dfscmd /map "\\scribes.local\Company Documents" \\srv2\documents
```

Use quotation marks (not Microsoft Word's smart quotes) to enclose any paths that contain spaces.

## Removable Storage

The new Windows 2000 Removable Storage MMC snap-in is the hub for all interactions between programs and any removable storage devices you have installed on the system. It is a tool for managing removable storage devices and media, as well as an API and underlying media database that software vendors can use to take advantage of Windows device and media management facilities. This saves software vendors from having to reinvent the wheel.

The Removable Storage MMC snap-in is where you manage removable storage devices and media. Although many Removable Storage-compatible programs provide device and media management abilities from within the programs, the Removable Storage console is the definitive place to turn if you have major device or media management tasks to do or have problems to address.

Use the Removable Storage console to manage and allocate the devices and media and prepare them for use with Windows 2000 Removable Storage-compatible programs. As such, you use Removable Storage for almost every task except manipulating data on media—a task that is reserved for applications, such as a backup program or hierarchical storage management program like the bundled Remote Storage.

This section covers some of the history behind Microsoft's decision to include the Removable Storage MMC snap-in in Windows 2000, briefs you on its potentially new terminology and conventions, and shows you step by step how to use it to manage your media and devices.

## Benefits and Requirements

One of the primary advantages that Windows (all versions) has over MS-DOS is that programs no longer need their own device drivers. Instead, peripheral and system manufacturers write a single driver for the operating system and all Windows applications automatically gain access to the device.

Although previous versions of Windows created a much-improved foundation for device support, programs still needed to be hard coded with device drivers to use some device types—just as with MS-DOS.

Perhaps the most important type of device that has historically fallen outside the Windows built-in device driver support is the removable storage device. Although Windows 95/98 and Windows NT support some types of removable drives directly in the file system—notably floppy or hard disk-based devices such as Iomega Zip and Jaz drives and their competitors—most removable storage devices remain unsupported or only partially supported by the operating system. This inconsistency requires backup programs (and other programs that need access to removable storage devices) to directly support all devices the program wants access to, leaving device support limited and varied from program to program. This isn't a happy situation.

To remedy this situation, Windows 2000 introduces the Removable Storage API and the Removable Storage MMC snap-in. Hardware vendors can now write a single Windows 2000 driver with Removable Storage support, and all Windows 2000 applications that are Removable Storage-aware can use any device that Removable Storage recognizes.

Windows *does* have built-in support for removable devices such as tape drives that use the Win32 tape/disk API. However, the support isn't as functional as it could be, and the Removable Storage API supplements this API with a more robust API that provides a media database as well as other features that were previously left up to individual programs to implement. Note that devices with drivers not written to explicitly support the Removable Storage API might not be recognized in Removable Storage. Devices using Windows NT drivers won't be available for use in Removable Storage.

In addition to the behind-the-scenes improvements, Removable Storage handles almost all aspects of maintaining removable storage, except the actual handling of data. Your programs handle the data writing. (Removable Storage also doesn't support volume management such as media siding or striping.) Removable Storage makes it easy to keep track of and handle your media, whether in a stand-alone drive or in a robotic library, and it also allows you to easily perform any other media-related and drive-related tasks.

What are the requirements for using Removable Storage? The first requirement, not surprisingly, is a removable storage device. (And, yes, you should make sure that it's in the Hardware Compatibility List.) Devices with Windows NT 4 drivers probably won't do here. If you don't have a Windows 2000 driver for the device, Removable Storage probably won't recognize it, even if some other programs do. (All programs that use the Removable Storage API require that Removable Storage recognize and configure a device before the program can use it.)

If you plan to use a robotic media library with Removable Storage and want the library to be automatically configured (trust us, you do), make sure that all drives in the library are connected to the same SCSI (or similar) bus as the drives' associated media changer, and that no other devices reside on this SCSI bus. Also make sure that the library supports drive-element address reporting. (Check with the device manufacturer on this.)

It's not required, but you should try to keep the number of media to under 1000 so that Removable Storage's database doesn't start to slow down.

## Concepts and Terminology

Removable Storage has its own language relative to removable devices. You might already know this terminology, but some of it might be new and strange (or old, but nonetheless strange). In the interest of speaking the same language, here's a quick discussion of how Removable Storage handles its tasks, as well as the terminology it uses.

### Removable Devices and Libraries

*Removable storage* collectively refers to removable storage devices and their associated media (tapes or disks) as libraries. Although this term is more applicable to robotic optical or tape libraries, the term is also applied to stand-alone drives such as Zip, CD-ROM, and tape drives that hold only a single tape or disk.

Before you purchase a removable storage library to use with Removable Storage, check the Hardware Compatibility List (HCL) to make sure that Windows 2000 fully supports the device. Also check to make sure that the program you plan to use the device with supports the class of device. Some programs such as Remote Storage support only a subset of the devices in the HCL, mainly for functionality reasons instead of compatibility.

### Media Pools

Media pools are perhaps the most important Removable Storage concept to understand. All removable media belong to a *media pool*, which is basically just a group of media that all have the same properties (more on this later), and media are available for use by applications only if they belong to the appropriate media pool. This is important, and you might miss it (as we did) if you just blindly throw a piece of media in the library and start the backup program—and find that no media is available for the application.

Two types of media pools exist: system pools and application pools. All media that aren't reserved for use by an application reside in one of the three system media pools. See Table 17-2 for a description of the three system media pools.

The *free media pool* is where applications look when they need media and no media exists with space available in the application's pool. Therefore, you should try to keep some media in the free media pool so that applications can draw from it as necessary.

**Table 17-2.** *The three system media pools and their purposes*

System Media Pool	Purpose
Free	To hold empty (blank but formatted) media available to all applications.
Import	To hold newly added media to the system that has a recognizable format but has never been used in the system before. You can move the media to the free media pool if you want to erase the media or to an application pool to use in a particular application.
Unrecognized	To hold unrecognized media until they can be moved into the free pool or an

application pool by a user or an application.

An *application media pool* is any media pool that applications create to hold their own media. For example, the Windows 2000 Backup program creates its own media pool, as does Remote Storage. Applications can create multiple media pools, or multiple applications can share the same media pool, although most require media to be in their own application pool.

## Removable Storage Media Identification

Removable Storage keeps track of all media that you insert into the removable storage libraries. Removable Storage accomplishes this in one of two ways: by using on-media identifiers or by using barcodes.

*On-media identifiers* are small data stamps that Removable Storage imprints on the media the first time you insert them into a removable storage library. The identifier has two parts: a label type and a label ID. The label type identifies the format used on the media, and the label ID uniquely identifies the tape or disk. Removable Storage uses these two identifiers to determine which media pool to place new media in and to keep track of all the media in the system. Table 17-3 shows how Removable Storage deals with recognized and unrecognized labels.

**Table 17-3.** *Removable Storage and media identifiers*

	Label Type Recognized	Label Type Unrecognized
Label ID Recognized	Media placed in appropriate media pool and database updated to show media is online	
Label ID Unrecognized	Media placed in import media pool	Media placed in unrecognized media pool

If you have a robotic library that has a barcode reader, you can use it to quickly keep track of all media that goes with the library. Removable Storage can use either the on-media identifier or the barcode to identify the media, although using the barcode is often much faster than using on-media identifiers because you don't have to mount each piece of media to keep track of it.

Removable Storage handles media that have file systems on them (such as CD-ROMs and Zip disks) a little differently than other types of media. The label type for these media is usually the format type (NTFS, FAT, or CDFS), and the label ID is the volume serial number. Additionally, in the case of CD and DVD media, Removable Storage permits multiple media with the same label ID (such as a CD-ROM tower with multiple copies of the same disc), as the media can function interchangeably.

## Media States

Removable Storage uses *media states* to figure out the current status of a piece of media, both in terms of the physical state of the media—whether it is being used or sitting idle; and in terms of the media's availability for additional data—for example, whether the media is full, formatted incorrectly, or reserved by a single program. Removable Storage refers to these two types of media states as Physical states and Side states, and they are displayed in the Removable Storage MMC snap-in when you view the removable storage libraries.

Libraries and drives also have their own states, but they are fairly self-explanatory and less important than media states.

**Physical States** Physical states describe the actual physical availability of the media—is the media in the drive, and if so, is it ready to be used? Removable Storage recognizes the following five Physical states:

- **Idle** The media is in the library or shelved offline in a changer.
- **In-use** The media is currently in the process of being mounted or dismounted.
- **Loaded** The media is mounted and available for read/write operations.
- **Mounted** The media is mounted but not yet available for read/write operations.

- **Unloaded** The media has been dismantled and can be removed from the drive.

**Side States** A *side* is where information is actually stored on a tape or disk, and yes, it does refer to which physical side of the tape or disk information is stored on. Side states in Removable Storage indicate media use; Physical states report media readiness.

Side states are used in part to determine which media pool to place the media into, and as such, Removable Storage examines not only the formatting information for the media, but also the on-media identification labels (discussed earlier in this chapter) to determine whether the media belongs in one of the system media pools or in an application media pool. Media pools can hold only media in the same state as the pool—for example, the import pool can only contain sides that are currently in the Imported state, the unrecognized pool can only contain sides in the Unrecognized state, and so on. The nine Side states that Removable Storage uses are as follows:

- **Allocated** The side is reserved by an application.
- **Available** The side is currently available for use by applications.
- **Completed** The side is in use but full, so it's unavailable for further write operations.
- **Decommissioned** The side is no longer available for use because it has reached its allocation maximum.
- **Imported** The side label type is recognized, but the label ID hasn't yet been cataloged into a media pool by this computer's Removable Storage tool.
- **Incompatible** The formatting of the side is incompatible with the library. The media should be removed.
- **Reserved** The side is unavailable to all applications except the application that allocated the opposite side. Applies only to dual-sided media where one side has already been allocated.
- **Unprepared** The side has been placed in the free media pool but doesn't yet have a free media label. This state is temporary and changes to the available Side state barring a problem.
- **Unrecognized** Removable Storage can't recognize the side's label type and ID.

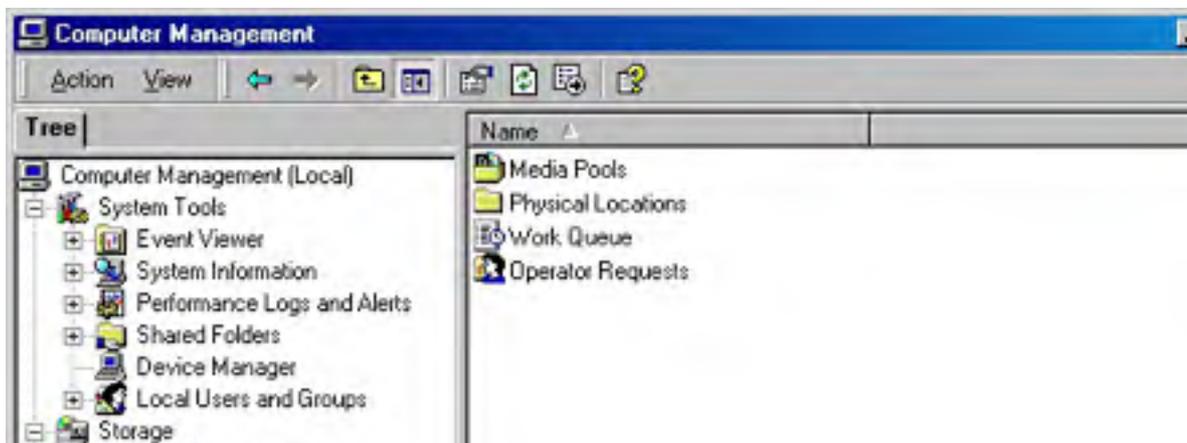

## Use and Management

The Removable Storage console is a tool for managing removable storage devices and media.

### Opening the Removable Storage Snap-In

The Removable Storage MMC snap-in isn't listed by itself in the Administrative Tools folder like many of the server management consoles are; instead, you'll have to either load it directly from a blank MMC window, use the Run dialog box, or access it from the Computer Management snap-in.

To access Removable Storage from the Computer Management snap-in, launch the Computer Management snap-in from the Administrative Tools folder on the Start menu, and then expand the storage root in the console tree and select Removable Storage from the tree, as shown in Figure 17-9.

**Figure 17-9.** Removable Storage displayed in the Computer Management console.

To open the Removable Storage snap-in directly, choose Run from the Start menu and either type `%SystemRoot%\System32\Ntmsmgr.msc` into the text box provided to open the snap-in directly, or type `mmc` to open a blank MMC and then open the Ntmsmgr snap-in from the `%SystemRoot%\System32` folder.

## Managing Libraries

Because libraries are the actual physical drives or robotic changers that hold the removable media, the tasks involved with managing libraries are all physically oriented: configuring libraries added to the system, enabling and disabling libraries, changing the available media types, working with robotic libraries, and cleaning libraries. Use the following sections to help you with these and other chores.

**Configuring Libraries** When you first connect a removable storage device to the system, Windows 2000 tries to recognize and configure it. When you launch Removable Storage, it performs its own device configuration and attempts to configure all removable storage devices connected to the system. All compatible stand-alone removable drives are automatically configured, although some robotic libraries aren't. For a robotic library to be automatically configured, all drives in the library must be connected to the same SCSI bus as the drives' associated media changer. The library must also support drive-element address reporting. (You're going to need to check with the device manufacturer on this one; we can't help you here.)

As mentioned in the section entitled [Benefits and Requirements](#), earlier in this chapter, Removable Storage recognizes devices somewhat independently of Windows 2000, and a device that is recognized by Windows 2000 won't necessarily be recognized by and compatible with Removable Storage. As usual, check the HCL to make sure that your device is supported.

If the robotic library isn't automatically configured, you *can* configure the device manually. However, it's a rather tricky process involving manually editing the system registry, among other tasks. If you want to do this, consult the drive's manufacturer.

**Enabling and Disabling Libraries** To enable or disable a removable storage library (making the library unavailable for use by applications), open Removable Storage and then follow these steps:

1. Open the Physical Locations folder in the console tree.
2. Right-click the library you want to enable or disable, and then choose Properties from the shortcut menu.
3. Select or clear the Enable Library check box at the bottom of the General tab, and then click OK.

**Inventorying Libraries** Removable Storage automatically creates an inventory of the media as you insert them into the library (actually, each time a library door is accessed). However, you might want to change the way Removable Storage updates the media inventory, or you might want to force Removable Storage to recheck the inventory.

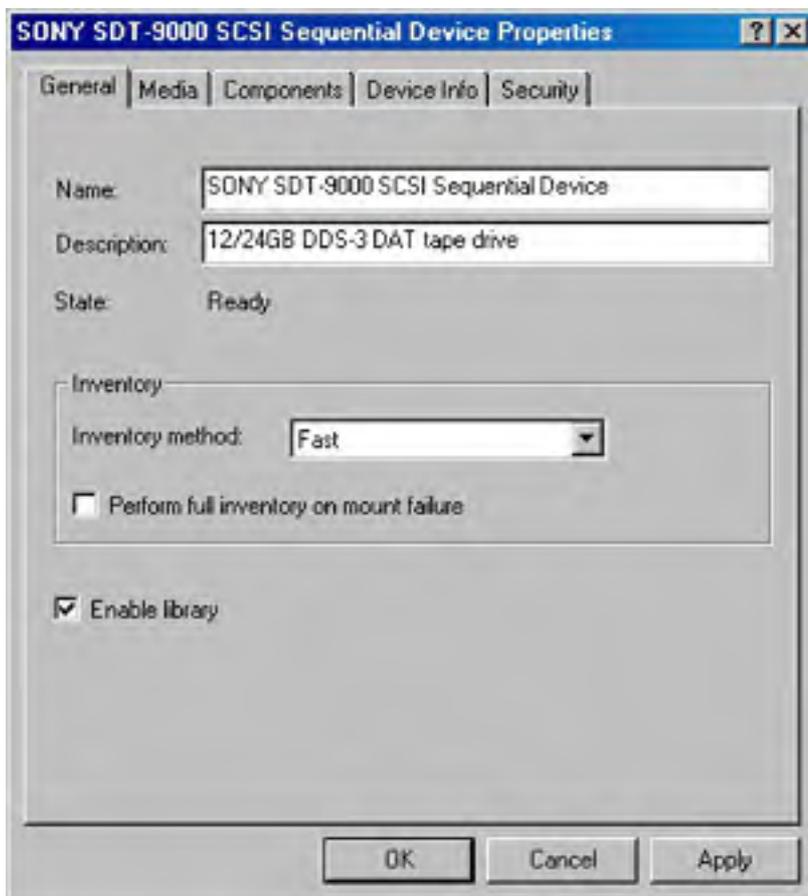

This topic really applies only to robotic storage libraries. Stand-alone drive libraries don't need any special attention to keep their inventories up-to-date.

To accomplish these tasks, follow these steps:

1. To inventory the robotic storage library, right-click the library in the Physical Locations folder of Removable Storage and choose Inventory from the shortcut menu. Removable Storage inventories the library according to the default method specified for the library.
2. To change the default method of inventorying for a library, right-click the library in the Physical Locations folder of Removable Storage and choose Properties from the shortcut menu. Then choose an option from the Inventory Method drop-down list box, described in Table 17-4.
3. Clear the Perform Full Inventory On Mount Failure check box if you don't want Removable Storage to conduct a full inventory every time the library fails to mount a tape or disk (Figure 17-10).

**Table 17-4.** Library inventory methods and their descriptions

Inventory Method	Description
None	No automatic inventory is performed.
Fast	Performs a quick inventory by checking which slots have had media swapped.
Full	Mounts each media in the library and reads the media's on-media identifier. Can be slow on libraries with a lot of media.

**Figure 17-10.** The Properties dialog box for a storage library.

**Changing Available Media Types** If the storage library supports more than one type of media,

you might need or want to change the media that Removable Storage supports in the library. To do so, follow these steps:

1. Open the Physical Locations folder in the console tree of the Removable Storage snap-in.
2. Right-click the library you want to configure, and then choose Properties from the shortcut menu.
3. Click the Media tab, and then click Change to add or remove media support for the library.
4. To disable the support for a certain media, select a supported media from the Selected Types list on the left and click Remove.
5. To add a media to the list of media the library supports, choose a media type from the list on the right and then click Add. Note that the storage library must be able to physically accept the media as well as recognize and perform the desired operations on the media.

**Setting Door and Inject/Eject Port Timeouts** All libraries have at least one inject/eject port that is used for inserting and removing media from the library, and robotic libraries also often have a door that can be opened to directly access media in a particular drive. To set the amount of time allowed before Removable Storage times out the port or door, thereby preventing further operations with it, follow these steps:

1. Open the Physical Locations folder in the console tree of the Removable Storage snap-in.
2. Right-click the library you want to configure, and then choose Properties from the shortcut menu.
3. Click the Components tab, and then enter a timeout period in minutes for the library door (if available) and inject/eject ports.

To open a library door, right-click the library and then choose Door Access from the shortcut menu. When prompted, you can open the door and access the media (you have until the door timeout period expires). However, whenever you open the library door, Removable Storage needs to perform a full inventory unless you use a barcode reader. Therefore, it's preferable to use the inject/eject port in most circumstances.

**Enabling and Disabling Individual Drives in a Library** If you have a storage library with multiple drives, you can disable or enable individual drives as needed. To do this, follow these steps:

1. Open the Physical Locations folder in the console tree of the Removable Storage MMC snap-in.
2. Select the library containing the drive you want to configure, and then double-click Drives.
3. Right-click the drive you want to enable or disable, and then choose Properties from the shortcut menu.
4. Clear the Enable Drive check box in the General tab to disable the drive.

**Cleaning Libraries** Most removable storage libraries need to be cleaned—depending on the use and drives—once a week or more. Because of this ongoing need, Removable Storage makes it easy to clean the drives and keep track of when you last did so.

To clean a robotic library, right-click the library you want to clean and choose Cleaner Management from the shortcut menu. Then use the Cleaner Management Wizard to clean the drive.

To clean a stand-alone library, manually insert the cleaning tape and clean the drive as instructed by the drive manufacturer or the tape manufacturer. When you're finished, open the Physical Locations folder in the console tree, expand the appropriate library, and then right-click the drive you cleaned in the pane on the right and choose Mark As Clean from the shortcut menu.

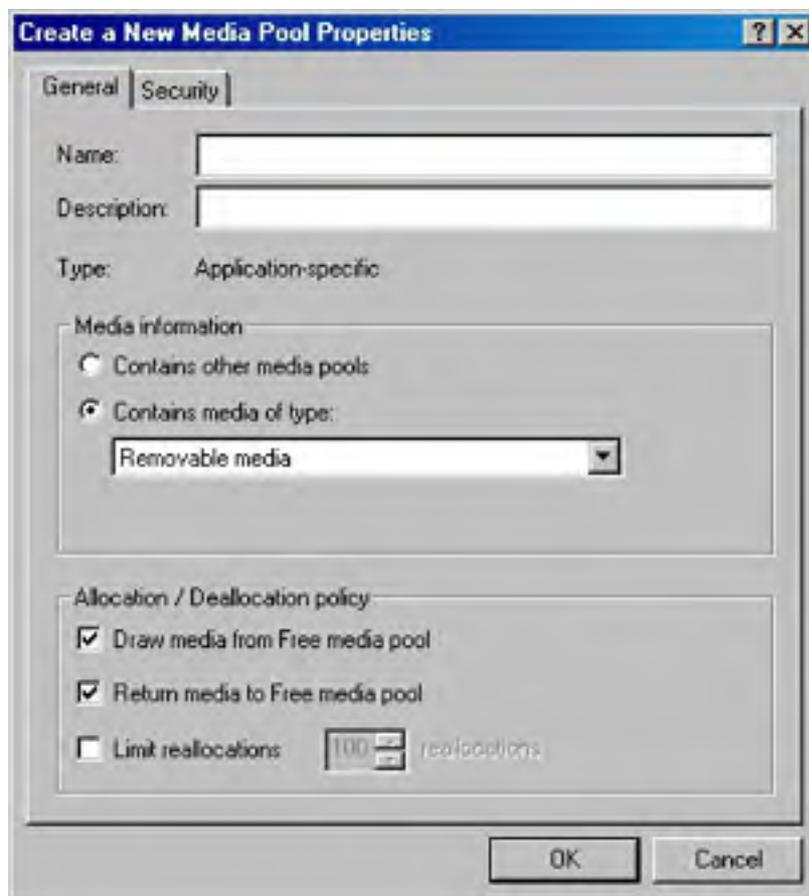

## Managing Media Pools

Handling media pools is the most important task that you perform with Removable Storage. Applications draw from either the free media pool or one or more application media pools when they require media. The following sections cover all of the media pool management tasks you'll need to perform, including creating and deleting media pools, as well as configuring application media pools to automatically move media to and from the free media pool as necessary.

To move a piece of media from one media pool to another, drag the media from its current location to the media pool in which you want to store it.

**Creating Media Pools** Most of the time Removable Storage and your applications create all of the media pools you'll need, but there might be times when you want or need additional pools. To create additional media pools, follow these steps:

1. Double-click Media Pools in the console tree, and select the Media Pools folder to create a new root media pool, or select a media pool that can contain other media pools if you want to create a child media pool.
2. Choose Create Media Pool from the Action menu.
3. In the Create A New Media Pool Properties dialog box shown in Figure 17-11, enter a name for the media pool into the Name box.

**Figure 17-11.** The Create A New Media Pool Properties dialog box.

You can reconfigure a media pool at any time by right-clicking the media pool and then choosing Properties from the shortcut menu.

4. Enter a description of the purpose of the media pool in the Description box.
5. To make the media pool hold other media pools, select the Contains Other Media Pools option.

6. To configure the media pool to actually hold media (as opposed to other media pools), select the Contains Media Of Type option and choose the media type you want to store in the media pool from the drop-down list box.
7. Select the Draw Media From Free Media Pool check box if you want the media pool to take media from the free media pool when no media are available in this media pool. Selecting this option is generally prudent, as it reduces the need to manually manage the media.
8. Select the Return Media To Free Media Pool check box if you want the media pool to return media to the free media pool when it is no longer needed. This is also usually a good idea.
9. To limit the number of times the media pool draws media from the free media pool, select the Limit Reallocations check box and enter the number of reallocations you want to allow. You might want to do this to leave some media in the free media pool for other media pools to draw from should they have no available media in their own pool.
10. To change the permissions for the media pool, click the Security tab and assign the appropriate access permissions for the media pool.

You can create a media pool to hold different types of media—perhaps for a backup program that needs access to the tape drive as well as a magneto optical (MO) drive. To do this, create a media pool that stores other media pools, and then open the new media pool and create a child media pool for each media type you want to use.

**Deleting Media Pools** When an application media pool is no longer required—either you've uninstalled it or you no longer use the application for which the media pool was created—you might want to delete it. To do so, move all media in the media pool you want to delete into another media pool, select the media pool you want to delete, and then click the Delete toolbar button.

**Configuring Media Pools** To change the way the media pool works—perhaps to change whether or not the media pool draws media from the free media pool when necessary or to change the media type for the media pool—follow these steps:

1. Right-click the media pool you want to configure and then choose Properties from the shortcut menu.
2. In the Media Pool Properties dialog box, modify the name for the media pool in the Name box, if necessary.
3. Change the description of the purpose of the media pool in the Description box.
4. To make the media pool hold other media pools, select the Contains Other Media Pools option.
5. To configure the media pool to actually hold media, select the Contains Media Of Type option and choose the media type you want to store in the media pool from the drop-down list box.
6. Select the Draw Media From Free Media Pool check box if you want the media pool to take media from the free media pool when no media are available in this media pool. This is generally a smart move, as it reduces the need to manually manage the media.
7. Select the Return Media To Free Media Pool check box if you want the media pool to return media to the free media pool when the media is no longer needed. This is also usually a good idea.
8. To limit the number of times the media pool draws media from the free media pool, select the Limit Reallocations check box and enter the number of reallocations you want to allow.
9. To change the permissions for the media pool, click the Security tab and assign the appropriate access permissions for the media pool.

## Managing Physical Media

*Physical media*—tapes or disks—are the reason storage libraries and media pools exist. Actually dealing with the physical media is pretty easy, and the kind of tasks involved include inserting and ejecting media, mounting and dismounting media, enabling and disabling media, and moving media between media pools. This is simple stuff, but we'll quickly walk you through it anyway.

**Injecting and Ejecting Media** Injecting (inserting) and ejecting media in stand-alone drives is pretty simple: to inject, place the media in the drive; to eject, press the eject button. You don't really require any help with that. However, robotic storage libraries can be a little more complex, and you should normally use Removable Storage to handle injecting and ejecting media into these libraries rather than using only the device's physical buttons or ports. To inject or eject media from a storage library, follow these steps:

1. To inject a tape or disk into the storage library, right-click the library and choose Inject from the shortcut menu. Follow the instructions presented by the Media Inject Wizard.
2. To eject a tape or disk from the storage library, expand the Physical Locations folder and then open the storage library containing the media you want to eject.
3. Double-click the media icon in the console tree to display all media inserted in the library.
4. Right-click the media you want to eject, and then choose Eject from the shortcut menu.
5. Follow the instructions in the Media Eject Wizard to eject the media.

**Mounting and Dismounting Media** When you insert a piece of media in a library, the media is in the Idle state and can't be immediately accessed by an application. To be used, the media must first be mounted, after which it is in the Loaded state. Most applications automatically mount the media as needed; however, you can also manually mount media. To do so, right-click the media and then choose Mount from the shortcut menu.

To eject a piece of media, first the media must be idle. Normally if an application is finished accessing the media, the media returns to the Idle state; however, if the media is currently in the Loaded state and you need to eject the media immediately, you need to manually dismount the media before you eject it. To dismount the media, right-click the media and then choose Dismount from the shortcut menu.

**Disabling Media** If you want to make a particular piece of media unavailable for use, consider ejecting it and storing it somewhere. However, if you want to keep the media in the library yet prevent it from being used, use the following steps:

1. Right-click the media in Removable Storage and choose Properties from the shortcut menu.
2. Clear the Enable Media check box in the General tab. Click OK.

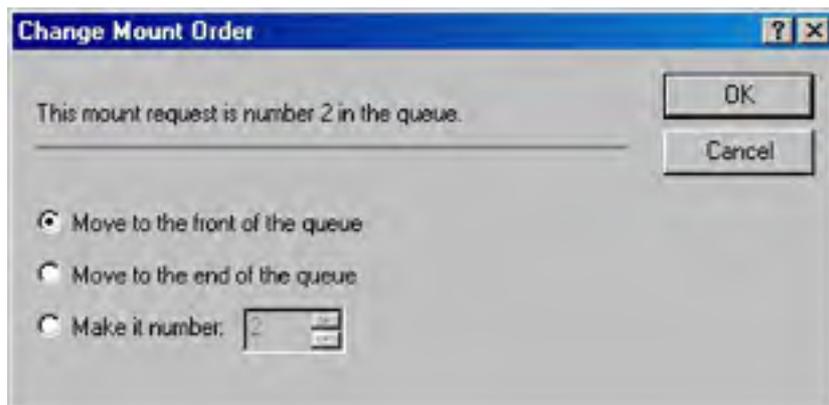

## Using the Work Queue

The work queue is a list of all activities that have been performed in Removable Storage and acts in much the same way as the Windows 2000 event log does, except that the work queue lists actions that need to be performed as well as completed actions.

To view the work queue or the operator requests list, select the appropriate list from the console tree in the Removable Storage MMC snap-in. The work queue lists all actions performed or pending in Removable Storage, along with any other information about the action. To perform a task using the work queue, follow these steps:

1. To view any additional information about an action, such as additional error messages on failed actions, right-click the action and choose Properties from the shortcut menu.
2. To cancel a pending action, right-click the action and choose Cancel Action from the shortcut menu.
3. To adjust the priority of a pending action, right-click the pending action and choose Reorder. Removable Storage displays the Change Mount Order dialog box, shown in Figure 17-12.

- To move the request to the beginning of the queue, select the Move To The Front Of The Queue option.

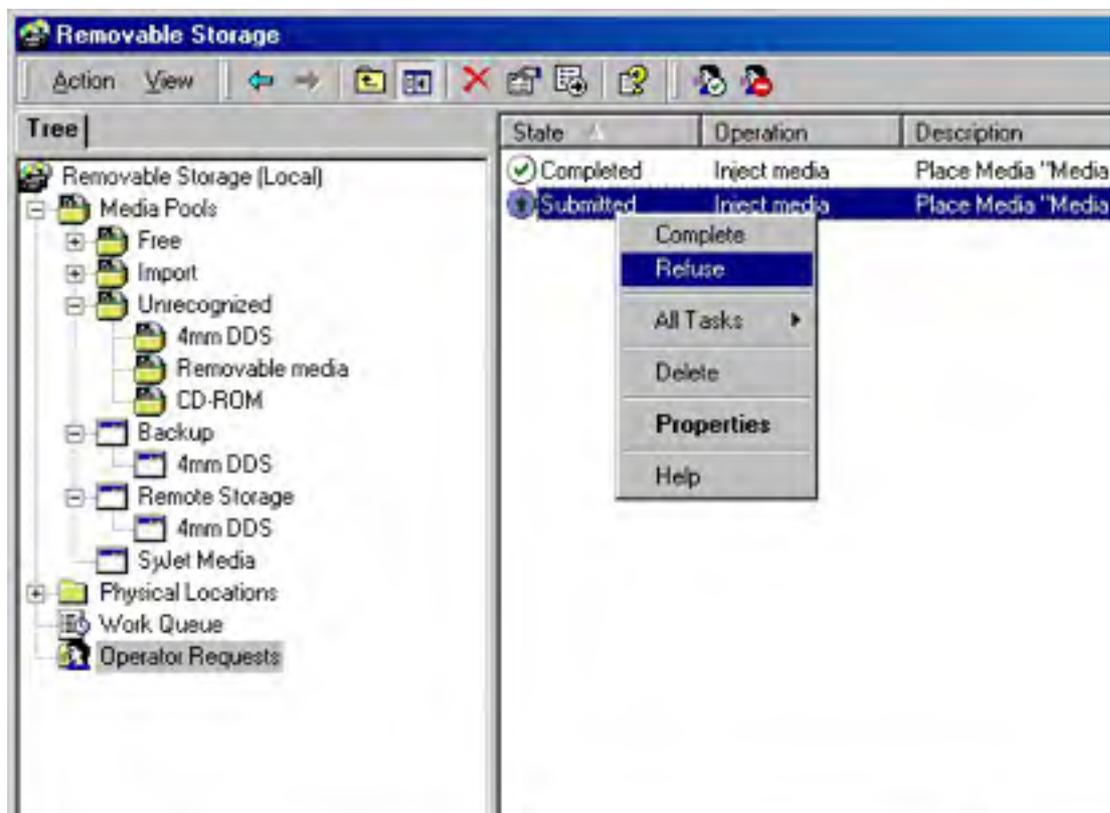

**Figure 17-12.** The Change Mount Order dialog box.

- To move the request to the end of the queue, select the Move To The End Of The Queue option.
- To specify exactly which place in the queue the request should be, select the Make It Number option and select the number in the queue that you want the request to be.

## Working with Operator Requests

Operator requests occur when an action requires direct operator interventions, such as the insertion of offline media or the need for a new cleaning cartridge. Usually when an operator request occurs, the system displays a message indicating that a specific action is required. Perform the action and click OK to resolve the request. If you want to refuse the request or manually mark the request as completed, follow these steps:

- Select Operator Requests in the Removable Storage console tree.
- Right-click the pending operation, and choose Refuse from the shortcut menu to cancel the request, or choose Complete from the shortcut menu after fulfilling the request, as shown in Figure 17-13.

**Figure 17-13.** *The operator requests list in the Removable Storage snap-in.*

3. To modify how long Removable Storage keeps old operator requests, right-click Operator Requests in the console tree, choose Properties from the shortcut menu, and then use the Operator Requests Properties dialog box to change these settings.
4. To change how Removable Storage notifies you when an operator request is due, right-click the Removable Storage root in the console tree, choose Properties from the shortcut menu, and then set the values for the Send Operator Requests To Messenger Service and the Tray Icon For Pending Operator Requests check boxes as desired.

## Remote Storage

Like money and RAM, you can never have too much hard disk space. Because of this universal truth, Windows 2000 includes the ability to extend hard disk capacity using tape and other archival media.

This ability is provided by Remote Storage, which takes advantage of the Windows 2000 built-in, from-the-ground-up support for hierarchical storage utilities and enables Windows 2000 to extend an NTFS volume almost infinitely. Remote Storage does this by transparently migrating infrequently used files to tape while keeping them easily accessible.

Users see migrated files as if they were still stored on the disk instead of on tape. Even when users access migrated files, the only noticeable differences are a small dialog box informing them that the file is being recalled from tape and a somewhat longer file load time. Except for the setup and configuration of Remote Storage, this feature adds little or no burden to administrators. Remote Storage performs all migration and recovery from tape automatically (unless the required media is offline, in which case Removable Storage places a request for an operator to retrieve the media).

To help you capitalize on this new lease on a hard disk's life, the following sections examine key concepts and requirements of Remote Storage, its setup and configuration, and its data recovery and protection.

With hard drive capacities measured in the hundreds of gigabytes and terabyte storage solutions not unreasonable, many companies pass on remote storage and simply buy more hard drives or RAID solutions. However, if your company needs to archive large quantities of data, large-capacity tape drives remain unmatched.

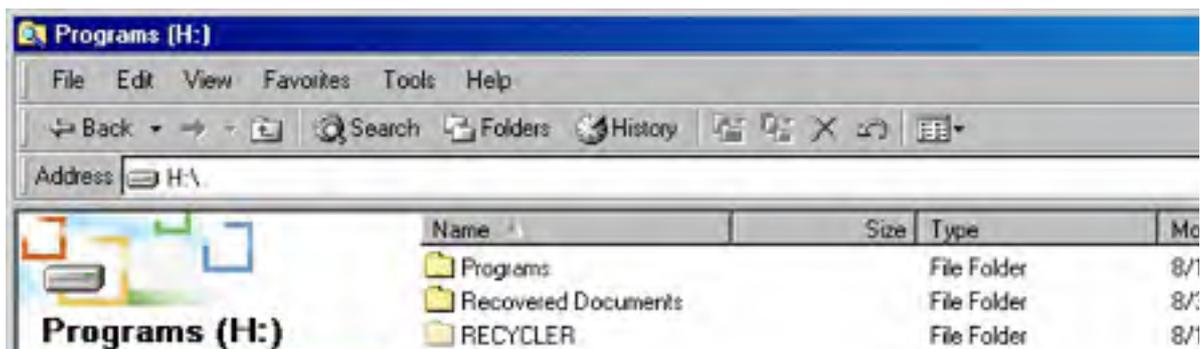

## Concepts and System Requirements

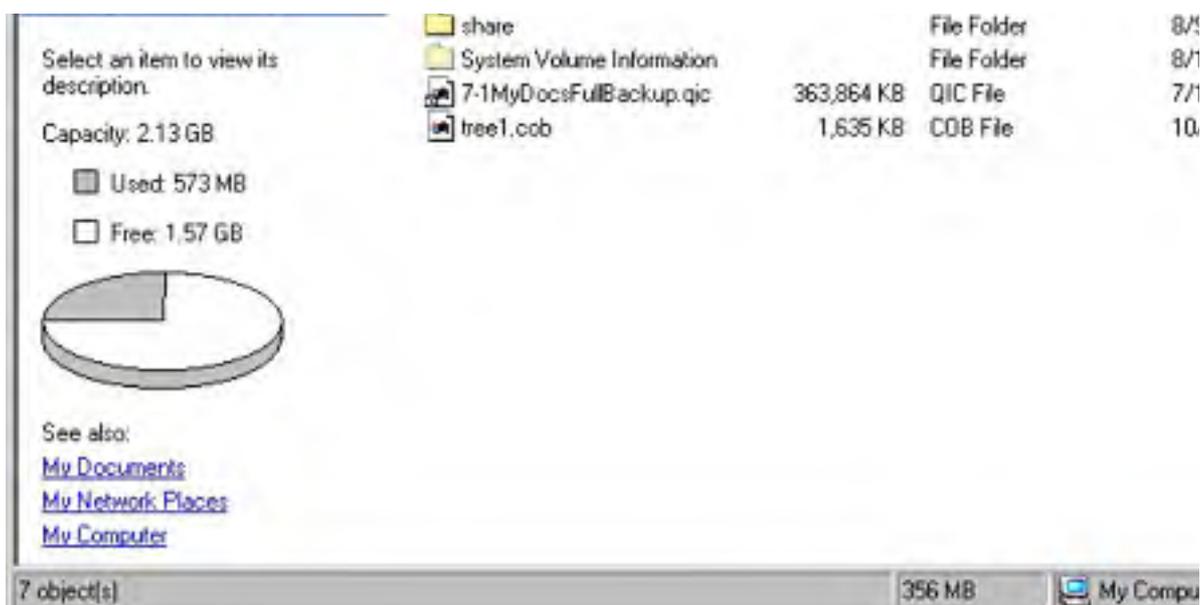

You probably have some questions about the purpose of Remote Storage: How does it interact with other programs such as the backup program and antivirus program? What kind of hardware and software do you need to make it work? We had the same questions when we first encountered Remote Storage, so we provide you with some background here that you can use to answer those nagging questions.

### Purpose

Remote Storage is also known as Hierarchical Storage because it allows for two tiers of data storage. The first tier, local storage, is the standard hard disk or removable disk drive hosting an NTFS volume (such as an Iomega Jaz drive). The second tier, provided by Remote Storage and aptly referred to as the remote storage tier, is the tape drive or robotic tape library. Data is initially stored in local storage, and once the data has *settled down* (has not been accessed within a specified period of time), it is copied or migrated to remote storage but also left intact, or cached, in local storage for quick access. (Note that Remote Storage only manages files physically on a volume—it doesn't follow Dfs links.) Finally, as local storage fills up and it becomes necessary to free up space for additional data, the files that have settled down and been migrated to remote storage are converted to placeholders or links, freeing up the space they used to consume.

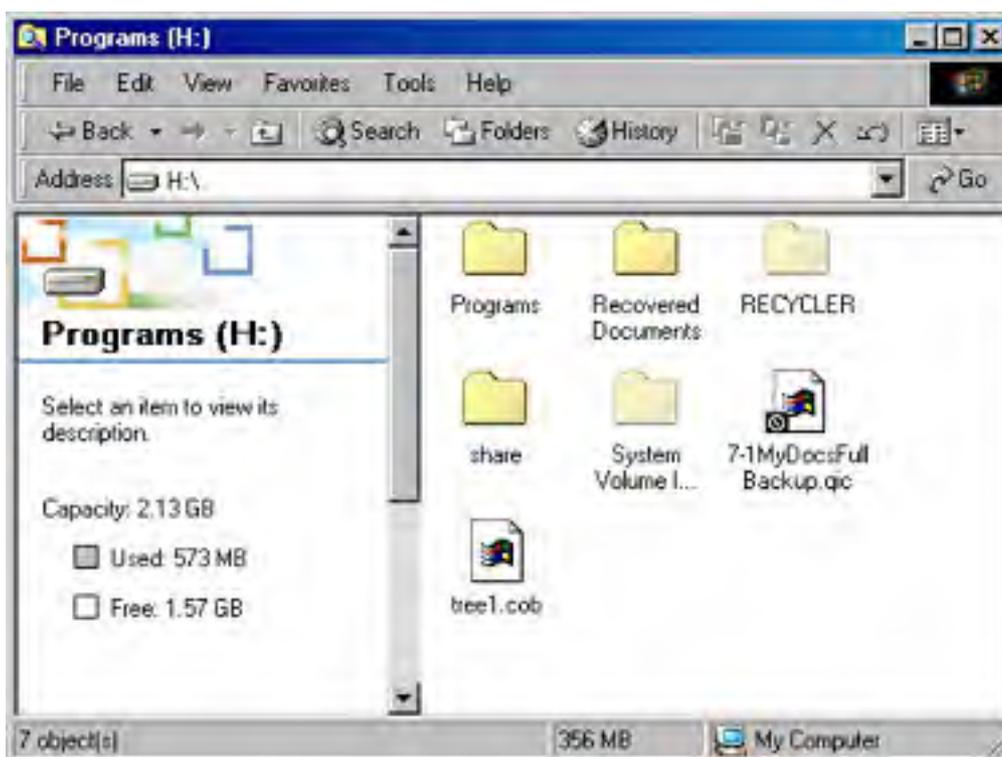

Files that have been moved to remote storage and are no longer cached locally still appear to be resident in local storage (Figure 17-14). These placeholders look and act the same as normal locally stored files, except for a couple of small differences.

**Figure 17-14.** Windows Explorer in Details view.

The first difference is that the icon for the file that was moved to remote storage has a small clock face on it to indicate that to open the file, a user has to wait while Windows 2000 retrieves the file from remote storage (Figure 17-15).

**Figure 17-15.** Windows Explorer in Large Icon view displaying a remote storage placeholder.

The second difference is that, although Windows Explorer shows remote files using the same amount of disk space as when the files were stored locally, and it doesn't change how disk quotas work (remote files count against a disk quota the same as local files do), Windows Explorer does subtract remote files from the total space used on a disk estimate. In other words, Windows 2000 treats remote files exactly the same as local files except when calculating the amount of free space on a disk, at which point Windows 2000 recognizes that remotely stored files take up no local disk space. Windows Explorer also adds a Remote Storage tab to the Properties dialog box of managed volumes, allowing administrators to view and change the settings on managed volumes directly from within Windows Explorer.

When a user accesses a remotely stored file, the Recalling From Remote Storage dialog box appears, explaining that Windows is recalling the file from Remote Storage (Figure 17-16). If a user doesn't want to wait for the file, he or she can click Cancel and leave the file in remote storage. Otherwise, the file is restored into local storage and its last-accessed-date timestamp is reset, preventing it from migrating to remote storage until the file has settled down.

**Figure 17-16.** *The Recalling From Remote Storage dialog box.*

Copy and move operations performed on placeholders act a little differently than normal file copy and move operations. Placeholders that are renamed or moved to a different location on the same volume don't need to be recalled from remote storage. However, when a user copies the file, Remote Storage recalls the file and then copies it to the new location. (Note that the new file is in no way linked to the old file in remote storage, just like you would expect from a copied file.) When a user moves a placeholder to a different volume, Remote Storage recalls the file, copies it to its new location, and then deletes the original file.

### **Program Compatibility**

Compatibility with Windows 2000 programs is an important Remote Storage issue. Although Remote Storage is thoroughly integrated into the operating system, some programs might not behave optimally unless they are specifically made aware of Remote Storage. Two examples are backup programs and antivirus programs.

Backup programs that aren't Remote Storage aware can back up all locally stored data and data links, but they have no way of backing up data that has been moved to remote storage (except by restoring the remotely stored files, rendering Remote Storage useless). If a backup program is Remote Storage aware (such as the Windows 2000 Backup program), you might have the option to retrieve files from remote storage and back them up along with all locally stored data, and then return the files to remote storage when finished.

Many antivirus, backup, search, and indexing programs that aren't Remote Storage aware have a nasty tendency to access every file they check, thereby resetting Remote Storage usage data, as well as pulling files from remote storage to check them for viruses. Remote Storage-aware programs don't have this liability.

#### **Real World**

##### **Microsoft Office FindFast**

Microsoft Office 97 causes all Word documents, PowerPoint documents, and HTML files in remote storage to be recalled at the end of Office 97 installation. You can stop this by terminating the Findfast.exe process. You should turn FindFast off by using the FindFast Control Panel tool and by making sure that the Findfast.exe shortcut isn't in the Startup folder on the Start menu. Microsoft Office 95 and Office 97 might also recall files from remote storage when you use the Edit menu's Find command.

Fortunately, Remote Storage has a workaround for programs that aren't Remote Storage aware. Remote Storage limits the allowable number of successive recalls from remote storage. If a program recalls a file from remote storage and requests that another file be recalled within 10 seconds of the last file being recalled, Remote Storage counts this. When the count reaches a configurable limit (the default is 60), Remote Storage prohibits further recalls during that session. Setting a limit doesn't usually bother normal users but can prevent an antivirus program that isn't Remote Storage aware from inadvertently restoring all remote storage files.

## Data Safety

You're probably wondering how to ensure that your data is adequately backed up when working with Remote Storage. If a file has been moved to tape, what happens if the tape gets damaged or lost? What happens if the link to the file in local storage is lost? You can assuage your fears of data loss in several ways. The first way you're already familiar with—frequent and thorough backups.

Most companies combine making regular backups of the local storage systems with creating copies of Remote Storage's media, the second way of protecting data. Thus, every time you back up the local storage, you make a copy of the Remote Storage media and keep that with the local storage backup. This step ensures that the entire storage system is backed up: both the local storage tier and the remote storage tier. You can also protect the data by using a Remote Storage-compatible backup program to back up data in remote storage along with the local storage backup. The recovery process is the same as that for any other type of backup.

To summarize, if you want to thoroughly protect the data and you have the ability to copy the Remote Storage media, use a strategy similar to the following one (for more specific information, see the section entitled [Data Recovery and Protection](#), later in this chapter):

- Back up the local data regularly.
- Validate local volumes managed by Remote Storage regularly.
- Make more than one copy (up to three) of the Remote Storage media master, and regularly synchronize these copies with the media master each time you perform a full backup.
- Optionally take a media copy and add it to the backup set (as described later in this chapter). This allows you to keep the complete data together, and removes the limitation of three media copies.
- Consider backing up data in remote storage at the same time as you back up local storage. It might take longer and use more media, but it offers greater data protection and flexibility in case of a disaster.

Although Remote Storage media isn't the easiest type of media from which to extract data, it isn't difficult for an unsavory individual with a stolen Remote Storage tape. Always keep close tabs on your media—store them in a secure location.

## System Requirements

Remote Storage isn't particularly resource intensive, and as such, it works well on almost any system that meets the recommended system configuration for Windows 2000 Server. Note that you can't run Remote Storage on a Windows 2000 Professional machine, and Remote Storage can manage volumes formatted only with NTFS 5.

However, Remote Storage is somewhat fussy about the removable storage subsystem you use. The drive needs to be recognized by Removable Storage; you should use hardware only in the Hardware Compatibility List. Additionally, at shipping, Remote Storage supports only SCSI-class 4 mm (DAT), 8 mm, and DLT tape libraries that Removable Storage recognizes. Remote Storage doesn't support optical drives (including CD-RW and DVD-RW), QIC tape libraries, or any type of removable disk drive (Jaz, Zip, and so on). Some of these restrictions might change in future versions of Windows (Windows .NET Server supports magneto optical disks), but some devices such as QIC tapes and Jaz drives just aren't meant for Remote Storage, so forget about them. If you're thinking about QIC tapes, you probably don't need Remote Storage—you need another hard disk.

Microsoft recommends that you avoid using Remote Storage with Exabyte 8200 tape libraries.

Client systems using Windows File Manager can't access files managed by Remote Storage, which precludes Windows 3.x clients from accessing these files. Also, Windows 95 users should refrain from using File Manager if they want to access Remote Storage files (or maintain any dignity; they've had seven years to learn Windows Explorer).

Remote Storage won't fail over on a server cluster.

## Setup and Configuration

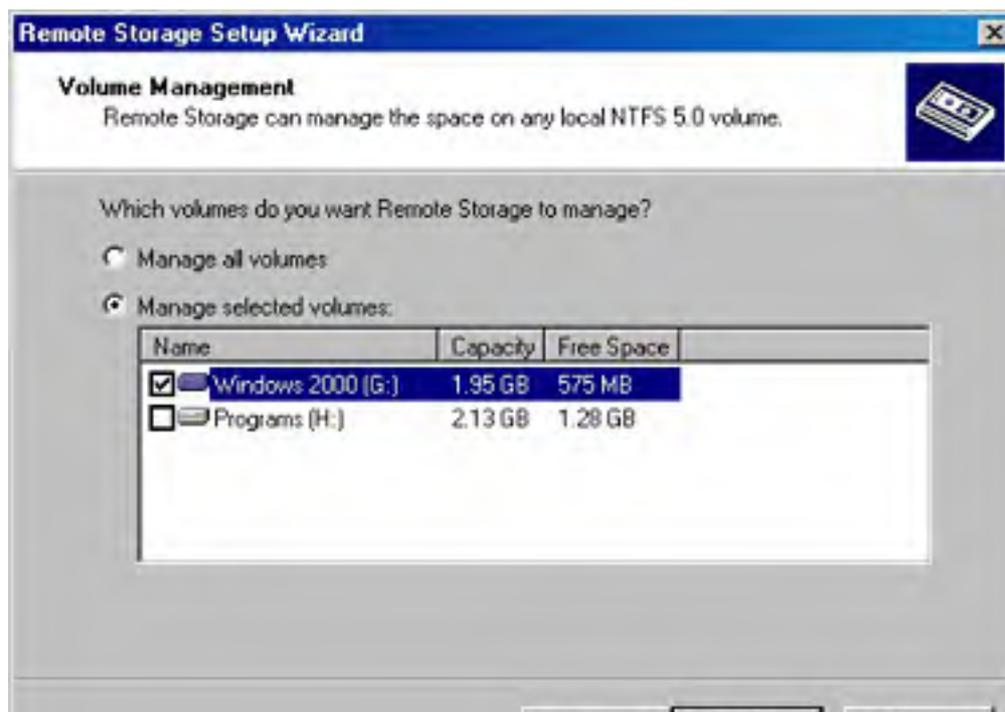

The following sections explain how to set up Remote Storage, how to configure it optimally, and how to ensure that your data is appropriately protected from disaster.

If you launch Remote Storage and walk through the Remote Storage Setup Wizard before you configure the system with a supported storage library, you need to uninstall and reinstall Remote Storage to use it, as Remote Storage won't detect added devices after installation.

## Setting Up Remote Storage

Remote Storage is easy to set up. Just make sure that the storage library you want to use with Remote Storage is connected and configured, and then follow these steps:

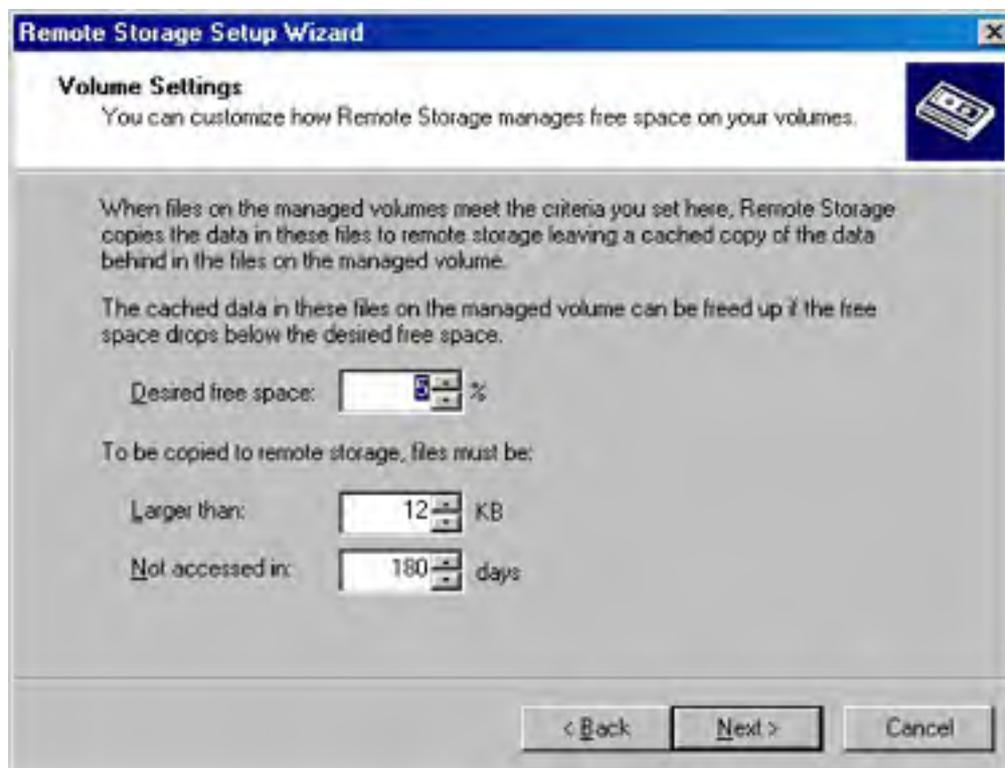

1. Open the Add/Remove Programs tool from the Control Panel.
2. Click Add/Remove Windows Components in the left pane.
3. Select the Remote Storage check box, if it isn't already selected, and click Next.
4. Restart the computer.
5. Launch Remote Storage from the Administrative Tools folder on the Start menu. The Remote Storage Setup Wizard appears. Click Next. The wizard detects any compatible storage devices and checks the security settings.
6. On the next screen, shown in Figure 17-17, select the volumes with which you want to use Remote Storage (only NTFS volumes appear), and then click Next.

**Figure 17-17.** The Volume Management screen of the Remote Storage Setup Wizard.

7. In the Desired Free Space box, enter the minimum amount of free space you want available on the managed volumes, as shown in Figure 17-18.
8. In the Larger Than box, enter the size of the smallest files you want Remote Storage to migrate to tape if more disk space is needed.

**Figure 17-18.** The Volume Settings screen of the Remote Storage Setup Wizard.

9. In the Not Accessed In box, enter the number of days that need to have passed since the file was last accessed for the file to be eligible for migration to tape. Click Next.
10. Select the media you want Remote Storage to use from the Media Types drop-down list box (only detected, supported media are listed). Click Next.

Be sure to select the correct media type because it can't be changed later.

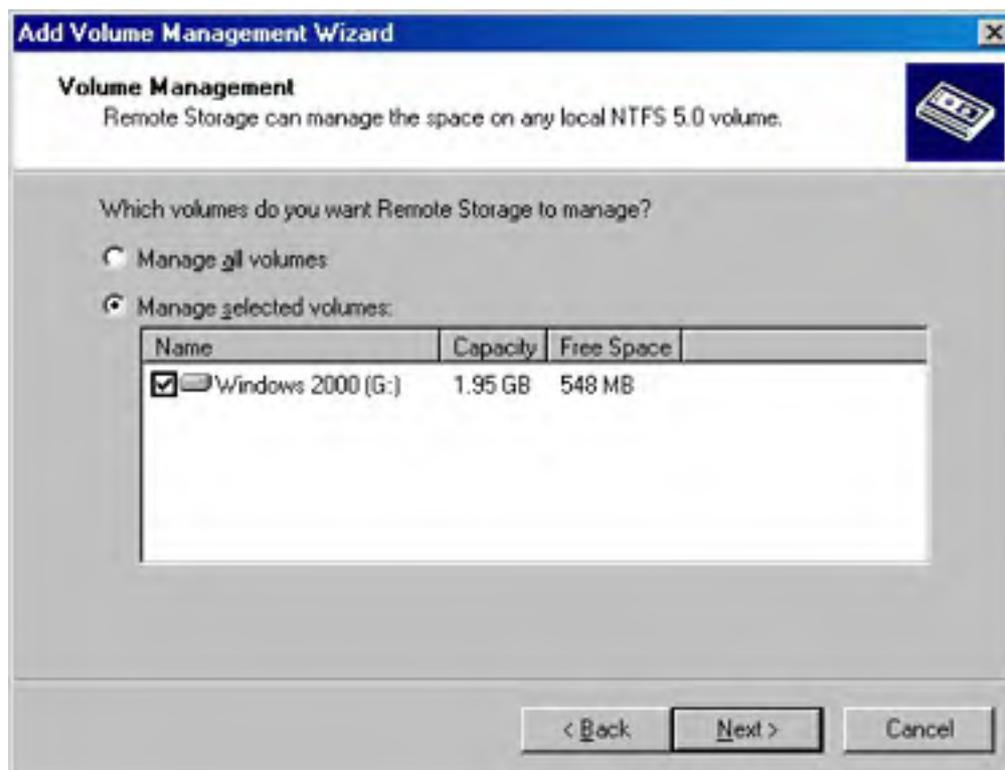

11. Click Change Schedule to change when Remote Storage copies files to tape, or click Next to continue.
12. Review the settings you entered, and then click Finish to complete the Remote Storage setup.

## Setting Up Additional Volumes with Remote Storage

If you want to set up additional storage volumes on the system for use with Remote Storage after you've already completed the initial setup, you can use the Add Volume Management Wizard. To do so, follow these steps:

1. Launch the Remote Storage MMC snap-in from the Administrative Tools folder on the Start menu, or enter `%SystemRoot%\System32\RsAdmin.msc` into the Run dialog box or at a command prompt.
2. Select the Managed Volumes folder in the console tree.
3. Click the New Managed Volume(s) toolbar button to launch the Add Volume Management Wizard, and then click Next on the first screen.

4. Select the check box next to the NTFS 5 volume you want, or choose the Manage All Volumes option to instruct Remote Storage to manage all eligible volumes (Figure 17-19). Click Next.

**Figure 17-19.** The Volume Management screen of the Add Volume Management Wizard.

5. In the Desired Free Space box, enter the amount of free space you want to have on the volume, as a percentage of total space.
6. Enter the minimum file size you want Remote Storage to migrate to tape in the Larger Than box. Note that migrating files smaller than 12 KB generally doesn't make sense because they don't take up much room, but you can change this setting as needed.
7. In the Not Accessed In box, enter the number of days that must elapse since a file was last accessed before the file is eligible for migration to remote storage. Click Next. Keep in mind that setting this number too high limits the amount of disk space that Remote Storage can free up, but setting it too low causes an unnecessary amount of recall from tape.
8. Review the settings on the final wizard screen, and then click Finish.

## Changing Volume Settings

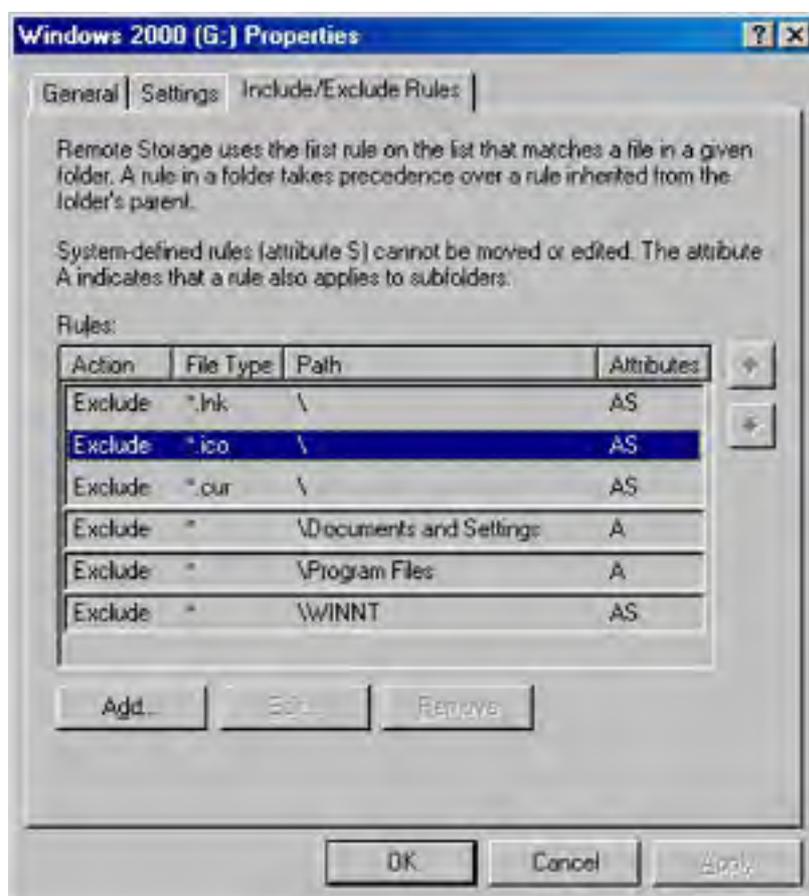

Remote Storage uses a set of rules to govern which files are eligible for migration to remote storage. You set these rules initially when you set up a storage volume on the computer for Remote Storage to manage, using either the Remote Storage Setup Wizard or the Add Volume Management Wizard. However, you might want to change these settings later or add exclusions such that certain file types never get migrated to tape. To do this, follow these steps:

1. Launch the Remote Storage MMC snap-in from the Administrative Tools folder on the Start menu.
2. Select the Managed Volumes folder in the console tree, right-click the volume you want to configure, and choose Settings from the shortcut menu.

3. In the Desired Free Space box, enter the amount of free space you want to have on the volume, as a percentage of total space.

You can also change a managed volume's settings by right-clicking the volume in Windows Explorer, choosing Properties from the shortcut menu, and then clicking the Remote Storage tab. However, you can't change inclusion and exclusion rules from here.

4. Enter the minimum file size you want Remote Storage to migrate to tape in the Larger Than box. Most users find that if anything, they'll want to increase this file size, although if you have a lot of seldom-accessed smaller files, you could consider lowering this setting also.
5. In the Not Accessed In box, enter the number of days that must elapse since a file was last accessed before the file is eligible for migration to remote storage. Keep in mind that setting this number too high limits the amount of disk space that Remote Storage can free up, but setting it too low causes an unnecessary amount of recall from tape.
6. Click the Include/Exclude Rules tab to create or modify rules that specify file types to exclude from Remote Storage, as shown in Figure 17-20.
7. Select a rule that you want to modify (some rules can't be changed), and then click Edit to modify the rule or Remove to delete it.

**Figure 17-20.** The Include/Exclude Rules tab of a managed volume's Properties dialog box.

- To add a new rule, click Add to display the Edit Include/Exclude Rule dialog box, shown in Figure 17-21.

**Figure 17-21.** The Edit Include/Exclude Rule dialog box.

- Enter the folder path you want to apply the rule to in the Path box, or enter a backslash to apply the rule to the entire volume.
- In the File Type box, enter the type of file that you want to include or exclude from Remote Storage.
- Select Exclude Matching Files if you want to exclude files matching the criteria from Remote Storage.
- Select Include Matching Files if you want to explicitly allow Remote Storage to manage files matching the criteria. This is useful if you want to make an exception to an exclude rule for only a certain folder.
- Select the Apply Rule To Subfolders check box if you want Remote Storage to apply the rule to all subfolders of the folder listed in the Path box.

## Turning Off Remote Storage for a Managed Volume

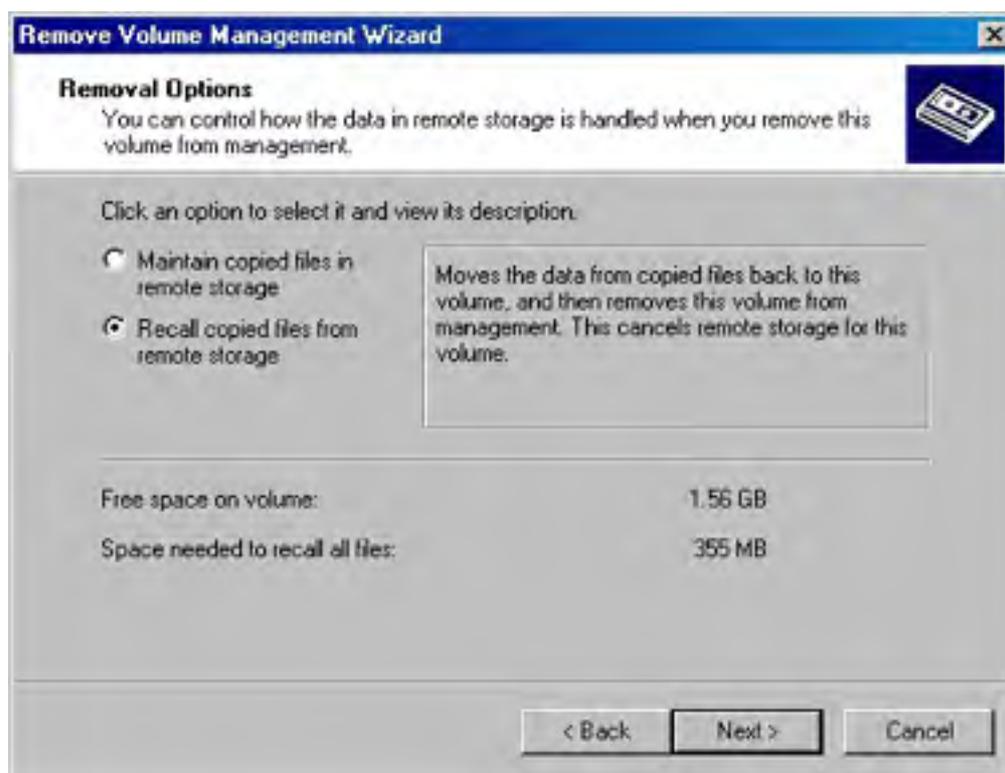

If you plan to uninstall Remote Storage, discontinue managing all of the volumes and recall the files in remote storage. This step is important because if you don't, files stored in remote storage will be lost.

You might also want to do this if you plan to perform a complete (clean) reinstallation of Windows 2000. Recalling the data allows you to either leave the data intact on the drive while reinstalling Windows, or back up the data using a backup program that isn't Remote Storage aware. (If you want to reformat the drive, you can back up the data and then restore it once you're finished with the installation.) If you don't recall the data or back up all data (including data in remote storage) before doing a clean reinstall of Windows 2000, you're left performing a somewhat complicated and risky Remote Storage recovery procedure. See the section entitled [Data Recovery and Protection](#), later in this chapter, for more information.

Another case in which you might choose to discontinue Remote Storage's management of a volume is when the library you're using for the volume fills up and you don't want the remote storage database to include offline media. In this instance, you can discontinue Remote Storage's management of the volume, which tells Remote Storage to stop adding files to remote storage but to not recall the files already in remote storage.

Whatever the reason for ending Remote Storage's management of a volume on the system, you can use the Remove Volume Management Wizard to remove a managed volume from Remote Storage as follows:

1. Launch the Remote Storage MMC snap-in from the Administrative Tools folder on the Start menu.
2. Click Managed Volumes in the console tree.
3. Right-click the volume you want to remove from Remote Storage and then choose Remove from the shortcut menu. Click Next when the Remove Volume Management Wizard opens.
4. To recall all files from remote storage and place them back on the managed volume so that Remote Storage is no longer used at all on this volume, select the Recall Copied Files From Remote Storage option, shown in Figure 17-22. Note that the managed volume needs to have enough free disk space to hold all recalled files.

**Figure 17-22.** The Removal Options screen of the Remove Volume Management Wizard.

5. To stop Remote Storage from adding files to remote storage while letting it continue to manage the files currently in remote storage, select the Maintain Copied Files In Remote Storage option, and then click Next.
6. Click Yes in the dialog box that opens.
7. Review the settings and then click Finish to implement them.

### Performing Tasks Manually

Remote Storage is configured to perform almost all operations automatically, using the Windows 2000 Scheduled Tasks folder. However, sometimes you might need to immediately copy all eligible files to remote storage, create additional free space on a managed volume, or validate all placeholders. To perform these tasks, follow these steps:

1. Launch the Remote Storage MMC snap-in from the Administrative Tools folder on the Start menu.
2. Click Managed Volumes in the console tree.

3. Right-click the volume you want to perform a task on, choose All Tasks from the shortcut menu, and then choose the appropriate task from the submenu. See Table 17-5 for a description of the tasks you can perform.
4. Click OK in the dialog box that opens.

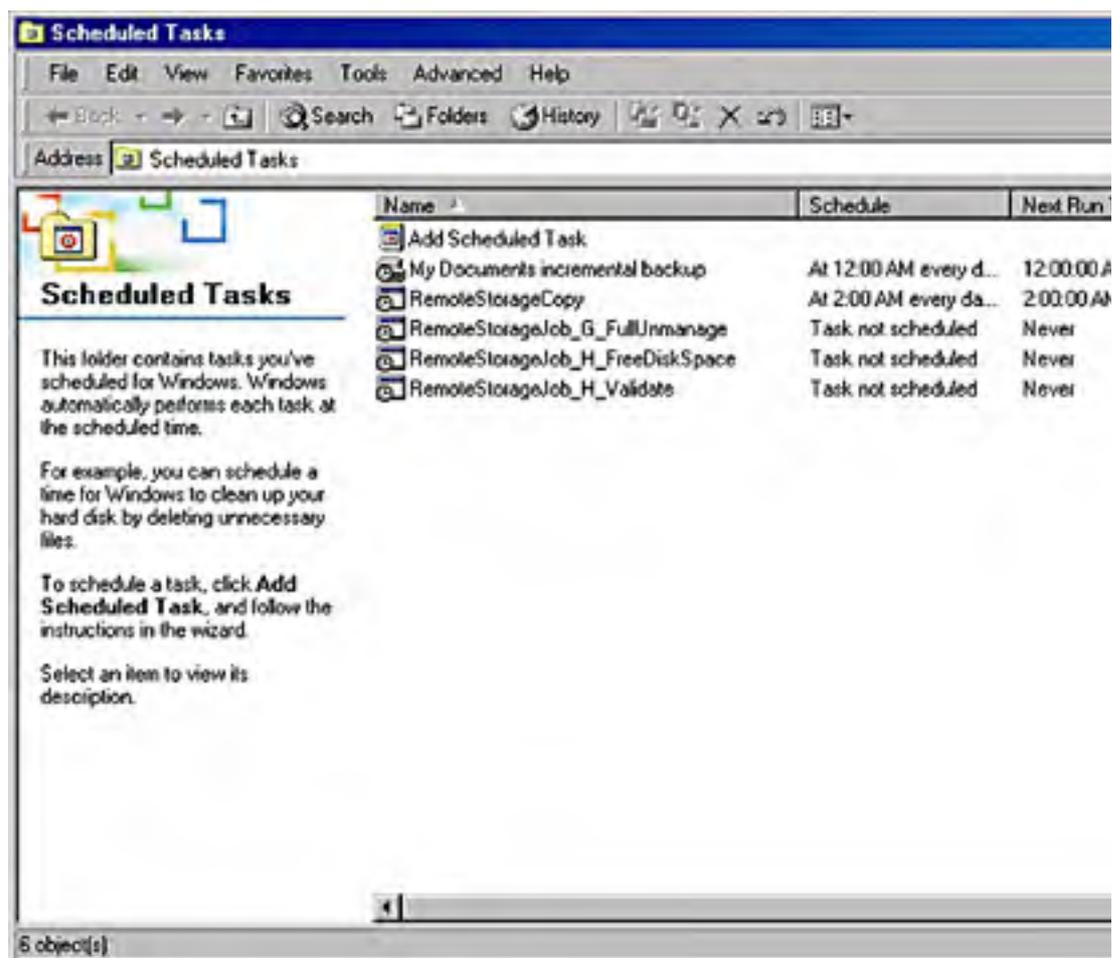

**Table 17-5.** Tasks that you can perform manually

Task	Description
Copy files to remote storage	Immediately copies all eligible files on the managed volume to remote storage.
Validate files	Verifies that all placeholders and locally cached files are still linked to valid data in remote storage, and updates volume statistics.
Create free space	Removes all cached data from files that have already been migrated to remote storage. This creates free space only if there is data cached locally.

## Viewing Remote Storage Tasks

Remote Storage places all tasks in the Scheduled Tasks folder—both tasks that Remote Storage performs automatically and tasks that you perform manually. To view the tasks or modify when (or whether) they are performed, follow these steps:

1. Open the Scheduled Tasks folder by opening the Start menu and choosing Programs, Accessories, and then System Tools (Figure 17-23).

**Figure 17-23.** The Scheduled Tasks folder.

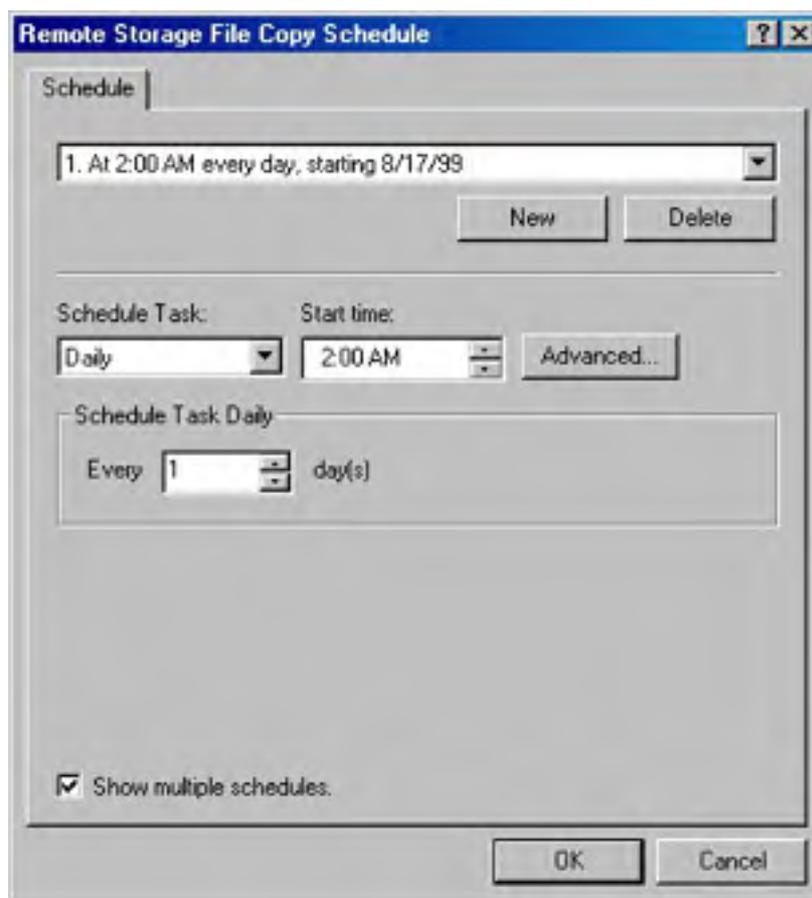

2. To perform a scheduled task immediately, right-click the task and choose Run from the shortcut menu.

3. To cancel a currently running task, right-click the task and choose End Task from the shortcut menu.
4. To view the properties of the task (perhaps to change the schedule), right-click the task and choose Properties from the shortcut menu.

### Changing Task Schedules

To change the schedule Remote Storage uses to copy files to remote storage, or to validate placeholders and cached files or create free disk space, follow these steps:

1. To change the Remote Storage file copy schedule, right-click the Remote Storage root in the Remote Storage console tree and choose Change Schedule from the shortcut menu.
2. Click Change Schedule.
3. Use the dialog box provided to set up the schedule, shown in Figure 17-24.

**Figure 17-24.** The Remote Storage File Copy Schedule dialog box.

4. To make multiple schedules, select the Show Multiple Schedules check box and use the New and Delete buttons to add or remove schedules.
5. To modify advanced scheduling information, click Advanced.
6. To modify the schedules for other Remote Storage tasks, open the Scheduled Tasks folder by opening the Start menu and choosing Programs, Accessories, and then System Tools.
7. Right-click the task and choose Properties from the shortcut menu.
8. Click the Schedule tab and then modify the scheduling information as described in steps 4 and 5.

### Setting Recall Limits

As described in the section entitled [Program Compatibility](#), earlier in this chapter, the Remote

Storage recall limit feature can come in handy because programs that aren't Remote Storage compatible such as backup, antivirus, and search programs have an annoying knack for pulling all the data out of remote storage, making Remote Storage fairly useless.

When you set a recall limit, also known as a runaway recall limit because it limits only recalls that take place within 10 seconds of the last recall, you prevent these automatic assaults on the remote storage by stopping runaway recalls from remote storage. This usually doesn't affect end users because most users aren't that fast, unless they're performing a mass copy operation. To configure the recall limit, follow these steps:

1. Right-click the Remote Storage root in the Remote Storage console tree and choose Properties from the shortcut menu.
2. Click the Recall Limit tab, shown in Figure 17-25.

**Figure 17-25.** The Recall Limit tab of the Remote Storage (Local) Properties dialog box.

3. In the box provided, enter the number of successive recalls that take place within 10 seconds of the last recall that you want to allow before preventing further recalls. If the users frequently perform mass copy operations and you use Remote Storage-aware applications, you might want to set this limit higher; otherwise, leave it alone or reduce it as needed.
4. If you want to exempt users with administrative privileges from this limit, select the Exempt Administrators From This Limit check box.

Selecting the Exempt Administrators From This Limit check box allows incompatible applications run by an administrator to potentially recall all files from remote storage if the administrator doesn't explicitly kill the process recalling the data.

## Data Recovery and Protection

You might think that because data stored remotely is on tape, it's safe. Perhaps in some ways it is safer than when it's located on a local hard disk, but data protection is even more important for remotely stored data because of the inability of tape devices to have fault tolerance such as mirrored drives. Also, because the technology is new, an administrator is more likely to make an error that prevents data recovery from remote storage. Therefore, you must learn about and implement a good data protection plan.

Because even the best data protection plans can't always prevent a disaster, you must also know how to recover data if a problem occurs. The following sections teach you how to protect and recover data with Remote Storage.

## Understanding Data Protection Strategies

The strategy you use to protect the remotely stored data will vary somewhat depending on your ability to create copies of the Remote Storage media. (You need two drives of the same media type to do this.)

Most of you don't need to be told to back up Windows 2000 itself—you know that backing up your operating system is as important as backing up your data. However, if you're one of those rare administrators who doesn't already do this, you should know that the entire Remote Storage database is stored in only two places: the `%SystemRoot%\System32\RemoteStorage` folder and on each media master tape. If the local folder is deleted, you're stuck restoring from your Remote Storage tapes—a complicated procedure (described in Microsoft Knowledge Base article Q235469). We highly recommend that you perform full backups of all essential servers.

**Single Drive Strategies** If you're using only a single tape drive with Remote Storage, back up the local files according to your preexisting backup plan. For example, you might perform an incremental backup every night and a full backup every weekend. For full backups, make sure that you instruct the backup program to back up migrated Remote Storage data, or else you won't have any backup of data in remote storage. Note that this almost certainly means backing up to a different drive than the one holding the Remote Storage media. If you don't have another backup device, consider purchasing a duplicate of the Remote Storage device and follow the advice in the next section, "Multiple Drive Strategies"—you'll be better off in the end.

You probably don't need to back up migrated files on the differential or incremental backup schedule because files that are added to remote storage probably haven't changed since the last full backup. In the event of disaster, restore these files to local storage from the last full backup. If the files have changed since the last full backup *and* have been migrated to remote storage and had their local cache removed (if you have a long backup schedule or a short migration schedule and a full volume), you can restore the files from a recent differential or incremental backup. Keep in mind, of course, that the longer you go between full backups, the more incremental patches you'll have to apply if you need to restore from backup (a good reason to use differential backups instead), or the more data that is lost if you don't frequently perform incremental backups. See [Chapter 35](#), "Using Backup," for more information on using the Windows 2000 built-in backup utility.

The backup schedule that is best varies from situation to situation. Always closely evaluate the importance of the data. The more important the data, the more stringent the backup strategy and fault tolerance plans need to be.

In addition to the regular backup schedule, frequently verify the remote storage placeholders and cached files to make sure that they are still linked to valid data in remote storage. Note that Remote Storage automatically creates an appropriate validation schedule during installation.

**Multiple Drive Strategies** Multiple drives of the same media type provide additional flexibility in Remote Storage. Although the backbone of the data protection plan will still rest on a good backup plan, you can supplement this by creating copies of the remote storage media and frequently synchronizing the copies.

Back up the local files according to your preexisting backup plan. For full backups, you can choose to instruct the backup program to back up migrated Remote Storage data. This provides some extra insurance by eliminating the need to deal with Remote Storage when recovering; instead, you simply restore all data to local storage and don't even worry about Remote Storage. This is a good idea if you have the facilities (and time) to do it. Otherwise, back up only local storage according to the normal backup schedule.

You can't restore Remote Storage files to another computer. If you want to be able to restore data to another computer, you must use backups that also backed up migrated remote storage files.

In addition to your backup schedule, you should make one to three copies of the *media master* (the media that holds the remote storage data), and routinely synchronize them. If the media master fails, you can re-create it from one of the copies. If you don't back up the migrated remote storage files during the full backups, make sure that you synchronize a media copy and keep it with your full backup. This ensures that the full backup has all data backed up.

If you want to keep your backup sets complete, either perform a full backup (including data in Remote Storage) or back up only local storage, and then add a synchronized media copy to the backup set (by dragging it to the Backup media pool). The media copy you add to the backup set is removed from the Remote Storage media pool, allowing another media copy to be generated to replace it.

In addition to the regular backup schedule, you should frequently verify the remote storage placeholders and cached files to make sure that they are still linked to valid data in remote storage. Remote Storage automatically creates a validation schedule when you install it, and this is usually fine for most purposes. Just make sure that it covers all the volumes Remote Storage manages.

### Working with Media Copies

Because you can't create fault-tolerant arrays of remote storage devices, Microsoft provides the ability to create copies of Remote Storage media so that some level of redundancy exists for remotely stored data. The next several sections show you how to work with media copies: how to specify the number you want, how to delete them, how to synchronize them, and how to re-create a failed media master from a media copy.

Place new media in the free media pool instead of manually in the Remote Storage pool. Remote Storage automatically takes and appropriately formats media from the free media pool when necessary.

**Changing the Number of Media Copies** You don't explicitly create media copies for Remote Storage; instead, you specify how many you want and Remote Storage automatically goes about creating them. When one copy is finished, Remote Storage begins creating the next copy, provided enough media is available in the Remote Storage application pool or free media pool. Each group of media copies is called a *media copy set* and includes one copy of each of the media masters. (It's possible to have more than one media master when the amount of data in remote storage is too big to fit on one tape.) To specify the number of media copy sets you want, follow these steps:

1. Right-click the Remote Storage root in the Remote Storage console tree and choose Properties from the shortcut menu.
2. Click the Media Copies tab, and then specify the number of media copy sets you want to create for each media master set (up to three maximum).

If you decide that you don't need as many media copy sets as you originally thought, you can decrease the number of sets that Remote Storage displays and accesses, as just described. However, note that doing so does *not* deallocate any media. If you want to free up media, you need to delete the media copies, as described in the next section.

**Deleting and Checking the Status of Media Copies** If you no longer need a media copy or want to check to see whether the media copy is functioning well (that is, to see if you have a bad tape), you should delete or check the media copies. Don't just reduce the number of copies Remote Storage supports. To delete or check on the status of a media copy, follow these steps:

1. Select the Media folder in the Remote Storage console tree.
2. Right-click the media master that is associated with the media copy you want to delete or check, and then choose Media Copies from the shortcut menu.

3. View the status information of the media copies, and then click the appropriate Delete Copy button for any media copies you want to delete.

**Synchronizing Media Copies** Synchronizing media copies is so easy it's ridiculous. Just open the Remote Storage MMC snap-in, right-click Media in the console tree, and then choose Synchronize Media Copies from the shortcut menu. The Media Synchronization Wizard appears and walks you through the rest of the process. It's a piece of cake.

You can't recall or copy data to remote storage while synchronizing media copies. Therefore, you might want to synchronize the media copies after hours.

**Adding Media Copies to Backup Sets** To create a complete backup set that includes a full backup of local and remote storage, you can either use Backup to perform a full backup that includes Remote Storage files, or you can perform a full backup of local storage and add a media copy to the backup set. You can then eject the media copy and keep it with the backup tapes, and you can also regenerate a new media copy (so you don't use up one of the three media copies).

To do so, open the Removable Storage console and then use the following procedure:

1. In the console tree, select Media Pools, then Remote Storage, and then the appropriate media type for your system.
2. Right-click the synchronized media copy and choose Copy from the shortcut menu.
3. Select the Backup media pool.
4. Right-click the appropriate Backup media pool and choose Paste from the shortcut menu. The media copy is added to the Backup media pool, so you can then eject it and keep it with the rest of your backup set. Remote Storage automatically regenerates the ejected media copy with media from the Remote Storage or free media pools.

**Recreating a Media Master in Case of Disaster** If the media master is damaged or lost, you can re-create it from a recently synchronized media copy. Note that you'll lose all data that has been migrated to remote storage since the last time you synchronized the media copy unless the data's local cache hasn't been erased yet. So follow these steps only if you're experiencing errors:

1. Make sure that you have sufficient media available in the remote storage pool or free media pool, and then open the Media folder in the Remote Storage console tree.
2. Right-click the most recently synchronized media copy for the media master that you want to re-create, and then choose Media Copies from the shortcut menu.
3. Click the Recovery tab and click Re-create Master.

**Recovering from Disaster** Disasters happen. Servers go down. Drives fail. The cable goes out during the Super Bowl. These are facts. However, if you're prepared ahead of time, you can reduce the negative impact of disaster when it strikes.

A few different types of disasters can occur with Remote Storage, and a few ways exist to recover from them. If the hard disk fails, restore locally stored files from the religiously kept backups, but be careful not to perform a Remote Storage validation operation until all incremental or differential backups are restored. As long as the Remote Storage database stored in the %SystemRoot%\System32\RemoteStorage folder isn't affected, you don't need to do anything else other than perform a validation operation to clean up any invalid placeholders.

If the hard disk storing Windows 2000 fails, restore the system from backup if possible. The system should function normally; however, you might see the following error when recalling a file from remote storage:

*Path\filename.doc*. The file cannot be accessed by the system.

If you experience this error, see Knowledge Base article Q235469 and perform the Restore A Damaged RSS Database procedure.

If you need to perform a clean reinstall of Windows 2000, the best approach is to first recall all data from remote storage. (Refer to the [Turning Off Remote Storage for a Managed Volume](#) section earlier in this chapter.) However, if a disaster occurs that precludes you from recalling the data and you can't restore the system from backup, you need to perform a special procedure to restore the Remote Storage database from the Remote Storage media after reinstalling Windows 2000.

The basic procedure is to perform a clean install of Windows into the same drive and folder as it was before, without installing Remote Storage, and then restore the Removable Storage database. Next, install Remote Storage and use the Rstore.exe command-line tool to restore the Remote Storage database. This is tricky business, so we're going to refer you to the *Windows 2000 Server Resource Kit* and Knowledge Base articles Q235469 and Q235032 for the exact procedures.

## Shared Folders

After examining the Distributed file system, Removable Storage, and Remote Storage, discussing sharing folders on the network or the Internet sounds a bit commonplace. Nevertheless, sharing folders is important and we're going to tell you how to do it anyway.

### Using the Shared Folders Snap-In

You can administer shared folders in Windows 2000 in two ways. You can right-click a shared folder in Windows Explorer and choose Sharing from the shortcut menu, or you can use the Shared Folders MMC snap-in. The Shared Folders MMC snap-in provides a way of viewing all of the file shares at once, along with the current connections and open files. Windows Explorer doesn't. Therefore, we're going to talk about the Shared Folders MMC snap-in now, and we'll talk about Windows Explorer later, in the section entitled [Configuring Web Shares](#).

To use the clearly superior Shared Folders tool (not that we're biased), follow these steps:

1. Open the Computer Management MMC snap-in from the Administrative Tools folder on the Start menu, or enter `%SystemRoot%\System32\Compmgmt.msc` in the Run dialog box or at a command prompt.
2. Expand the Shared Folders folder in the console tree (Figure 17-26).
3. Use the Shares, Sessions, and Open Files folders to view the current file shares on the system you're managing and to see how much activity the shares are getting.

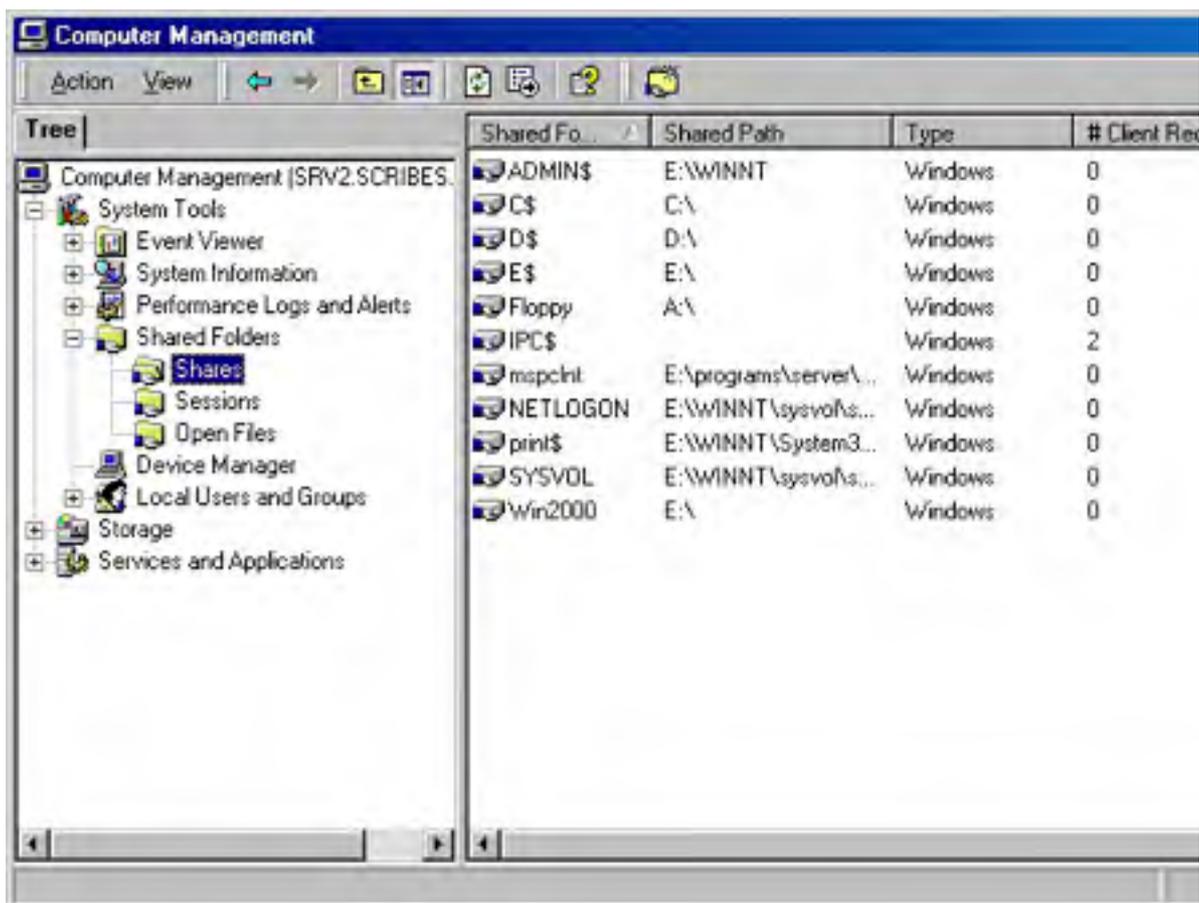

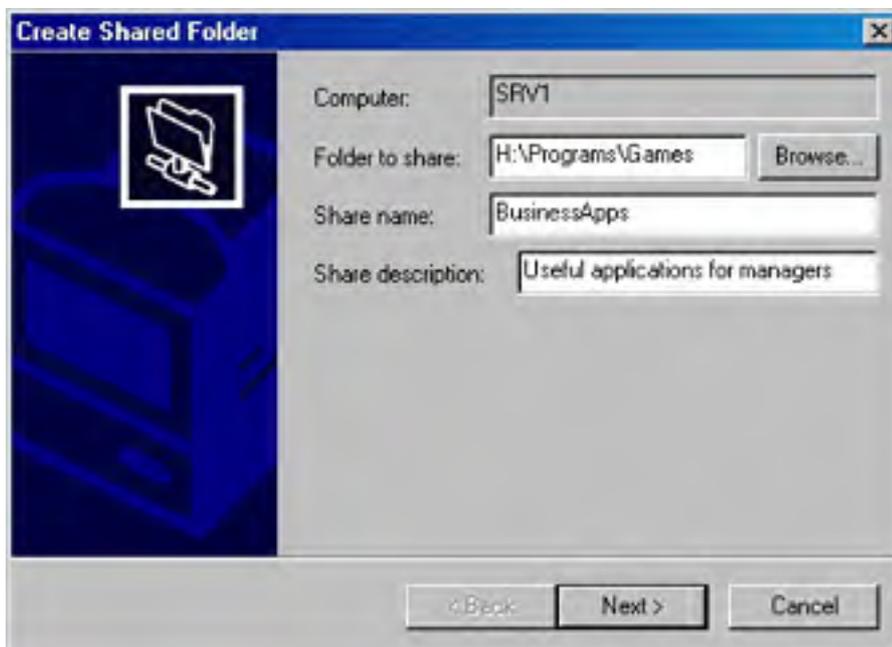

Figure 17-26. The Shared Folders tool in the Computer Management console.

### Setting Up Shared Folders

It's easy to share a folder or volume on the system with other users on the corporate network. Just follow these steps:

1. In the Computer Management console, open the Shared Folders folder in the console tree.
2. Right-click the Shares folder and choose New File Share from the shortcut menu.
3. In the Create Shared Folder dialog box shown in Figure 17-27, click Browse to locate or create the folder you want to share.

**Figure 17-27.** The Create Shared Folder dialog box.

4. Enter the name you want to give the file share. This name should ideally be DNS and NetBIOS compatible for the best interoperability with downlevel and non-Microsoft clients.
5. Enter a description for the shared folder in the Share Description box, and then click Next.
6. Optionally, specify the Share Level permissions for the folder, and then click Finish.

### **Real World**

#### **Setting Permissions**

We strongly recommend that you implement NTFS file-level permissions *instead* of share-level permissions. Using share-level permissions alone isn't secure enough in most instances, and using both introduces an unacceptable level of complexity.

However, there are some exceptions to this rule; for example, you might want to permit all authenticated users to access a volume in a certain subfolder but allow only a certain group to access the root directory. (Administrators can always access the root folder for a drive by connecting to the drive's hidden administrative share, for example, C\$.) In this instance, you could create two file shares: one at the subfolder level with no share-level security and one at the root folder level with share-level security to allow only the specified group access.

Somewhat more useful is the ability to hide file shares by adding the dollar sign (\$) character to the end of the share name. This notation allows any user to connect to the share—provided he or she knows the share name. Once users connect, they're still bound by NTFS security permissions, but this can be handy for storing useful power tools that an administrator might want to be able to access from a user's system and user account. File security isn't really an issue—you just don't want users mucking around with the files.

## **Ending Folder Sharing**

To stop sharing a folder on the network, follow these steps:

1. In the Computer Management console, open the Shared Folders folder in the console tree and then open the Shares subfolder.
2. Right-click the shared folder you want to stop sharing and choose Stop Sharing from the shortcut menu.
3. Click OK.

## Disconnecting Users

If you need to disconnect users from the server for some reason—say to close off the server while you update the files—follow these steps:

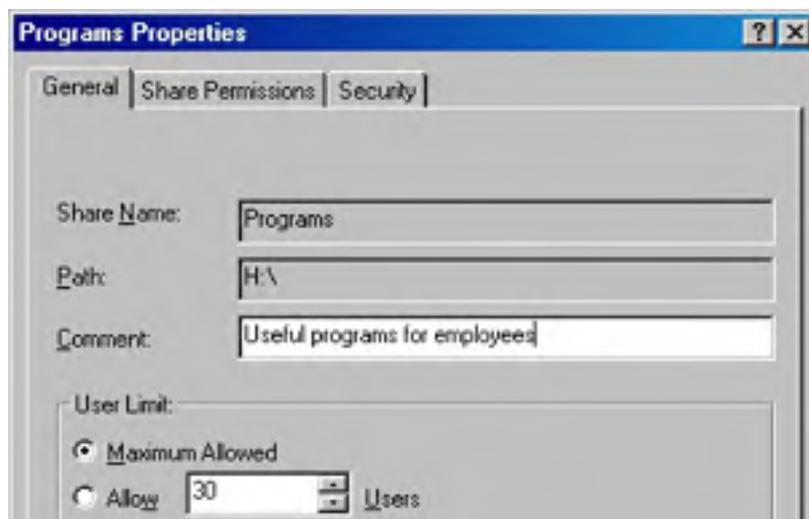

Be kind to your users and warn them before disconnecting them. Disconnecting a user who is working on a file can cause data loss and resultant ill feelings.

1. Open Shared Folders in the Computer Management console, and then open the Sessions subfolder.
2. Right-click the user you want to disconnect, and choose Close Session from the shortcut menu.
3. To disconnect all sessions, right-click the Sessions folder and choose Disconnect All Sessions from the shortcut menu.
4. To close an open file, click the Open Files folder, right-click the file you want to close, and then choose Close Open File from the shortcut menu.
5. To close all open files, right-click the Open Files folder and choose Disconnect All Open Files from the shortcut menu.

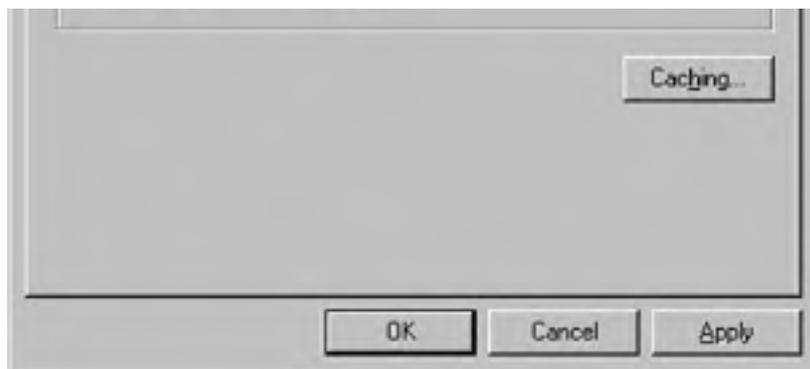

## Limiting Simultaneous Connections

You can limit the number of simultaneous user connections you want to allow to a shared folder so that a given shared folder doesn't overburden the server with user connections. To do so, follow these steps:

1. Open Shared Folders in the Computer Management console, and then open the Shares subfolder.
2. Right-click the shared folder you want to limit access to, and then choose Properties from the shortcut menu.
3. To place no limit on the number of connections you allow to the shared folder (other than that set by the number of licenses you have), select the Maximum Allowed option in the General tab, as shown in Figure 17-28.

**Figure 17-28.** The General tab of a shared folder's Properties dialog box.

4. To manually limit the number of connections you want to allow to the shared folder, enter the number of connections you want to allow in the Allow box, and then click OK.

File shares hosted on computers running Windows XP or Windows 2000 Professional support a maximum of 10 simultaneous users.

## Setting Permissions

As mentioned previously, you really shouldn't use share-level permissions in most instances unless you're not using NTFS file-level security. Share-level permissions allow or deny access to a shared folder depending on the user's group membership and the security settings of the file share and don't apply to locally logged-on users.

File-level security, on the other hand, has a much more granular level of control, providing the ability to grant or deny users and groups the ability to perform a wide range of actions on both folders *and* individual files for both network and local users. Because you would normally use NTFS permissions in a situation where security is important, we generally don't recommend setting share-level permissions. You *can* do it, however, so here's how:

1. Open Shared Folders in the Computer Management console, and then open the Shares subfolder.
2. Right-click the shared folder you want to set permissions for, and then choose Properties from the shortcut menu.
3. Click the Share Permissions tab and have at it (see [Chapter 10](#) for more information on permissions).

Although we discourage the use of share-level permissions, it is appropriate to replace the Everyone group with the Authenticated Users group (give it Full Control permission).

Click Caching in the General tab to control whether or not clients can cache the contents of the file share using the Offline Folders feature of Windows.

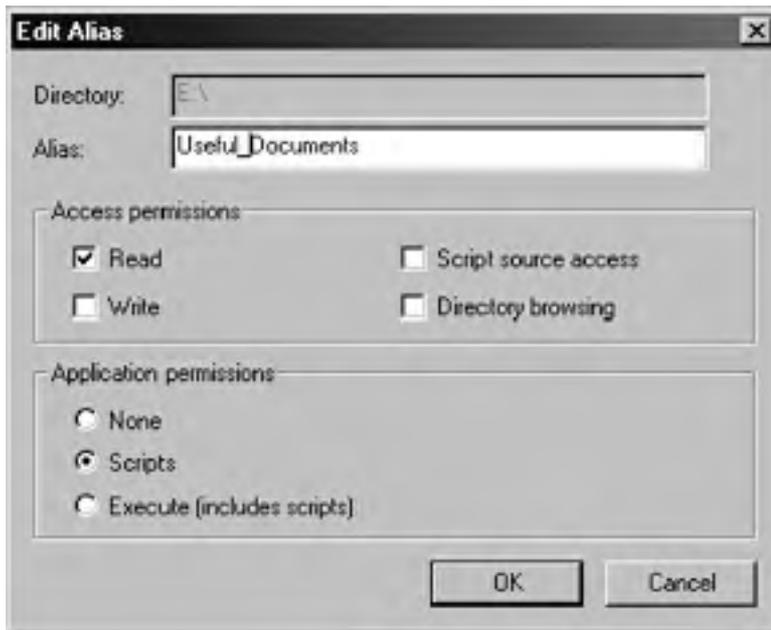

## Configuring Web Shares

You can share folders with users on your intranet, as long as Internet Information Services (IIS) is installed on the system. Although most administrators will set up Web shares using IIS (discussed in [Chapter 28](#)), you can also do it using Windows Explorer. However, before you go about installing IIS and publishing folders on your intranet or anywhere else, proceed to [Chapter 28](#) and review the security suggestions made there.

To share folders on your intranet using IIS, follow these steps:

1. Open Windows Explorer, right-click the folder or drive you want to share on the Web, and choose Properties from the shortcut menu.
2. Click the Web Sharing tab.

3. Choose the Web site you want to share the folder on from the Share On drop-down list box.
4. Select the Share This Folder option, and then in the Edit Alias dialog box that appears (Figure 17-29), enter the folder name you want to use for the share. Note that the alias you enter is appended to the Web site's name: *http://myserver.mycompany.com/alias*.
5. Set the access permissions for the folder by selecting check boxes in the Access Permissions section of the dialog box. (It *is* important to set these access permissions, especially if the server is visible on the Internet.)
6. Use the Application Permissions options to choose which level of permissions you want to grant to applications in this folder, and then click OK.

**Figure 17-29.** The Edit Alias dialog box.

For more thorough control over the Web shares, launch the Internet Services console from the Administrative Tools folder on the Start menu. See [Chapter 28](#) for more information about this.

## Summary

Shared Folders provides an easy way to administer and create file shares on the network, intranet, or Internet, whereas the Distributed file system provides a way of taking all of the disparate file shares and bringing them together into one hierarchical folder structure. Removable Storage provides a much-needed level of abstraction and management for removable storage devices of all types, allowing applications to focus on their core purpose: working with data, not devices and media. Remote Storage builds on this foundation by making it easier for companies to build and maintain immense libraries of archived data, at the same time making it vastly easier to retrieve archived data as necessary.

Together these technologies make Windows 2000 a more powerful server operating system, although one that is sometimes complex to administer. However, this complexity comes from the breadth of features Windows 2000 provides, and Windows 2000 uses these features well by empowering users with simpler and more powerful access to the files they need. Such a complex system requires sophisticated security capabilities. The next chapter covers how to plan a secure operating environment with Windows 2000.

# Chapter 18

## Planning for Security

Security, in definition and practice, has changed tremendously within just the past few years. Stretching technology to increase the scope and latitude of what we're able to accomplish exposes new and often venomous danger points. Amidst the legions of hackers, spies, terrorists, corporate raiders, professional criminals, and vandals, unprotected networks can fall prey to attack. Today's system administrator has real security threats to address and needs to implement a solution that is both safe and unobtrusive.

Microsoft Windows 2000 includes a bevy of configurable security features and options ranging from an entire public-key infrastructure to a protocol that protects individual packets as they cross the network. With that said, Windows 2000 security has come under intense scrutiny and many security gaps have been closed with fixes in Service Packs 1 through 3. Others, no doubt, are waiting to be discovered. However, with some care you should be able to maintain a highly secure Windows 2000 system, one that's more secure than any previous version of Windows and in line with the security offered by UNIX systems.

In this chapter, we introduce cryptographic smart cards, revisit some of the security components that are integral to earlier Microsoft products, and explore the new security features added to Windows 2000. We review the common denominators of security such as authentication, data protection, and access control. We tour the Windows 2000 public-key infrastructure and take a detailed look at some of the security-enabled protocols the server uses. We introduce virtual private networks (VPNs). Finally, we cover the underlying cryptographic application interface in Windows 2000, Microsoft Cryptographic Application Programming Interface (Cryptographic API, or CryptoAPI).

## Smart Cards

New to the Windows 2000 authentication suite is the support of cryptographic smart cards. A *smart card* is a tamper-resistant, credit card-like hardware token that can be used to add more protection to security-enabled protocols and applications. Unlike credit cards, which have magnetic strips on the back, smart cards use metallic contacts as the hardware interface and require a card reader—Plug and Play readers are recommended for use with Windows 2000. Manufacturers typically provide a software application interface, such as Crypto Service Provider, for use with Microsoft CryptoAPI, or they use a PKCS #11 module. Support for Gemplus, GemSAFE, and Schlumberger Cryptoflex smart cards is included with the Windows 2000 installation.

Smart cards provide the strongest form of user authentication in Windows 2000 aside from biometric technologies such as fingerprint recognition and retinal scanning devices that are becoming commercially available. Either a PIN or a password is required to access the card, which protects the user's credentials from both rogue parties and applications. In addition to storing public-key certificates and private keys, smart cards can also provide on-card functionality, such as digital signing, to ensure that a user's private key is never exposed.

Unlike software private keys, smart cards can also be moved from computer to computer with ease, providing a high portability level for a user's credentials. Included in the list of security features is the ability to block a smart card from the system after a certain number of unsuccessful logon attempts, making dictionary attacks impractical. (A *dictionary attack* is a password attack in which a malicious user sends hundreds or thousands of credentials by using a list of passwords based on common words or phrases.)

## Security Basics

The term *security* covers a lot of ground, and Windows 2000 uses a wide range of methods and mechanisms to implement security. However, before you can evaluate those mechanisms, you need to know what a good security system is designed to accomplish. For all the protocols, passwords, and secret keys, security revolves around three basic concepts:

- **Authentication** Confirming the identity of a person or entity before allowing accesses to a resource
- **Data protection** Ensuring the privacy and integrity of transmitted or stored data
- **Access control** Restricting the access of data and resources to privileged users

In addition to these three security mainstays, two other security features are discussed in this section: auditing and nonrepudiation.

### Authentication

*Authentication* describes the process in which a person or entity identifies itself to a second party. In general terms, this can mean showing a driver's license to a bank teller or inserting a bank card into an ATM and entering a PIN. In computer language, authentication is a bit more deductive. Unlike the bank teller, who has the luxury of personal contact, nearly all computer-related authentication scenarios are virtual. In a Windows 2000 environment, authentication involves two distinct processes: interactive logon and network authentication.

*Interactive logon* means logging on to either a domain account or a local computer. Previous versions of Windows were password-based only; Windows 2000 logon now allows smart card authentication. Once the user is logged on to the domain account, network authentication is required to identify the user to each network resource he or she requires.

### Proof of Identity

Typically, *proof of identity* comes in the form of a shared secret between the requestor and the authenticator: a password, a PIN, or an encryption key. The principal word here is "secret." The fulcrum of the entire authentication process is the authenticator's belief that the requestor—and only the requestor—possesses that secret. Once this fails to be true, the system, to some degree or another, is compromised.

Depending on the protocol being used, the shared secret is communicated to the authenticator, who then either grants or denies access. Secure protocols protect the secret in transit; more elaborate schemes don't send the secret at all. Public-key technology uses a *pair* of encryption keys—a private key that is never exposed and a public key that can be disseminated. The next section explores the types of protocols Windows 2000 uses to prove possession of identification credentials.

### Authentication Protocols

Clearly, the effectiveness of an authentication process and the safety of your secret depend on the protocol being used. Countless books before this one have guided users through installations that require choosing a unique password and then warned them against the hazards of losing the password. Yet how many of our passwords leave our fingertips and slip unprotected through a network? Table 18-1 shows the Windows 2000 protocols that are designed purposely to thwart would-be attackers and authenticate both internal and external users. Active Directory service maintains user accounts that hold security credentials for authentication purposes, such as passwords and public-key certificates, and it can store multiple security credentials for each of these protocols.

**Table 18-1.** *Authentication protocols*

Protocol	Used For
Kerberos version 5	Network authentication. Provides mutual authentication between user and resource.
Secure Socket Layer/Transport Layer Security (SSL/TLS)	Network authentication. Based on X.509 public-key certificates.

Windows NT LAN Manager (NTLM)	Network authentication. Used for Windows NT 4 compatibility.
Microsoft Challenge Handshake Authentication Protocol version 2 (MS-CHAP v2)	Network and dial-up authentication. Uses separate encryption keys for sending and receiving.
Extensible Authentication Protocol (EAP)	Network and dial-up authentication. Provides support for additional authentication schemes, including smart cards.
Password Authentication Protocol (PAP)	Network and dial-up authentication. Sends passwords in clear text.

## Hardware-Enabled Authentication

Hardware is used for authentication purposes to make it more difficult for someone to impersonate a requestor. By storing encryption keys on a smart card, a PC card, or any other cryptographic token, the logon becomes a more secure process. It requires an extra level of possession that a mere password does not. It requires something you *know*—a PIN or password to access the smart card—and something you *have*—the smart card itself. An attacker might somehow obtain your PIN, but without the smart card, the PIN or password is useless. To decrease the vulnerability of secret keys, well-designed cryptographic tokens generate encryption keys directly on the token and prohibit extraction of encryption keys, except possibly in encrypted form.

We're also beginning to hear much about the use of *biometrics* to facilitate authentication: fingerprint identification, face recognition, and hand geometry verification. Biometrics extend the logon requirements considerably, from something you know or have, to something you *are*.

### More Info

Federal Information Processing Standards Publication number 1401 (FIPS 140-1) is a standard published by the National Institute of Standards and Technology (NIST) that specifies security requirements for cryptographic modules. The standard identifies four levels of security: Levels 1-4, with Level 1 representing the lowest level of security and Level 4 representing the highest. You can find this standard at <http://csrc.nist.gov/fips/fips1401.htm>.

## Mutual Authentication

Authentication isn't necessarily a one-way street. Many times a requestor wants proof of identity from the authenticating host. For instance, when creating a secure link to a restricted directory over which confidential data is to be exchanged, the identity of both the client and the server is important. Protocols like SSL/TLS allow mutual authentication between client and server.

## Single Sign-On

One of the additional Windows 2000 security features is the ability to authenticate to any computer or resource on the network by logging on to a single domain account. Through single sign-on, the user can log on to a domain account once, with a single password or smart card. The user's single sign-on security credentials are stored in Active Directory, and each time a domain resource is required, a network authentication occurs transparently.

The advantages of single sign-on, as opposed to authenticating to each network resource when it's needed, are quite obvious. Users have fewer passwords to remember and fewer authentication screens to endure; administrators find it easier to manage only one account per user.

## Data Protection

The authentication schemes that protect passwords as they cross an unsecured network are critical to maintaining a secure system; equally important is the data you send once you're logged on. Whether it's a company's proprietary information or a personal credit card, the concern is the same: keeping network information from being read by unauthorized persons and preventing it from being modified.

Of course, sensitive information doesn't need to be on its way somewhere to be vulnerable. Tools like network sniffers can weed out data packets, but attacks can also occur on files sitting on a hard disk. In addition to network security, Windows 2000 provides security for your stored data.

## Data Confidentiality

The privacy of data, whether it's an e-mail message, input to a Web page, or distinct IP packets, is jeopardized once the information is transmitted over nonsecure communication lines, such as the Internet. Using encryption algorithms and keys, data privacy can be protected. Without the appropriate decryption keys, unintended recipients intercepting the transmission receive nothing but encrypted garbage.

Cryptographic operations use both an algorithm and a key. The *algorithm* is the specific mathematical process that performs the operation. The *key* is the input to the algorithm.

The strength of the encryption also depends on the algorithm used and the length of the key. With enough computing power, any encryption key can be broken. Windows 2000 supports a range of key lengths, from 40-bit encryption for export internationally, to 128-bit encryption for use within North America.

Typically, the bulk of data is encrypted using a cipher block algorithm (also known as a symmetric algorithm) and a key. The strength of this method lies in the cipher block chaining (CBC). Encrypting a block at a time, the output of one block is used as the input of the next. In this way, repeated patterns of data won't produce the same encrypted data. The input to the first block is a random number called an initialization vector (IV). The IV assures that each time a message is encrypted, a unique result is produced.

For confidentiality of transmitted data at the network level, Windows 2000 employs Internet Protocol security (IPSec). IPSec encrypts TCP/IP packets before transmission and decrypts them on receipt.

Confidentiality of stored data is also a concern. Although access to stored files can be restricted for certain users through file permissions, intruders who gain unauthorized access to your hard disk can modify those permissions. To combat this problem, Windows 2000 uses a transparent encryption scheme called Encrypting File System (EFS). Files on NTFS volumes can be encrypted and decrypted with users' EFS public/private key information. Users need only select the files to be encrypted. The actual encryption occurs behind the scenes. This system, however, allows only self-encrypting—files can't be encrypted and then shared with other users.

## Data Integrity

Although encryption can guarantee the confidentiality of a file, it can't guarantee the file's *data integrity*—that is, that the file has not been modified or tampered with. Fortunately, Windows 2000 also supports digital signing. *Digital signing* of a file, module, or other software component is somewhat like signing a contract on paper. The signer is responsible for what he or she signs. Whoever subsequently views the document and signature can tell who signed it.

However, digital signatures offer a great deal of security beyond that. A *digital signature* is generated by hashing the document and encrypting it with the signer's private encryption key. This procedure produces a signature that is cryptographically tied to both the signer and the content of the document. Changing the content breaks the signature.

On verification, the digital signature is decrypted with the signer's public key. The resulting hash is compared against a newly computed hash of the message. This process proves undeniably that the signer signed the message, because his or her key was used to verify the signature; in addition, it verifies that the contents of the document haven't changed because the encrypted hash matched the newly computed hash.

In Windows 2000, digital signing has two meaningful purposes. First, it guarantees the integrity of data stored locally or being passed over a network. Second, it authenticates modules or other software components that are obtained from untrusted sources, such as the Internet. Validating the signature of a module verifies that the software hasn't been tampered with and that it was signed by a trusted software publisher.

The two most common digital signature algorithms are RSA and Digital Signature Algorithm (DSA). DSA signatures are 40 bytes long, and the length of RSA signatures depends on the key size. A key pair, consisting of a public key and a private key, with a 128-byte public key typically produces a 128-byte signature.

## Access Control

As explained earlier, authentication is the first layer of security in the protection of network objects and resources. The second layer is *access control*—that is, controlling which resources can be accessed, by whom, and with which permissions. An authenticated user doesn't necessarily have authorization to access all files, printers, and registry keys. The manager for each object type enforces access control, but it's up to the object owner to determine which access control restrictions to impose.

Access is controlled by assigning rights to users and by setting permissions for objects. Permissions specify which users can access a specific object and which type of access is allowed. For example, the owner of a quarterly finance spreadsheet might set permissions that allow read/write access to the head of finance, allow read-only access to everyone in finance, and deny access to everyone else.

Groups of users have their own rights, and those can be specified when granting object permissions. In the previous example, establishing read-only permissions for everyone in finance probably means setting a group's rights, not setting users' rights individually.

Permissions can be explicitly set for an object, or for ease of administration, they can be inherited from parent objects. However, the granularity of access control doesn't stop at objects. Permissions can even be set for attributes of an object, allowing access to some fields, such as the e-mail address of a user account, but denying access to other fields, such as the user's telephone number. Standard object permissions include the following:

- Reading an object
- Modifying an object
- Deleting an object
- Reading an object's permissions
- Modifying an object's permissions
- Changing an object's owner

## Auditing

Another Windows 2000 security feature is *auditing*, which allows an administrator to keep tabs on events that could possibly compromise the system. Events such as logons and logoffs, access to files, and user account management can all be audited. The administrator can choose which objects to audit, which events on that object to audit, and which users or groups using that object to audit. Both successful and unsuccessful access attempts can be audited.

Viruses can leave trails of inappropriate writing of executables and DLLs. Auditing successful and failed write access to these files and monitoring the security log for unexpected occurrences gives you a head start at detecting viruses on your system.

In addition to auditing users' security-related events, Windows 2000 provides a means of tracking security management events because an audit trail reflects any changes in security policies. For instance, if an administrator changes the permissions of a particular object to deny access to a specific group, this change in permissions appears on the audit trail. [Chapter 19](#) shows how to manage the security log that Windows 2000 generates.

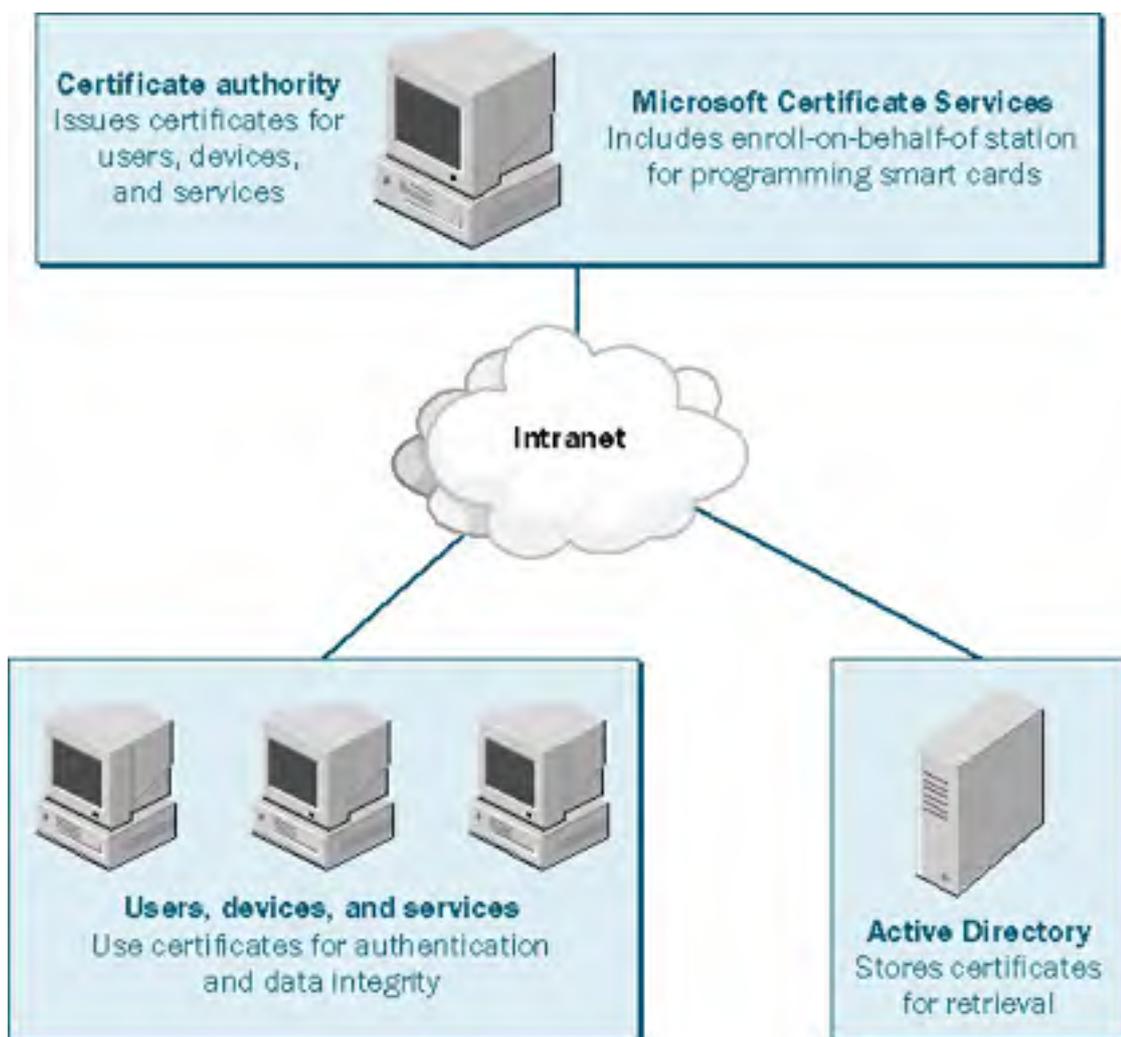

## Nonrepudiation

Finally, let's take a look at nonrepudiation, another Windows 2000 security feature. *Nonrepudiation* is undeniable proof that a correspondence was sent or received and usually refers to security-enhanced e-mail messages. Proof that a message was sent is a property exhibited by digital signatures. For undeniable proof of receipt, the recipient of a signed or encrypted message responds to the sender with a signed receipt.

Some e-mail packages allow for receipts of signed messages, but this doesn't necessarily demonstrate nonrepudiation. A *signed receipt* is undeniable proof that a message was received only if it is cryptographically tied to both the recipient and the original message.

## Public-Key Infrastructures

Now that we've looked at more basic security concepts, let's examine some of the security-enabled protocols. In recent years, public-key infrastructures (PKIs) have gained momentum in both commercial and government sectors. Based on public-key technology, a PKI describes a system of public-key certificate generation and management, including distribution and revocation. The important elements of this infrastructure are certificate authorities (CAs) that issue certificates, clients that use certificates, and directories that store certificates. Many PKIs use a registration authority that assures user identity and authorization before certificates are granted. Figure 18-1 shows a typical Microsoft Windows 2000 PKI.

**Figure 18-1.** A typical public-key infrastructure.

One of the distinct advantages of using public-key certificates for authentication is that servers no longer need to store and maintain a password list for their individual users. Because identification is based on a trust relationship with the CAs, the servers need to trust only the authority that issued the requestor's certificate. Once the chain of trust is determined and the certificate is verified, authentication can be established.

RSA Laboratories maintains a list of public-key cryptography standards (PKCS) that define public-key-related formats. Table 18-2 contains four notable standards.

**Table 18-2.** Important public-key cryptography standards

Standard	Subject
PKCS #7	Cryptographic Message Syntax Standard, the basis for Secure Multi-purpose

	Internet Mail Extensions (S/MIME). Defines the format of signed and encrypted messages. The degenerate case allows the exchange of public-key certificates and certificate revocation lists (CRLs).
PKCS #10	Certification Requests. Used by clients to request certificates from CAs.
PKCS #11	Cryptographic Token Interface. Analogous to Microsoft's CryptoAPI.
PKCS #12	Personal Information Exchange (PFX). Enables the encrypted transfer of private keys and associated certificates from one computer to another.

#### More Info

You can find a list of current Internet-draft categories associated with the Internet Engineering Task Force (IETF) at <http://www.ietf.org/1id-abstracts.html>. A number of categories listed there are relevant to this chapter: IP Security (IPSec), Public-Key Infrastructure (X.509; PKI), S/MIME Mail Security (S/MIME), and Transport Layer Security (TLS).

## Public-Key Encryption vs. Symmetric-Key Encryption

Although PKIs depend heavily on public-key technology, many of the functions performed by PKI entities combine public-key encryption and symmetric-key encryption. *Symmetric-key encryption* has been around for hundreds of years. It involves the use of a single encryption key for both the encryption and decryption of data. Encrypting data this way is analogous to placing a document in a safe and locking it with a key. When the document needs to be retrieved, the same key is used to unlock the safe. Relatively speaking, this method is secure and fast. Unfortunately, this type of encryption doesn't lend itself well to encrypting data to a person. Because the key must remain private, the difficulty exists in transmitting the key. After all, if there's a secure means to send the key, why not send the message using that means to begin with?

*Public-key encryption*, also known as asymmetric encryption, emerged from the necessity to share encrypted data with people, where no secure path existed to pass an encryption key. Public-key encryption uses a pair of keys: a public key that is distributed, and a private key that remains secret. To encrypt a message to someone, the encryption algorithm uses the recipient's public key. The resulting encrypted message can be decrypted only by the recipient's private key. This method is analogous to a safe with an entry slot. Anyone can slip a document in, but only the person with the correct private key can retrieve it. This scheme works for self-encryption of files as well. The Windows 2000 EFS, for instance, protects data with the user's public key. To decrypt, the user's private key is accessed and used.

Unfortunately, public-key encryption algorithms are slow and are rarely used to encrypt large amounts of data. Instead, public keys are used to protect symmetric keys that encrypt large chunks of data. For example, suppose Rosemary wants to encrypt a portfolio to Harold. Rosemary encrypts the portfolio using a symmetric-key algorithm like the Data Encryption Standard (DES). She then encrypts the symmetric key with Harold's public key, producing an encrypted symmetric key. Harold, on receiving the encrypted portfolio and key, decrypts the encrypted symmetric key with his private key and uses the resulting symmetric key to decrypt the message.

Public-key encryption extends to digital signatures as well. Digital signature algorithms actually reverse the encryption process. Encrypting the hash of a message with a user's private key generates a digital signature. The signature can be verified later by decrypting the hash with the user's public key.

## Public-Key Certificates and Private Keys

Most public-key infrastructures, including Windows 2000 PKI, revolve around the use of X.509 public-key certificates. We know that PKI users have a private key and a circulated public key. A public-key certificate cryptographically binds a public key to the user who holds the corresponding private key. Certificates are issued and digitally signed by a CA. Table 18-3 lists the fields of an X.509 certificate.

When a certificate is used, it is validated by verifying the signature with the issuing authority's public key. As long as the issuing CA is trusted (or is within a trusted path), you can be certain that the user or entity named in the certificate holds the corresponding private key.

**Table 18-3.** *Public-key certificate fields*

<b>Certificate Field</b>	<b>Description</b>
X.509 version	Windows 2000 supports X.509 version 3 certificates.
Serial number	Unique number that the CA assigns to a certificate.
Signature algorithm	ID of the algorithm that the CA uses to digitally sign the certificate.
Issuer	Name of the CA that issues the certificate.
Validity period	A pair of dates indicating when certificate validation begins and when it ends.
Subject	Name of the certificate user.
Public key	Public key that, with the corresponding private key, makes up a user's key pair.
Extensions	Additional information that a CA can include in the certificate. Examples of extensions are alternate names, such as the user's email address; key usage, which indicates which operations a public key can be used for; and basic constraints, which show whether the certificate is a CA certificate.
Signature	Digital signature generated by the issuer.

Of course, certificates aren't issued solely to users. CAs have their own certificates. CAs can also issue certificates to services and devices that need to be accessed on the network. A Web server that accepts Secure Socket Layer-encrypted transmissions and a directory that provides two-way authentication are both good examples of entities that use certificates.

Even though certificates belong to users and other entities, that doesn't mean that a user or entity is limited to one certificate—or, for that matter, that a user can be a member of only one root hierarchy. Certificates are issued for many different purposes: server authentication, file encryption, and code signing, to name a few. A user holds any number of certificates and private keys under different CAs or under the same CA; each might differ in usage, privilege, key size, and algorithm. For example, a security model might need multiple levels of access with separate CAs handling each level. On the other hand, a single user might hold Level 2 and Level 4 certificates; another might hold Level 1 and Level 3 certificates.

Having certificates under different root certificate authorities (root CAs) is common, too. Consider Celine, a human resources director who has both an enterprise certificate, which allows her to access her company's human resources server, and a certificate from a commercial CA, which allows her to browse the company's 401(k) stock portfolio over the Internet.

At the very least, the functions of encryption and digital signatures should be split into separate certificates. Private keys used for encryption can be archived so that encrypted data of a lost key can be recovered. Because the integrity of digital signatures depends on sole possession of the private key, digital signature private keys should not be archived.

## **Certificate Authorities**

Certificate authorities exist to issue certificates for entities—including users, services, devices, subordinate authorities, or the CA itself—that meet the policy set forth for the CA. The CA accepts and fulfills certificate requests and revocation requests and might also manage the policy-directed registration process that a user completes to get his or her certificate. For information on how to install a CA using Microsoft Certificate Services, see [Chapter 20](#).

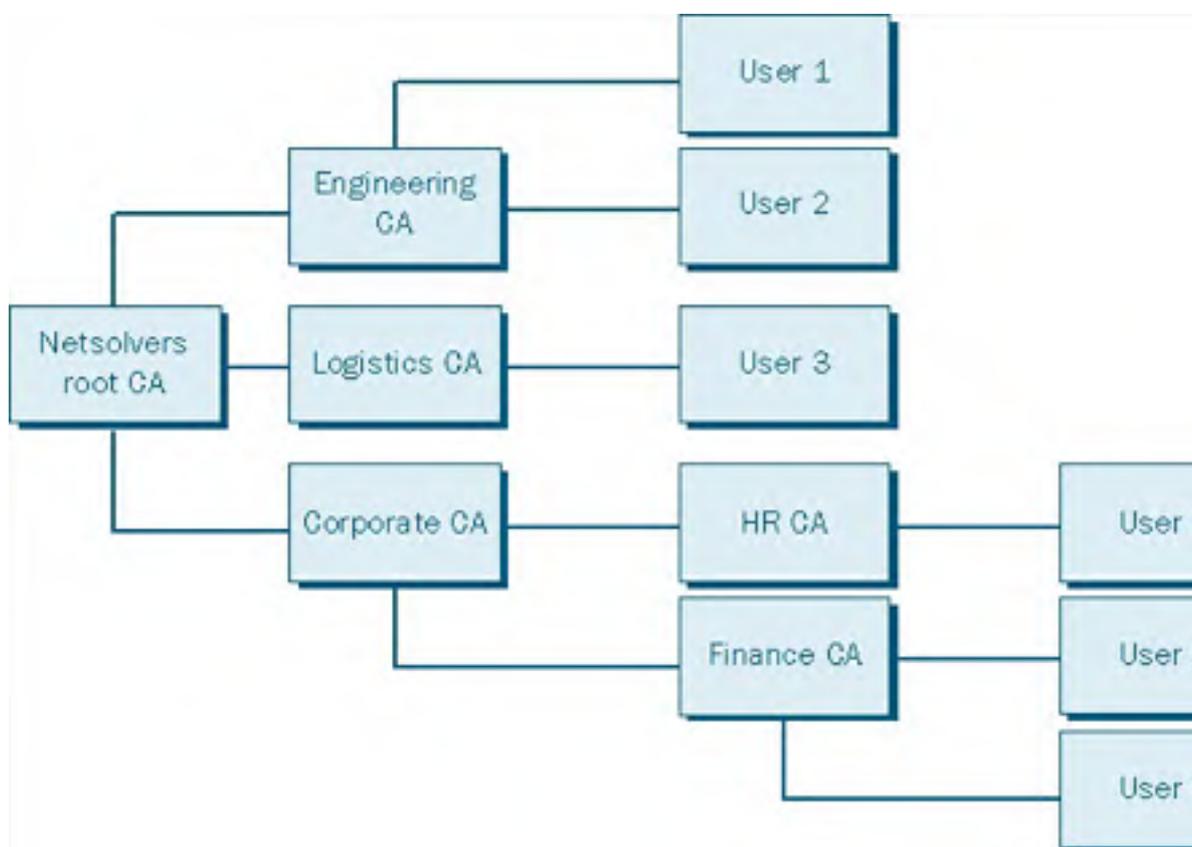

## **Root and Subordinate Certificate Authorities**

CAs can issue and revoke certificates for a host of users, but larger companies might be too big to administer with a single CA. In addition, enterprises might want to delegate authority of certain certificate types, or they might have divisions that manage their own resources and need to enforce separate certificate-issuing policies. Production, for instance, might want to issue certificates to anyone whose email address is within the company domain. Engineering might require a picture ID for registration. On the other hand, by using autonomous CAs, users between the two divisions are cryptographically isolated. A digitally signed message sent from a user in production to a user in engineering has no common basis of trust.

To solve this dilemma, CAs can be stacked hierarchically. Root CAs preside over domains, using a certificate they issue to themselves (a self-signed certificate). They also issue certificates to subordinated authorities and in general do *not* issue user certificates. Subordinate authorities issue certificates to users and other end entities and might also issue certificates to other subordinate CAs. Root CAs are implicitly trusted—subordinate CAs and clients derive trust from the root.

Figure 18-2 shows an example of a CA hierarchy. By stacking CAs hierarchically, an enterprise can manage the certification system from a single authority while delegating control of policy decisions to discrete authorities.

Windows 2000 also distinguishes between enterprise CAs and stand-alone CAs. The primary difference is that the enterprise CA uses Active Directory for user information and policy decisions and can publish certificates and CRLs to Active Directory. The stand-alone CA requires the certificate requestor to supply all user-identifying information.

**Figure 18-2.** A certificate authority hierarchy.

### Chain Verification and Trust

Before a received digital signature can be verified, the signer's certificate must be validated. This is true of any application, whether it's a service, device, or user performing the verification. Without a hierarchical chain back to a trusted root CA, the identity of the user in the certificate can't be confirmed.

Chain verification is a two-step process. The first step is to build the certificate chain from the signer's certificate to a trusted root CA. Consider the CA hierarchy in Figure 18-2. Suppose User 1 in engineering is trying to verify a signature from User 5 in finance. User 1 builds the certificate chain for User 5 back to the root CA, Netsolvers root CA, which is in User 1's trusted store. The certificate chain, built bottom up, would be User 5: Finance CA: Corporate CA: Netsolvers root CA. The verifying entity obtains these certificates from the transmission protocol if they're included or from an accessible certificate store. The root CA certificate, because it's the pivotal trust component, should always come from a protected, trusted certificate store such as Active Directory.

The second step of chain verification is to verify the certificate chain top down. The verifying entity checks each certificate for validity, starting with the trusted root. Validity checking includes verifying the certificate's digital signature, checking the certificate's validity period, and ensuring that the certificate hasn't been revoked. Depending on policy, applications might also check any certificate extensions that the certificate contains.

Currently, typical PKI implementations include two-tier or three-tier hierarchies. As the popularity of the public-key infrastructure spreads, CA vendors will make more attempts to unite and centralize certificate authorities and root certificate authorities, resulting in longer certificate chains.

### Cross-Root Certification

Even with a central root CA and a multitiered CA hierarchy that spans the breadth of a company, users might need to verify digital signatures under different root CAs. This verification is especially important when integrating commercial CAs, such as Verisign, to perform code signing, among other tasks. Using cross-root certification, root CAs can be connected so that validation paths of certificates under different roots extend back to the user's root CA.

### Certificate Registration

Before being able to use his or her generated public/private key pair for encryption or digital signatures, a user must first obtain a certificate from a CA. A user does this by sending a certificate request—which includes his or her name and public key—to a CA. A number of registration models can exist depending on the registration policy a CA wants to uphold. Many commercial CAs handle PKCS #10 certificate requests and also allow Web-based certificate generation.

For more secure needs, a registration authority can act as a certificate-requesting agent to ensure proper proof-of-identity procedures and to forward certificate requests to the CA. Microsoft Certificate Services includes an enroll-on-behalf-of station where administrators, using enrollment agent certificates, can program smart cards for users. Figure 18-3 shows two examples of certificate request scenarios.

In the first example, a client requests a certificate from an enterprise CA, perhaps using the Certificates snap-in Certificate Request Wizard. User information and certificate rights are obtained from Active Directory. The Certificate Request Wizard generates a public/private key pair for the user. The public key is included in the certificate request and sent to the CA. The private key is saved on the user's computer. On receipt of the certificate request, the CA issues and signs the certificate and pushes it to a directory where other users and entities can retrieve it.

The second example shows an administrator programming a smart card through the enroll-on-behalf-of station. In this case, the private key is written directly to the card. In neither scenario is the private key exposed to the CA or anyone else. Again, once the certificate is issued, it's written to a directory for public availability. The smart card is returned to the user and is ready for authentication.

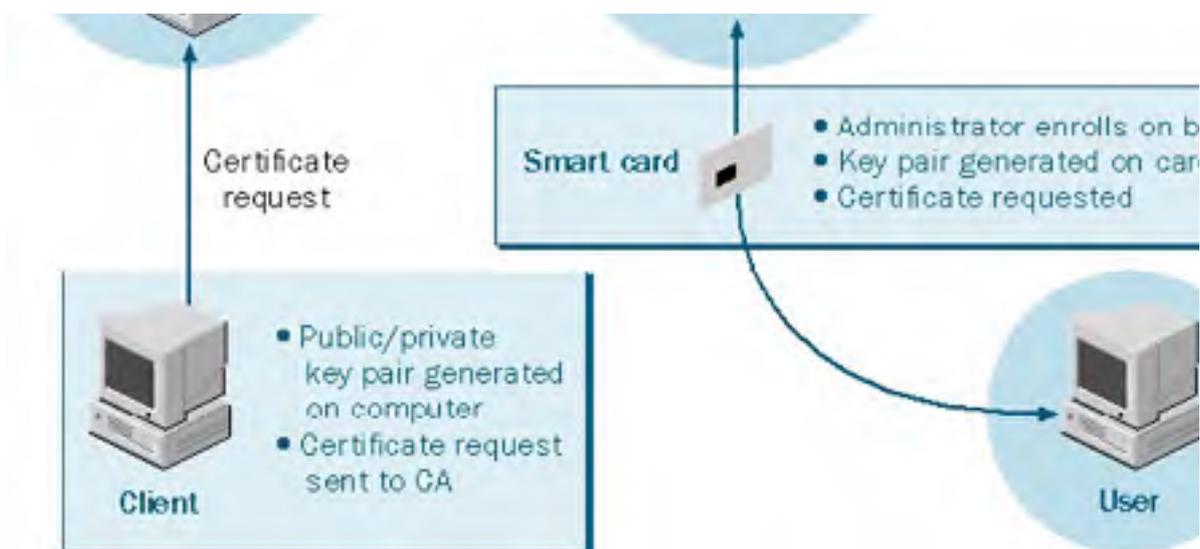

Figure 18-3. Two certificate request scenarios.

## Certificate Directories

An important piece of the PKI is the directory in which certificates are stored and from which they can be retrieved. To encrypt data to a user, the user's public-key certificate is needed. Similarly, when verifying a digitally signed message, the certificate chain back to the verifier's root must be established.

In a Windows 2000 environment, Active Directory acts as a repository for certificates; any user or computer with appropriate rights can retrieve them. In addition, external users' certificates can be mapped to Active Directory user accounts.

Typically, once a client application retrieves a given certificate, it caches the certificate locally to save the overhead of another retrieval. Use the Certificates snap-in to view stored certificates by purpose or by storage category, such as personal or trusted roots.

## Certificate Revocation

In addition to issuing and signing certificates, CAs are responsible for maintaining a list of certificates that are no longer valid. This list, called a certificate revocation list (CRL), is digitally signed by the issuing authority.

Such a list is a necessary requirement for a public-key infrastructure. Consider Julio, a laptop user who dials in to his company's network to access a server that contains finance accounts. He uses his certificate and corresponding private key to authenticate himself to the finance server. Now suppose Julio's laptop is stolen. In the past, a compromised password might have resulted in the administrator changing the user's password.

In a public-key infrastructure, however, verification is based on possession of a private key. The finance server has no knowledge of a specific user, only the CAs that it trusts. By using the CRL as a revoking mechanism, the finance server can retrieve a current list of revoked certificates. Once the stolen certificate has been placed on the CRL and the CRL has been published and retrieved, verification of the certificate results in a failure and access is denied.

Like user certificates, a CRL is digitally signed by the issuing CA and can be verified with the CA's certificate. Table 18-4 describes the fields of an X.509 CRL.

Table 18-4. Certificate revocation list fields

CRL Field	Description
X.509 version	X.509 CRLs version. The current CRL version is X.509 version 2.
Signature algorithm	ID of the algorithm that the CA uses to digitally sign the CRL.
Issuer	Name of the CA that issues the CRL.

Last update	Date and time that the current CRL is issued.
Next update	Date and time that the next CRL will be issued.
List of revoked certificates	Each entry in the list includes the certificate serial number and the date when the certificate was revoked. Optional extensions can be added, such as a reason flag.
Extensions	Optional information that the CA can include in the CRL.
Signature	Digital signature that the issuer generates.

Just as with the certificate registration and issuing procedures, policies are established for CAs that dictate certificate revocation. These policies should include such procedural decisions as how often CAs refresh their CRLs, which mandatory and discretionary extensions CAs can include in their CRLs, and under what circumstances certificates get revoked. Under one policy, for instance, certificates of employees who leave the company are subject to revocation. Under another, a user merely being denied certain privileges is grounds for revoking his or her certificate.

Because certificates have a validity period, CRLs need contain only revoked certificates that aren't yet expired. Once a certificate expires (in other words, the Valid To date has passed), verifying entities refuse the certificate and it can be removed from the CRL.

We should also consider CRL dispersal. The rate at which CRLs are issued, or "refreshed," is a policy decision made by the CA and can be as frequent as once a day. For highly secure domains, the refresh rate can be even more frequent. To be current, verifying entities need to obtain the latest CRL. Microsoft Certificate Services allows CRLs to be published to Active Directory, to a URL for HTTP access, or to a CRL file.

## Certificate Renewal

Another set of certificate policy decisions relates to the certificate renewal procedure—specifically, *whether* certificates are allowed to be renewed, *when* they are renewed, and *how* they are renewed. Renewing certificates with the same key allows a user to extend the life of a public/private key pair. In contrast, renewing a certificate with a different public key once a user's certificate expires could make it difficult to read previously encrypted messages.

## Security-Enabled Protocols

Security in Windows 2000 exists at different levels—from the protection of entire messages at the application level, to secure channels, to the protection of data packets within IP. The security protocols residing at these different layers provide mechanisms not available at other layers.

S/MIME, for example, provides public-key-based encryption, integrity, and authentication of e-mail messages at the application level. SSL resides beneath the application layer, adding security to application protocols. IPSec, on the other hand, provides application-independent data protection at the IP layer. The following sections examine Windows 2000 security protocols.

### Secure Multipurpose Internet Mail Extensions

S/MIME is included with Microsoft Outlook and Outlook Express. It uses private-key certificates to secure e-mail messages and files in accordance with the PKCS #7 standard. It supports both encryption and digital signatures. By nesting single S/MIME contents, messages can also be signed and then encrypted, or signed multiple times.

#### Signed Messages

A PKCS #7 digitally signed message includes the message signature, the signature algorithm, and information about the signer. Optionally, the signer's certificate or certificate chain can be added, as well as any CRLs that the verifier might need. Authenticated attributes, which are protected by the digital signature, and unauthenticated attributes can also be added to the PKCS #7 content. The time at which a message is signed is an example of an authenticated attribute.

The content that is signed might or might not be included in the PKCS #7 message. If the content isn't included, the verifier needs both the PKCS #7 content and the original file that was signed to complete the verification. If the original file is easily available, this method saves the overhead of having redundant data.

#### Encrypted Messages

The current PKCS #7 standard requires the use of two algorithms for message encryption. Because public-key algorithms are slow, the message is first encrypted with a symmetric-key algorithm, such as DES. The small symmetric key is then encrypted to the recipient, using a public-key algorithm, such as RSA. In this way, a message can be encrypted to multiple recipients while the actual content has to be encrypted only once.

The PKCS #7 message includes the encrypted content and symmetric-key algorithm along with information for each recipient. This information contains the symmetric key encrypted to that specific recipient. On receipt, an application searches the list of recipients for one that matches the current user's certificate. It then decrypts the symmetric key with the user's private key and subsequently decrypts the message.

#### Other Content Types

The degenerate case of the PKCS #7 message allows for the absence of the content and any signature information. This format provides a transport for certificates and CRLs. Table 18-5 shows the typical file extensions for different PKCS #7 files.

**Table 18-5.** Common PKCS #7 file extensions

Extension	Description
.P7M	PKCS #7 encrypted file or signed file with content added
.P7B	PKCS #7 file extension
.P7S	PKCS #7 signature file (signed file without the content)
.P7C	PKCS #7 certificate or CRL-only file

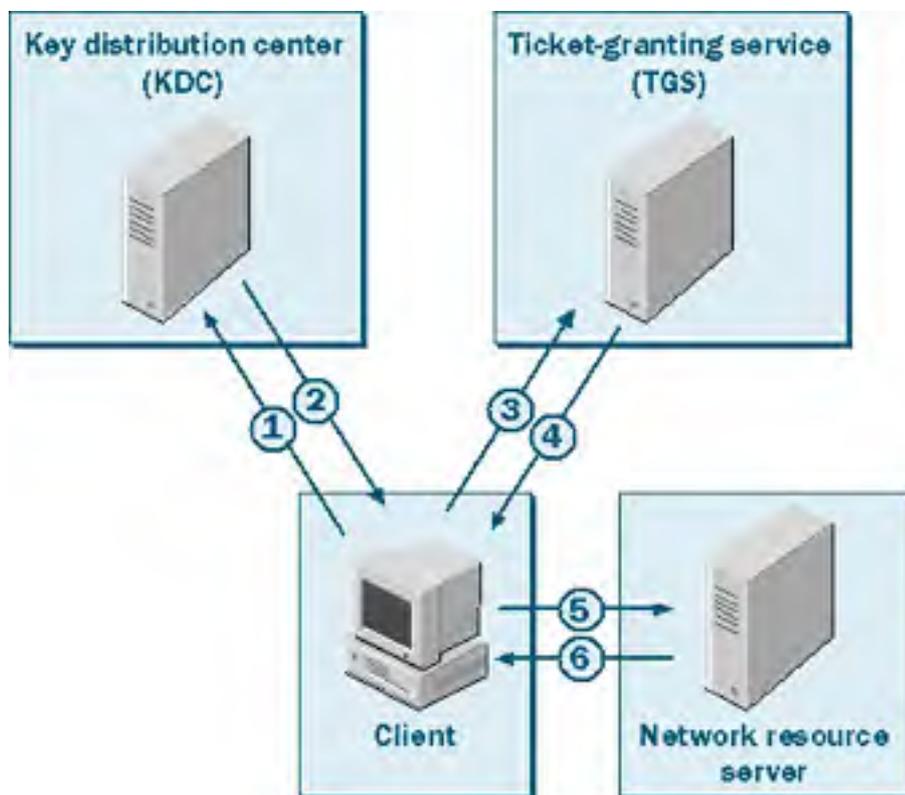

## Kerberos Version 5

Kerberos is another authentication security protocol used by Windows 2000. It is used over a nonsecure network to mutually identify the requestor (user) and authenticator (network resource). Once identified, the user and network resource can encrypt transmissions to ensure privacy.

Kerberos works by issuing tickets to users for accessing resources on the network. Before exploring the high-level details of Kerberos, you need to understand some objects and services.

- **Ticket** A packet of data that allows a client to access a resource. It includes an encrypted piece of client information that, when decrypted, confirms identity.
- **Ticket-granting ticket (TGT)** A special ticket that allows the client to obtain temporary tickets from the ticket-granting service for each authentication.
- **Key distribution center (KDC)** A service that runs as part of Active Directory and administers TGTs.
- **Ticket-granting service (TGS)** A service that is accessed by a client with a TGT and that administers tickets for network resources.

The use of a ticket-granting service keeps the user from having to log on for each resource request. Figure 18-4 shows the details of a client using Kerberos to authenticate to a server. The steps are enumerated next.

**Figure 18-4.** A client using Kerberos to authenticate to a server.

1. A client authenticates once to the key distribution center by using a password or smart card.
2. The KDC issues a TGT to the client, for access to the TGS.
3. When the client wants to access a network resource, such as the corporate finance server, he or she requests a service ticket from the TGS, sending the TGT as proof of identity.
4. The TGS replies with a service ticket for use at the requested network resource server.
5. The client sends the service ticket to the network resource server for access.
6. To mutually authenticate, the network resource server replies with a packet that the client can decrypt.

Once a client completes the first two steps, steps 3 through 6 can be repeated each time a user needs to access another resource.

The advantage of this mechanism is that all Kerberos authentication occurs behind the scenes. The user needs to enter a password only once into the KDC—authentication to all other resources happens transparently.

## Windows NT LAN Manager

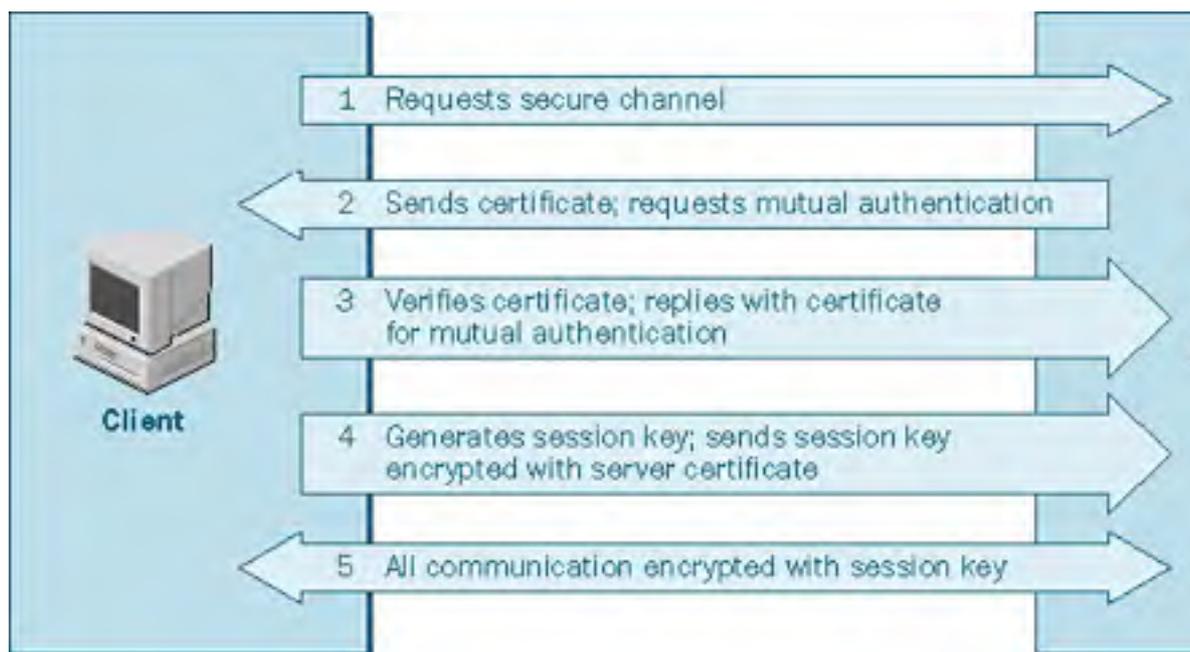

Windows NT LAN Manager (NTLM) is the primary authentication mechanism for Windows NT 4. In Windows 2000, it is replaced by Kerberos as the default authentication protocol. NTLM is included as part of Windows 2000 for configurations that involve authentication between Windows NT and Windows 2000 machines.

## Secure Socket Layer

Another Windows 2000 security protocol, Secure Socket Layer (SSL), uses public-key technology to provide a secure channel for applications communicating over a nonsecure network. A Web browser and Web server, for instance, could use SSL to communicate securely over the Internet. Before sending encrypted data, the client and server must engage in a security handshake to authenticate the parties involved and establish security levels. The handshake is a multipart process:

1. The client initiates connection with a request for a secure channel.
2. The server responds with its public-key certificate and can optionally request the client's certificate for mutual authentication.
3. The client verifies the server's certificate. If the server requested the client's certificate, the client sends it and the server verifies it.
4. The client generates and encrypts a session key with the server's public key found in its certificate.
5. All communication between the server and client is symmetrically encrypted and decrypted using the session key.

Figure 18-5 illustrates the SSL handshake process. In addition to authentication, the SSL handshake allows the two parties to agree on security parameters. Because of SSL's positioning, it can add security to application protocols such as HTTP, Telnet, FTP, Gopher, and NNTP.

**Figure 18-5.** The SSL handshake process.

## Internet Protocol Security

Finally, the Windows 2000 IPSec security protocol provides end-to-end security of network data using encryption, digital signature, and hashing algorithms. The IPSec driver protects individual packets before they reach the network and unwraps the protection once they're received. Because the IPSec driver resides at the IP transport layer, individual applications don't need to handle the specifics of data security during transmission. Data passed through the network from security-ignorant applications can still be protected. Because IPSec protects the packets of data—not the actual link—IPSec can provide security for networkwide transmissions, and only the two computers engaging in communications need to know about it.

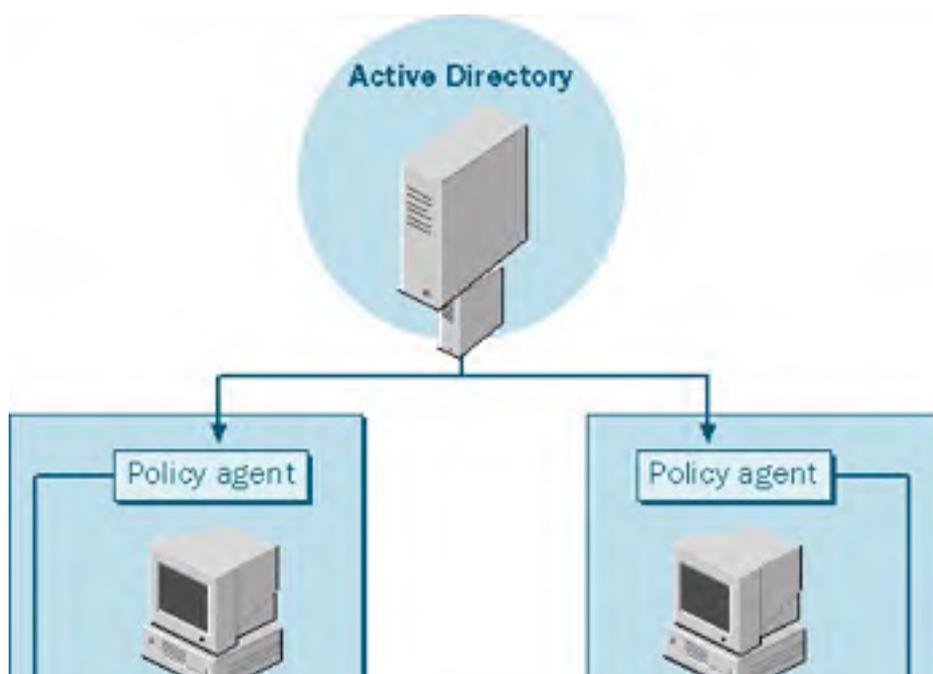

IPSec provides a number of security features:

- **Authentication** Use of a digital signature verifies the identity of the sender.
- **Integrity** Use of hash algorithms ensures that data hasn't been altered.
- **Privacy** Use of encryption protects data from being read.
- **Anti-replay** Prevents packets from being re-sent by an attacker to gain unauthorized access.
- **Nonrepudiation** Use of public-key digital signatures proves message origin.
- **Dynamic rekeying** Ability to generate keys during communication so that parts of transmissions are protected with different keys.
- **Key generation** Diffie-Hellman key agreement algorithm allows two computers to agree on a key without ever exposing it.
- **Key lengths** Provides configurable key lengths for export restrictions or highly sensitive transmissions.

## IPSec Policy Management

An important component of IPSec is the policy agent. The policy agent begins during system startup and is responsible for retrieving IPSec policy information from either Active Directory or the registry and feeding it to the IPSec driver. For domain computers, the domain policy information is acquired from Active Directory at startup and at policy-defined retrieval intervals. For stand-alone systems or systems that are offline, the policy agent retrieves policies from the registry. When an offline machine reconnects, the retrieved domain policy overrides the local policy.

Figure 18-6 shows how policy information is transferred from Active Directory to the IPSec driver. The IPSec policy agent retrieves security policies and feeds them to the IPSec driver.

**Figure 18-6.** How policy information is transferred from Active Directory to the IPsec driver.

[Chapter 19](#) describes how you can use IPsec Policy Management to define and manage IPsec policies for single computers or entire domains. Windows 2000 also provides predefined policies that can be customized to specific needs.

### How IPsec Works

Before data can be protected and transmitted between two IPsec-enabled machines, a negotiation must take place to agree on which keys, mechanisms, and security policies to use to protect the data. This negotiation produces a security association (SA).

For IPsec communications, an initial SA called Internet Security Association and Key Management Protocol (ISAKMP) is established between the two computers to provide a method of key exchange. Using the ISAKMP for protection, a second negotiation takes place to produce a pair of IPsec SAs and keys, one for inbound and one for outbound communications. Specifically, these SAs include an agreed algorithm for encryption and integrity and the agreed IPsec protocol to use. The two IPsec protocols are:

- **Authentication Header (AH)** Provides data authentication, integrity, and anti-replay to IP packets
- **Encapsulating Security Payload (ESP)** Provides confidentiality along with data authentication, integrity, and anti-replay to IP packets

The IPsec SAs and keys are loaded into the IPsec driver on their respective machines and are used to protect data during transmission.

## Virtual Private Networks

Before we start discussing virtual private networks (VPNs), what they mean, and why they're useful, take a second to consider that acronym, VPN: "virtual," as in simulated, "private," as in secret and confidential, and "network," as in a collection of computers.

Logically, a VPN is simply an extension of a private network. In reality, private networks are geographically isolated from remote users and other private networks by nonsecure communication lines such as the Internet. By using a secure, network-level protocol like IPSec, a private link can be emulated between two separate networks. What is actually the wrapping of data before it passes through nonsecure extranets or intranets is perceived by both requestor and authenticator as a private dedicated line. Because data packets are protected by encryption, any in transit interception results in unreadable data.

Unlike using IPSec for peer-to-peer transmissions, VPNs use a dedicated server that is tied to the private network. By accepting connections from only VPN-authorized clients, the VPN server allows private traffic within the physical enclave to proceed normally without requiring additional internal security.

Before you can establish a VPN connection, VPN authorization must be confirmed for the client. Authorization is based on the remote access policies set by the network administrator and on the dial-in properties of the client requesting the connection. Once a user is determined to be authorized and one-way or mutual authentication occurs, the VPN can be established. Windows 2000 includes two protocols that are used to encapsulate data over the virtual private network:

- **Point-to-Point Tunneling Protocol (PPTP)** Provides data encryption using Microsoft Point-to-Point Encryption
- **Layer Two Tunneling Protocol (L2TP)** Provides data encryption, authentication, and integrity using IPSec

## Remote Access VPNs

An authorized but isolated user can access the protected resources of a private or hidden network by authenticating to the network's VPN server and establishing a VPN connection. The remote user can be at home or on the road needing to connect through an ISP and the Internet, or the remote user can be part of the same intranet but detached from the secure or hidden network.

For example, suppose engineering has a hidden enclave within an enterprisewide network, complete with secret documents and alpha-version software. They want to grant access to the hidden network to the VP of Engineering but don't want to compromise the confidentiality of the information as it crosses the company's intranet. By providing a VPN server that blocks unauthorized users but allows the vice president to authenticate and establish a VPN connection, engineering's secret network is extended to one more user.

Simply because you have a VPN connection to a private network does not mean that you have full access. You still need the correct permissions to access specific resources.

Once the client establishes a VPN connection with the VPN server, the user appears to be accessing the private network directly. Figure 18-7 shows remote access for an Internet-based VPN.

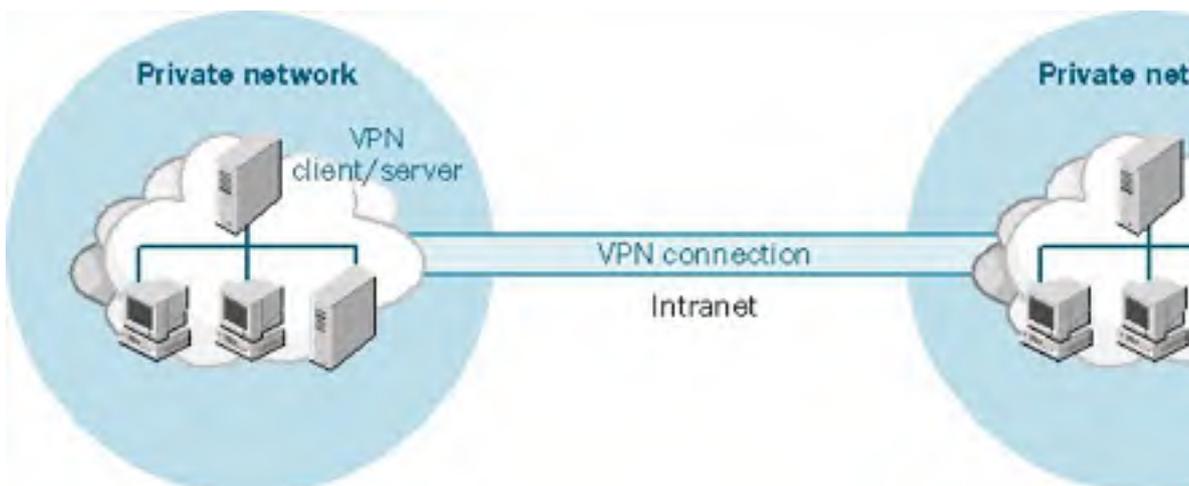

**Figure 18-7.** Remote access for an Internet-based VPN.

## Router-to-Router VPNs

A VPN connection can also be established for two mutually exclusive private networks. In this case, both the VPN client and VPN server are routers. Like remote access VPNs, router-to-router VPNs can involve enclaves that are part of the same intranet, or they can involve private networks that require the Internet infrastructure for communication. Figure 18-8 shows a router-to-router connection for an intranet-based VPN.

**Figure 18-8.** A router-to-router VPN connection.

Here the VPN client authenticates itself to the VPN server, and a secure VPN connection is negotiated. Again, the logical appearance in both cases is that the private networks are physically connected. You'll find more on VPNs in [Chapter 32](#).

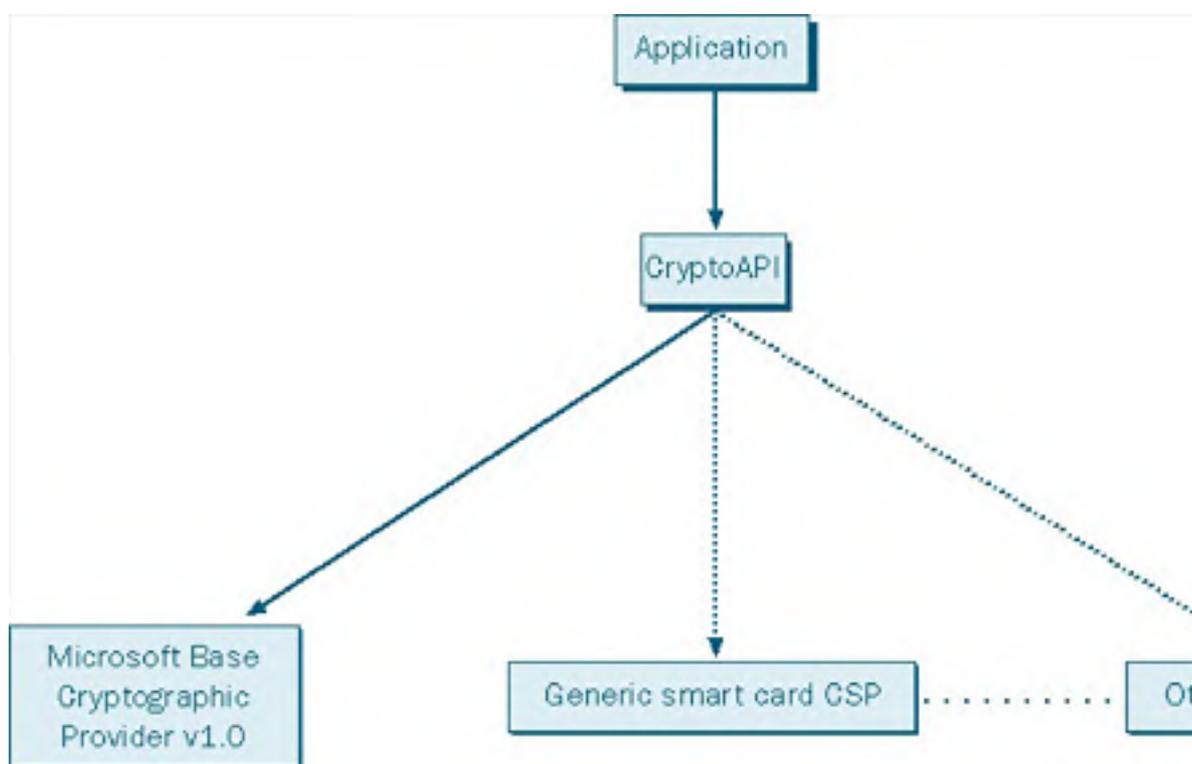

## Security Modules

This chapter would be incomplete without a brief glance at the underlying interface that supports Windows cryptographic-enabled applications, such as Microsoft Certificate Services and Microsoft Internet Explorer.

### Cryptographic Application Programming Interface

Microsoft's CryptoAPI provides a standardized set of cryptographic functions, such as CryptGenKey, CryptVerifySignature, and CryptEncrypt, that allow applications to offer security without having to maintain their own cache of keys or certificates or know the particulars of the cryptographic device they're using. Because private keys are handled within the bounds of CryptoAPI, applications don't need to fumble around with unprotected private-key information.

When used, CryptoAPI passes each of its cryptographic calls off to one of a number of cryptographic service providers (CSPs) that actually perform the operation. Figure 18-9 shows the relationship between the API and the service providers.

**Figure 18-9.** Cryptographic service providers "plugged in" to CryptoAPI.

### Cryptographic Service Providers

Cryptographic service providers vary according to the algorithms they use, the key lengths they support, and the cryptographic tokens with which they interface. A vendor introducing a new type of smart card, for instance, writes a CSP for its smart card that "plugs in" to the CryptoAPI. Being able to plug in allows applications to use a myriad of new and existing services without having to particularize their cryptographic calls to any one vendor-defined interface.

By displaying a list of available CSPs and allowing the user to choose, applications can take advantage of emerging technologies with little, if any, modification to their source code. Because CSPs provide the specific interface to the cryptographic device, whether it's software based or hardware based, they are responsible for any initialization required, such as PIN or password validation.

## Summary

This chapter covered basic security concepts as well as the major security components of Windows 2000. The next two chapters continue with Windows 2000 security. [Chapter 19](#) describes how to implement the concepts and components described in this chapter; [Chapter 20](#) explains how to install and configure Certificate Services.

# Chapter 19

## Implementing Security

In the realm of computer security, one of the most common and critical mistakes administrators make is to confuse the presence of security features with a secure system. It's not enough to piece protocols, methods, and algorithms together into a collage of security. In such environments, the weakest link usually goes unnoticed until it's too late. To be effective, system security must be applied as a whole, and it needs to be well designed, complete, and easy to maintain.

Well-designed systems are accompanied by policies that dictate how, when, and at what level security is applied. Complete systems provide multilevel security that is both sound and as transparent to the user as possible. Easily maintained systems allow administrators to centrally manage security and keep track of critical events.

With features like security templates, public-key cryptography, Internet Protocol security (IPSec), and comprehensive auditing procedures, Microsoft Windows 2000 makes it easy to apply security policies to individual computers or to scale them to domains or entire enterprises.

### Real World

#### Security Checklist

Implementing computer and network security is like staying healthy—it's not a matter of just popping some pills or working out regularly; a full-body approach is necessary. As such, Microsoft makes some specific recommendations for keeping systems secure, which we've listed here (for a detailed explanation of these suggestions, see <http://www.microsoft.com/technet/security/tools/chklist/w2ksvrcl.asp>, or refer to the appropriate sections of this book):

- Implement appropriate physical security for servers and network hardware (and desktops as necessary).
- Eliminate FAT (make sure all hard disk partitions are using NTFS).
- Rename the Administrator account, and create a strong password for it (use a different password for each server).
- Set appropriate password policies and account lockout policies for your network.
- Disable unnecessary services, especially IIS. If not doing file or printer sharing, disable the Server service.
- Don't install unnecessary applications such as e-mail, Microsoft Office, or utilities.
- Disable unnecessary accounts.
- Check folder permissions.
- Disable the Guest account.
- Protect the registry from anonymous access.
- Apply appropriate registry ACLs.
- Restrict access to the Local System Authority (LSA).
- Remove unnecessary file shares.
- Install antivirus software and the latest virus definition files.
- Install the latest service pack.
- Install security hot fixes, as appropriate for your network.

## Physical Security

The most secure operating system and network in the world is of only limited use if a hacker (or disgruntled employee) can walk up to your server and access it physically. With physical access to a computer, there are a lot of things an unethical person could do—from simply turning the system off, to booting from a floppy and wiping the hard drive clean (or stealing data), to actually making off with the hardware.

The absolute first requirement of computer security is physical security. At a minimum, you should take the following precautions. Evaluate your own environment and security requirements to determine what additional steps, such as biometric or smart card controls, might be appropriate.

- Place servers in a locked server room. Only those with a demonstrated need should have access to the key or combination. A system that tracks when and by whom the room was entered is preferred.
- Use case locks on your servers and don't leave the keys in them.
- Place network hubs, routers, and switches in a locked cable room or wiring closet.
- Restrict floppy drive access to administrators only on servers, or remove the floppy drive if it's not necessary.
- Set a BIOS password on all systems to prevent unauthorized access to the BIOS or booting to an insecure operating system.
- Change the operating system selection timeout period to 0 so that Windows boots automatically.
- Install case locks on client systems or publicly accessible systems.

## Using Templates to Implement Security Policies

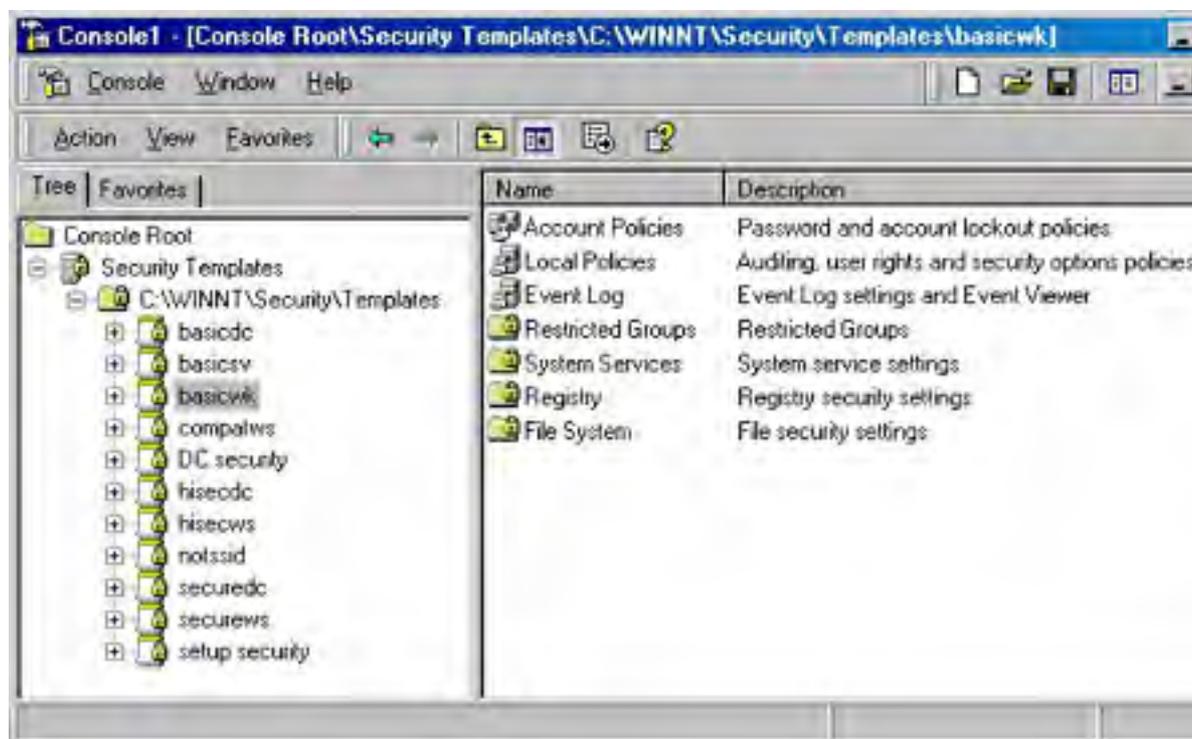

Windows 2000, as you now know or are quickly learning, has a rich and diverse range of security features. With these features, however, comes a multitude of security policies and attribute settings that need to be configured. Configuring a system with policies consistent with your company's security needs is, in itself, no small task. Multiply that by all of the computers at your site or in your organization, and you've got yourself quite a chore. And that doesn't include the maintenance time required whenever company policies need to be reevaluated.

Enter security templates. A *security template*, quite simply, is a configuration file for all of the security attributes of a system. Security templates are powerful and help ease the strain of administration. Using a single interface, an administrator can generate a security template that reflects the company's security needs and then apply it to a local computer or import it into a Group Policy object in Active Directory. When you incorporate the template into a Group Policy object, all computers affected by that object receive the template settings.

## Running the Security Templates Snap-In

Security templates can be created and modified with the Security Templates snap-in of the Microsoft Management Console (MMC). To add the snap-in to the MMC, type *mmc.exe* in the Run dialog box, which is accessed from the Start menu. From the Console menu, choose Add/Remove Snap-In. Click Add in the Stand-Alone tab and select Security Templates from the list of snap-ins provided. Click Add in the Add Stand-Alone Snap-In dialog box to add the Security Templates entry to the Add/Remove Snap-In dialog box and then click Close. Click OK in the Add/Remove Snap-In dialog box, and the Security Templates snap-in is added to Console Root in the console tree.

In the console tree, expand Security Templates and the Security\Templates folder to display an initial list of templates. These are predefined templates that can be tweaked for a company's specific needs. When a new template is created or an existing one is copied, it's added to this list. Select any one of these preloaded policies, and the right pane of the console displays all of the security areas available for configuration (Figure 19-1).

**Figure 19-1.** Predefined security templates.

Essentially, each template in the list represents a single readable .INF file. The snap-in is merely an interface for modifying these security template files. The files can be found in the system root folder under *%SystemRoot%\Security\Templates*. The following is a small excerpt from the *securews* template (*Securews.inf*), showing the Account Policies area:

```
[System Access]
;-----
;Account Policies - Password Policy
;-----
MinimumPasswordAge = 2
MaximumPasswordAge = 42
MinimumPasswordLength = 8
PasswordComplexity = 1
PasswordHistorySize = 6
RequireLogonToChangePassword = 0
ClearTextPassword = 0
```

## Examining Template Policies

Each template contains attribute settings for the seven areas of security configurable in Windows 2000. Double-click a security area in the right pane of the console or expand the console tree in the left pane to display the specific sections.

### Account Policies

The Account Policies area includes policies pertaining to user accounts. It contains Password Policy, Account Lockout Policy, and Kerberos Policy.

### Local Policies

The Local Policies area includes policies pertaining to who has local or network access to the computer and how events are audited. This area contains Audit Policy, User Rights Assignment, and Security Options.

### Event Log

The Event Log area contains attributes that determine how the application, security, and system event logs behave. Log attributes include maximum size and access restriction. Event logs can be viewed in Event Viewer.

### Restricted Groups

The Restricted Groups security setting is for adding members to built-in user groups, which have predefined capabilities, or to other administrator-defined groups that might be privileged. Built-in user groups include Administrators, Power Users, and Backup Operators.

### System Services

The System Services area includes security attributes of all system services on the local computer. System services include file services, print services, network services, and telephone services.

### Registry

The Registry area contains security attributes for existing registry keys, including auditing information and the access permissions.

### File System

The File System area allows the configuration of access permissions and auditing of specific directories and files on the local system.

## Using Predefined Templates

The predefined templates supplied by Windows 2000 can be used as is, or they can be customized to conform to a more rigorous security requirement. These templates span a range of security levels and represent typical security scenarios for the different types of computers found in a system—namely workstations, servers, and domain controllers. Table 19-1 shows some of the predefined security templates, categorized by security level.

**Table 19-1.** *Some predefined security templates*

Security Level	Template Name	Description
Default	basicwk	Default workstation template
	basicsv	Default server template
	basicdc	Default domain controller template
Secure	securews	Secure workstation or server template
	securedc	Secure domain controller template
Highly secure	hisecls	Highly secure workstation or server template
	hisecls	Highly secure domain controller template
Compatible	compatws	Compatible workstation or server template
Out of the box	Setup security	Out-of-the-box default settings template
	DC security	Out-of-the-box domain controller settings template

## Default Security Templates

The basic security templates for workstations, servers, and domain controllers contain Windows 2000 default settings for account and local policies, as well as typical values for event log maintenance and basic permissions for system services. In addition, these basic templates include default access permissions for system files, directories, and registry keys that, when applied, overwrite the existing security settings of these objects and their children. These basic templates, however, intentionally omit user rights assignments so as not to overwrite any assignments made by application setup programs. This omission means that the basic security templates can be applied to a machine to reset the security configuration of that system.

A closer look at the three basic templates reveals minor differences among them. Whereas the basic workstation template includes default configurations for necessary system services, the basic server template adds default configurations for automatic startup of server-only services, such as Microsoft SMTP Service and License Logging. The basic domain controller template omits system services configuration completely. The basic domain controller template is more suited for a domain controller that services users.

## Secure Security Templates

Two secure templates are provided: one for the domain controller and a combined template for the workstation and server. With stricter password and lockout policies and with audit logs that restrict guest access and hold up to five times the audit information of the basic templates (10 times for the domain controller), the secure templates provide a medium layer of security.

The secure templates also enable more of the auditing features than the basic templates do. Unsuccessful logon events and privilege use, as well as successful and unsuccessful account management and policy changes, are configured for auditing. In addition, the secure domain controller template provides auditing for object and directory service access. Account and local policies also appear in the secure domain controller template, although they are absent from the basic domain controller template. Because the permissions of files, folders, and registry keys are configured securely by default, these security areas are omitted in this template type.

### Real World

#### Strengthening the Secure Template Without Going Too Far

The secure template is generally a good template to apply to workstations and servers. Additionally, however, you should consider the following settings that can improve security without compromising functionality to the extent that the high-security templates do. All of the following settings are located in the Local Policies-Security Options container except the first one, which is located in the Local Policies-Audit Policies container:

- **Audit System Events** Success or Failure

- **Additional Restrictions For Anonymous Connections** No access without explicit anonymous permissions
- **Audit The Use Of Backup And Restore Privilege** Enabled
- **Do Not Display Last User Name In Logon Screen** Enabled
- **LAN Manager Authentication Level** Send NTLMv2 response only or refuse LM and NTLM (this blocks MS-DOS and OS/2 clients from logging on)
- **Number Of Previous Logons To Cache** 0 logons (but don't do this on laptops or your users will be unhappy)
- **Rename Administrator Account** Rename to something other than admin, root, or boss
- **Restrict CD-ROM Access To Locally Logged-On Users Only** Enabled
- **Unsigned Driver Installation Behavior** Do not allow installation
- **Unsigned Non-Driver Installation Behavior** Do not allow installation

## Highly Secure Security Templates

The highly secure templates are actually quite lean and concentrate on the security of communications in native-mode (Windows 2000) environments. In short, security attributes are set for digitally signing client-side and server-side communications and for signing and encrypting the secure channel data. Because maximum protocol protection is set, however, systems to which these templates are applied will not be able to communicate with machines running Microsoft Windows 95, Microsoft Windows 98, or Microsoft Windows NT. Aside from there being no Authenticated Users in the Power Users restricted group in the highly secure workstation/server (hiscws) template, the highly secure workstation/server and domain controller templates are essentially the same.

## Compatible Security Template

In the basic workstation template, Authenticated Users are, by default, Power Users. The secure and highly secure workstation templates remove Authenticated Users from the Power Users group. Because the goal of the compatible security template is to allow most applications to run successfully, but not at the cost of compromising the security levels of Power Users, this template also removes Authenticated Users from the Power Users group. With the Authenticated Users group downgraded, the template facilitates compatibility by lowering security on the folders, files, and registry keys typically accessed by applications.

We don't recommend that you use the compatible security template unless you're experiencing a specific compatibility problem that is fixed using this template. Instead, you should evaluate Windows 2000 compatibility technologies, Microsoft Windows XP, or a virtual PC program such as Connectix Virtual PC or VMware Workstation.

## Out-of-the-Box Security Templates

The setup security template contains out-of-the-box security settings for workstations and servers. The domain controller security template builds on the setup security template, adding default security settings for domain controllers.

## Modifying a Predefined Template

You can use a predefined template as a starting point for your own security scheme. First make a copy of it by right-clicking the template name and choosing Save As. Next specify a filename, being sure to retain the .INF extension. You can modify the attributes in any of the security areas of your new template by fully expanding the template tree to that area. For attributes, right-click an attribute name and choose Security from the shortcut menu to open the Template Security Policy Setting dialog box. For the Restricted Group, Registry, and File System folders, right-click the folder and choose Add Group, Add Key, or Add File, respectively.

## Defining New Templates

You can also choose to generate a security template entirely from scratch. In the console tree of the Security Templates snap-in, right-click the parent default template folder (%SystemRoot%\Security\Templates) and choose New Template. In the dialog box that appears, type a template name and a description of the template's purpose. The new template is saved as an .INF file in the Templates folder and is added to the list of available templates.

At this point, the new template file is empty, except for some version and description info. Viewing any of the policy attributes in the new template will list attributes as Not Defined. The Restricted Groups, Registry, and File System folders simply contain no entries.

For each security area, you can configure any or all of the security attributes or you can choose to leave that area unconfigured. To modify an attribute's settings, right-click the attribute in the right pane and choose Security. The Template Security Policy Setting dialog box appears. Select the Define This Policy Setting In The Template check box to enable the settings and set the attribute. Figure 192 shows the dialog box for the Retention Method For Security Log attribute. The stored settings in the various attributes represent a range of data types, including Boolean (enable, disable), integers (maximum file size), and dates and times.

**Figure 19-2.** The dialog box for the Retention Method For Security Log attribute.

It's just as easy to configure those security areas that contain a list of items instead of individual attributes. Right-click Restricted Groups, Registry, or File System, and select Add Group, Add Key, or Add File, respectively. You can then browse for the object to add and choose access permissions, ownership, and auditing information in the Access Control dialog box.

Once the security template is complete, save it by right-clicking the template name and choosing Save. It's then ready to be applied to the local computer or to a Group Policy object.

When creating new security templates for your system architecture, remember that security can be applied through the layering of templates. The configuration database allows templates to be imported one after another, so that the security policies in the different templates have a masking effect. Conflicts of specific attributes are resolved by giving highest priority to the most recently loaded template. This means that templates with varying degrees of security do not need to contain redundant data. Instead, basic security attributes can be applied with a standard security template that you load first. Higher level security templates then need to contain only security differences between the two levels.

## Applying Templates

A security template containing system security settings can be either applied to a local computer or pushed to a group of computers by importing it into a Group Policy object. Applying the template to a local computer is done through the Security Configuration and Analysis snap-in. See the section entitled [Importing and Exporting Templates](#), later in this chapter, for detailed instructions.

To import the security template into a Group Policy object, choose the target Group Policy object in the MMC. Expand the object, and then expand Computer Configuration and Windows Settings to display Security Settings. Right-click Security Settings and choose Import Policy. A list of security templates appears, each template being an .INF file. Choose the desired template.

Reduce the administrative hassle of configuring large arrays of security attributes by modifying predefined templates whenever possible.

## Using Security Configuration and Analysis

Security Configuration and Analysis is an MMC snap-in that allows an administrator to check the state of a system's security against one or more security templates and make appropriate modifications. Useful as both a setup tool and a maintenance tool, this snap-in lets you import predefined or modified security templates, analyze every security area against those templates with a single command, and view concise results. You can then synchronize system security to the template at once or resolve discrepancies on an attribute-by-attribute basis.

This tool, along with an appropriate security template, is invaluable for setting up the initial security configuration of a machine on which many security attributes and file, folder, and registry-key permissions have to be defined. A company or division's entire computer security policy can be translated into a single template and imported to quickly configure one or more machines. In addition, the snap-in is useful for maintaining the security level of a system. Invariably, in the course of resolving temporary network or administrative problems, security attributes become disabled and permissions of objects are set to full access. Periodically analyzing a system's security against its defining template allows you to locate and easily fix security flaws.

Finally, the tool permits you to export security templates that have been modified during the configuration of a machine or to reevaluate such templates in the Security Templates snap-in. If more than one template has been imported, you can save a single composite template that is the sum of all of the template settings.

### Opening a Security Database

Like any other MMC snap-in, Security Configuration and Analysis is added to the MMC by choosing Add/Remove Snap-In from the Console menu. Click Add and select Security Configuration And Analysis from the list of snap-ins provided.

Security templates are imported into a database, which is used to perform the analysis and configuration. Security database files use an .SDB extension. To create a new database or open an existing one, right-click Security Configuration And Analysis and choose Open Database. In the Open Database dialog box, select an .SDB file to open or type a new filename to create a database. When you type a new filename, a second dialog box appears allowing the import of a base security template. Choose a predefined template or a template modified with the Security Templates snap-in. The list of predefined templates is in the `%SystemRoot%\Security\Templates` folder. See the section entitled [Using Predefined Templates](#), earlier in this chapter, for an explanation of these security templates.

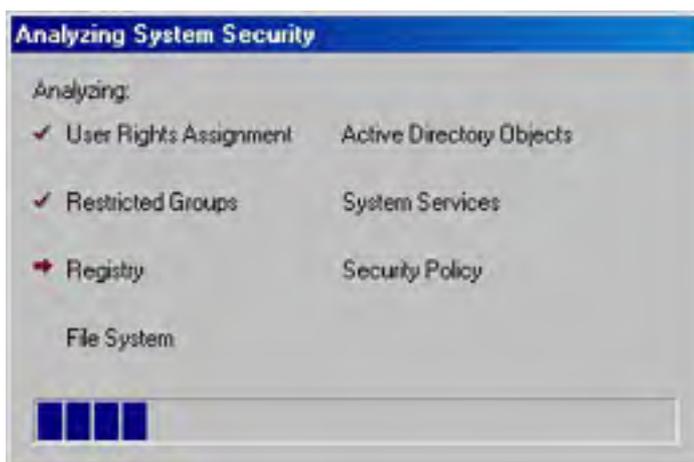

### Importing and Exporting Templates

Once you have opened a security database, you can import additional security templates into it. To do so, right-click Security Configuration And Analysis and choose Import Template. Select the .INF template file that you want to import. This template supplements the current database template or templates; it does not replace them.

In the process of analyzing and configuring a system's security with a database template, you might find it necessary to define a more precise policy and thereby modify the template. This modification is *not* saved to the original imported template; instead, it is saved as a database copy. To use the modified template on another machine, you'll need to export it. You can also combine multiple imported templates into a single composite template that you then export. To export a template, right-click Security Configuration And Analysis and choose Export Template. In the ensuing dialog box, choose a filename for the template, using the .INF extension.

### Analyzing Security and Viewing the Results

Once you have imported the necessary templates into the database, you can analyze the system. To analyze system security, right-click Security Configuration And Analysis and choose Analyze System Now. In the Perform Analysis dialog box, select the target path and filename of the analysis results. Click OK, and the Analyzing System Security progress window appears, as shown in Figure 19-3.

**Figure 19-3.** The Analyzing System Security progress window.

The analysis generates two types of results. First, the success and failure of each analyzed component is written to an error log. Second, the security areas listed under Security Configuration And Analysis in the console tree are populated. Each area gives the analysis results in an attribute-by-attribute comparison. When the analysis is complete, view the error log by right-clicking Security Configuration And Analysis and choosing View Log File. The log appears in the right pane with a date and timestamp; it reports on the completion of each analyzed area.

The following code is a small excerpt from a typical log file:

#### View Log File

```
07/03/2002 18:49:00
—Analysis engine is initialized successfully.—

—Reading Configuration info...

...

—Analyze Security Policy...
Analyze password information.
Analyze account lockout information.
Analyze other policy settings.
System Access analysis completed successfully.
Analyze log settings.
Analyze event audit settings.

Audit/Log analysis completed successfully.

Registry values analysis completed successfully.
```

This log file does not show discrepancies in individual attributes but rather integral errors in the analysis. To view the actual analysis results, expand Security Configuration And Analysis in the console tree. The familiar seven areas of system security appear: Account Policies, Local Policies, Event Log, Restricted Groups, System Services, Registry, and File System.

To view analysis results for any of these areas, expand the area and select a subcategory. Restricted Groups and System Services are not hierarchical and need only be selected. Figure 19-4 shows sample results for Security Options under Local Policies.

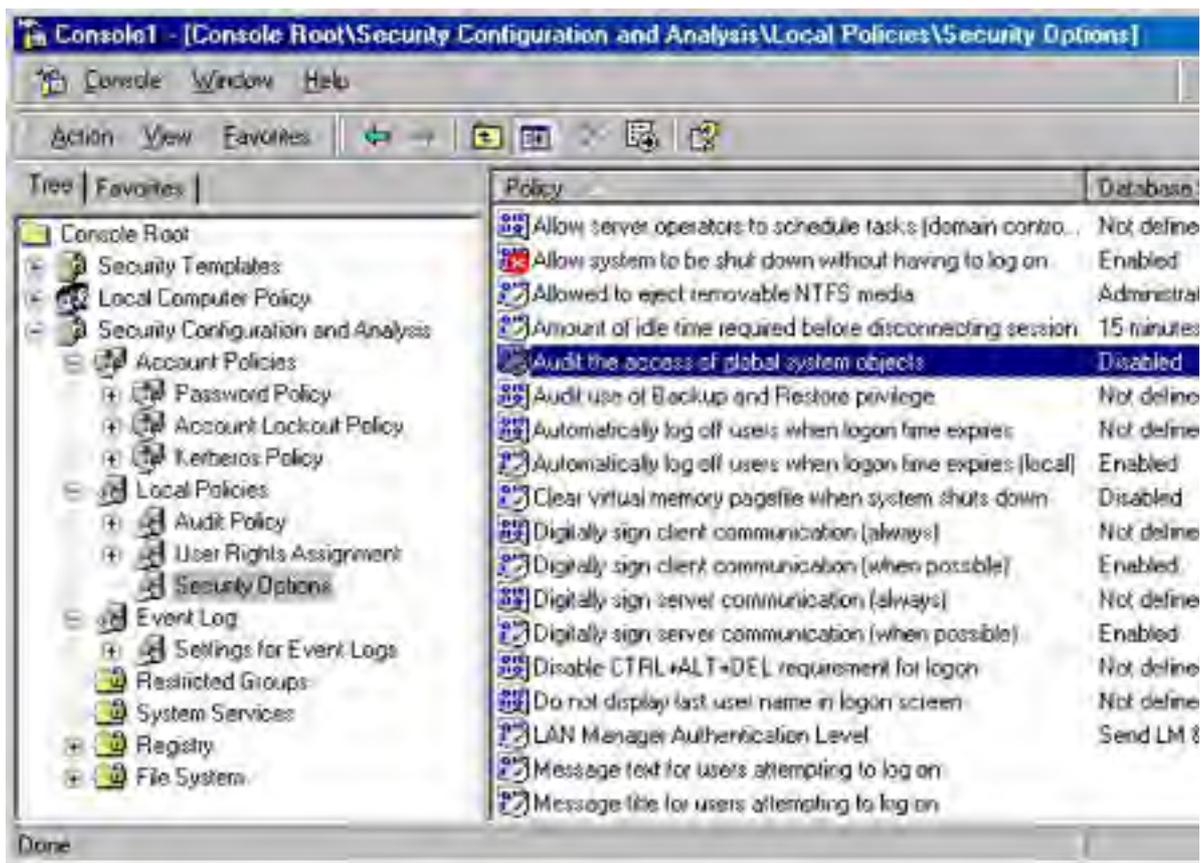

Figure 19-4. Analysis results for Security Options.

In the right pane of the console, each attribute is followed by two settings: the stored template (database) setting and the analyzed system (computer) setting. The icon for an attribute in which settings agree contains a green check mark. If the database and computer settings differ, a red "X" punctuates the attribute icon. Attributes that are not configured in the template are not analyzed, and no marking appears in the icon.

In the figure, all attribute settings agree except Allow System To Be Shutdown Without Having To Log On. This setting is enabled in the template but disabled on the system. Seven other attributes are not configured (defined) in the template and thus are not analyzed.

## Configuring Security

After you've successfully analyzed the system and found discrepancies between database and computer settings, you have a few alternatives. Depending on your evaluation of the results, you might decide that the current security template is not appropriate for this computer. A more stringent or relaxed template might be required, or perhaps vital attributes were left unconfigured and additional security areas need to be addressed. The solution is to import a template that is better suited to your particular security requirements. Templates can be added in increasing order of importance. New templates that are merged into the database override any conflicting attributes or permissions.

On the other hand, you might decide that the correct template was indeed used but that the computer settings are actually inappropriate. In this case, you'll want to change the database template so that further analysis won't show any discrepancies. To do so, right-click the offending attribute and choose Security to display a dialog box in which you can change the database template. For example, right-clicking the attribute showing a conflict in Figure 19-4 displays the dialog box shown in Figure 19-5. You can change the template setting to match the computer setting, or you can clear the Define This Policy In The Database check box to specify that the setting should no longer be considered during analysis.

Finally, you might determine that the security template is right on and that the system is in violation of your security policy and needs to be aligned. Once you've weeded out all of the template mismatches and only valid discrepancies remain, you'll want to configure the system. Do this by right-clicking Security Configuration And Analysis and choosing Configure Computer Now.

**Figure 19-5.** Reconciling a conflict between a system security setting and a template setting.

## Enabling Authentication

Among its many other tasks, the domain controller authenticates users to a network, using security policies and user authentication information stored in the Active Directory service. During an *interactive logon*, a user logs on to a domain account with a password or smart card. The domain controller confirms the user's identity with the information stored in Active Directory. Once an interactive logon to a domain controller has taken place, *network authentication* is performed for the user without any further effort on the user's part. The user can access resources on the network without having to reenter a password or smart card personal identification number (PIN). An interactive logon can also authenticate a user to a local computer rather than a domain account. With a local interactive logon, network authentication requires the reentry of a password any time the user needs to access a network resource.

The Kerberos version 5 authentication protocol is used for interactive logon and is also the default protocol for network authentication. Each domain controller includes Kerberos version 5. Both the key distribution center and the ticket-granting service are components of Kerberos and become integral parts of the domain controller. The key distribution center runs as part of Active Directory, which stores passwords and user account information for authentication. A Kerberos client is installed on all Windows 2000 workstations and servers. See [Chapter 18](#) for more information on Kerberos authentication.

Remote access clients, in addition to logging on to the network, must be authenticated by the remote access server before they can access the network. Smart cards and certificates, as well as password-based protocols, are used for dial-up networking. The next section explains how to obtain and use cryptographic tokens for network authentication, as well as how to configure remote clients and servers.

## Obtaining Smart Cards and Certificates

Smart cards combine the security of public-key cryptography with the portability of passwords. Before a smart card can be used for authentication, a logon certificate needs to be programmed onto the card. This is done by an administrator, who requests a smart card certificate from a certificate authority (CA) through an enroll-on-behalf-of station. See [Chapter 20](#) for information on preparing a CA to issue smart card certificates.

### More Info

Visit the PC/SC Workgroup Web site at <http://www.pcscworkgroup.com> for information on emerging smart card technologies and smart card vendors.

## Setting Up an Enrollment Agent

To request smart card certificates from a CA, the administrator needs a special certificate to sign the request. This certificate, known as an *enrollment agent certificate*, must be requested by a logged-on domain administrator from the dedicated machine that will be used to program smart cards. An enrollment agent certificate is a software-based certificate and private key that can be requested through the Certificates MMC snap-in. (See the section entitled [Requesting Certificates](#), later in this chapter.) Be sure to use the enrollment agent certificate template, as this is what authorizes the administrator to make smart card certificate requests.

It's possible, although highly inadvisable, to allow users to program their own smart cards by giving them access rights to the enrollment agent certificate template. Administrative programming and distribution of smart cards provides more accountability.

## Programming Smart Cards

Once the administrator has installed a smart card reader on a system and has obtained the enrollment agent certificate, the system is ready to program smart cards. Smart card installation adds a cryptographic service provider (CSP) to the system that will be selected during the smart card programming process. (See the section [Cryptographic Application Programming Interface](#) in [Chapter 18](#) for more information.)

The Web-based request process first generates a public/private key pair on your smart card. Using the public key and the user's name, the certificate authority issues and signs a certificate. Finally the certificate is added to the smart card. To program a smart card, follow these steps:

1. With the domain administrator as the current user, open Microsoft Internet Explorer and specify the certificate server URL. The URL is the name of the server followed by \Certsrv.
2. Select Request A Certificate and then click Next.
3. Select Advanced Request and then click Next.
4. Choose the Request A Certificate For A Smart Card On Behalf Of Another User Using The Smart Card Enrollment Station option. Click Next.
5. The Smart Card Enrollment Station Web page appears. Set the fields to the values shown in Table 19-2.
6. Click Submit Certificate Request.
7. After the request has been fulfilled by the certificate authority, you are prompted to insert the card and enter the smart card's PIN. This loads the certificate onto the card.

**Table 19-2.** Values for fields on the Smart Card Enrollment Station Web page

Field	Value
Certification Template	Smart card login
Certificate Authority	CA to issue certificate
Cryptographic Service Provider	The smart card manufacturer's CSP
Administrator Signing Certificate	The enrollment agent certificate (see the previous section)
User To Enroll	The name of the end user of the smart card

Smart card certificates for users requiring different functionality (such as encryption) can be programmed similarly by specifying a different certification template.

## Obtaining Software-Based Certificates

Authentication can also be accomplished with private keys and certificates residing on a local computer. See the section entitled [Requesting Certificates](#), later in this chapter, for information on how to obtain a certificate through the Certificates snap-in.

## Logging On with Smart Cards

Once a smart card reader has been installed on the target system and the user has obtained a properly programmed smart card from the administrator, the user can use the smart card to log on to the computer. To do so, the user simply inserts the smart card into the reader and enters a PIN when prompted to do so. This process takes the place of pressing Ctrl+Alt+Del and entering a user name and password.

To keep thieves from accessing the system by using a stolen card, the system tallies incorrect logon attempts. After three consecutive failures, the card is locked out of the system.

## Enabling Remote Certificate or Smart Card Authentication

As mentioned earlier, a user's public-key certificate, used for authentication, can be either programmed onto a smart card or stored locally on the computer. Follow the steps in the next two sections to enable dial-in authentication for each scenario.

### Authentication with Certificate on Smart Card

1. From the Start menu on the remote machine, open Control Panel and double-click Network And Dial-Up Connections.
2. Right-click the network or dial-up connection for which you want to enable authentication and choose Properties. In the Properties dialog box for the dial-up connection, click the Security tab (Figure 19-6).

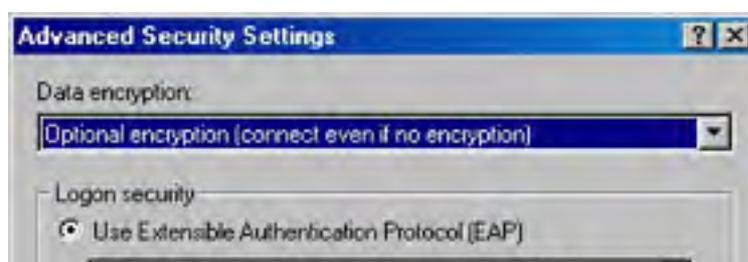

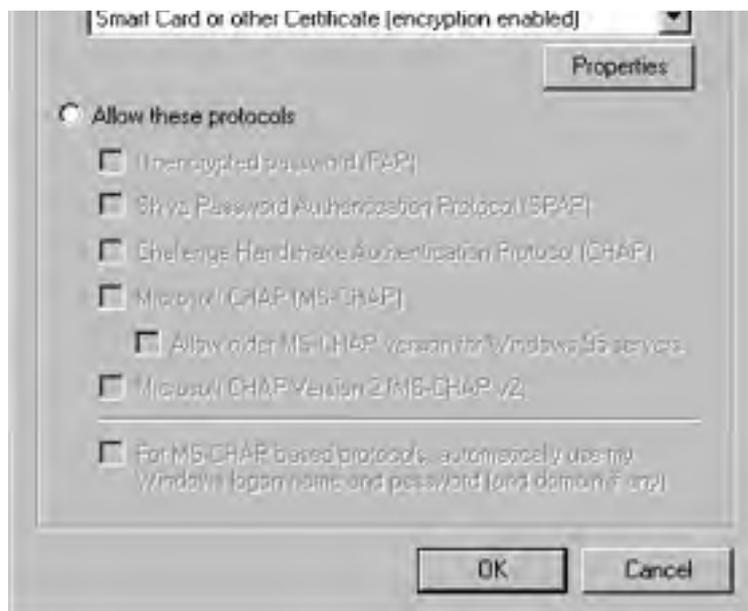

**Figure 19-6.** The Properties dialog box for the dial-up connection.

3. Ensure that Typical is selected and that the Validate My Identity As Follows list box is set to Use Smart Card, as shown in Figure 19-6. The Require Data Encryption check box can be selected for additional security.

### Authentication with Certificate Stored on Local Computer

1. From the Start menu on the remote machine, open Control Panel and double-click Network And Dial-Up Connections.
2. Right-click the network or dial-up connection for which you want to enable authentication and choose Properties. In the Properties dialog box for the dial-up connection, click the Security tab (Figure 19-6).
3. Select the Advanced option in the dial-up connection's Properties dialog box and click Settings. In the Advanced Security Settings dialog box, shown in Figure 19-7, select Smart Card Or Other Certificate (Encryption Enabled).

**Figure 19-7.** The Advanced Security Settings dialog box.

4. Click Properties to display the Smart Card Or Other Certificate Properties dialog box, as shown in Figure 19-8. To configure authentication for certificates residing in the local certificate store, select Use A Certificate On This Computer.

**Figure 19-8.** Setting properties for smart card or certificate authentication.

The Advanced Security Settings dialog box is also used to set alternate password authentication protocols for a connection. These protocols, listed under Allow These Protocols, range from the unencrypted Password Authentication Protocol (PAP) to version 2 of the Microsoft Challenge Handshake Authentication Protocol (MS-CHAP v2). One or more of these allowable protocols can be selected.

5. Two other certificate-specific options appear in this dialog box. First you can restrict connections to specific servers. To do this, select the Validate Server Certificate check box and activate one or both of the validation methods:
  - **Connect Only If Server Name Ends With** This option requires servers to be in a certain domain. For instance, enter *netsolvers.com* in this box to connect only to servers in the Netsolver domain.
  - **Trusted Root Certificate Authority** This option lets you choose which

certificate hierarchy the server belongs to. See the section [Importing Certificates](#), later in this chapter, for information on how to add a certificate as a root certificate authority.

The second option, Use A Different User Name For The Connection, keeps the authentication process from automatically using the certificate subject as the user name. This allows you to specify an alternate name.

6. Click OK to close the dialog box.

Whether you're using smart card-based authentication, password-based authentication, or a mix of the two, ensure that your remote access clients and remote access servers support at least one common authentication method.

## Configuring Authentication for a Remote Access Server

In addition to configuring the remote access client, you'll also need to set up the remote access server to allow smart card-based and certificate-based logins. Follow these steps to do so:

1. Launch Routing And Remote Access from the Administrative Tools folder on the Programs menu.
2. Right-click the name of the remote access server and choose Properties. In the Security tab, click Authentication Methods, ensure that the Extensible Authentication Protocol (EAP) check box is selected, and then click OK twice.
3. Back in the Routing And Remote Access dialog box, expand the remote access server and click Remote Access Policies. Right-click the policy that will be used when the smart card clients log on and choose Properties. Click Edit Profile, and in the Edit Dial-In Profile dialog box, click the Authentication tab. Select the Extensible Authentication Protocol check box. This also enables the EAP type; make sure that Smart Card Or Other Certificate is selected. Click Configure and select the machine certificate to use for authentication.

If clicking Configure returns an error stating that no certificate could be found, a machine certificate needs to be installed. This can be accomplished by ensuring that your enterprise CA is configured for auto-enrollment, which automatically allocates computer certificates for members of the domain. With this configured, run `secedit /refreshpolicy machine_policy` from a Windows 2000 command prompt on your remote access server to create a computer certificate.

## Implementing Access Control

In the real world, authorization is dictated by policy. When it comes to using resources, reading documents, or accessing rooms, different people have different access rights. The implementation of this policy can be locked safes or badge-access rooms. In the Windows 2000 environment, authorization is also based on policy. Different people or groups of people have different access rights. Policy here is implemented through access control. Quite simply, access control determines which users can access which resources. Resources in Windows 2000 include

- Files and folders, which can be accessed through Windows Explorer
- Shared volumes, folders, and files, which are allowed permissions on both NTFS and FAT file systems
- Active Directory objects, which are managed with the Active Directory Users and Computers snap-in
- Registry keys, which are managed with the Registry Editor
- Services, which are managed with the Security Configuration Tool Set
- Printers, which are configured through Settings on the Start menu

Each resource has a security descriptor associated with it that defines the object's owner, access permissions, and auditing information. Auditing of the object is discussed in the section entitled [Auditing](#), later in this chapter.

For Active Directory objects, administrative responsibility can be delegated to group administrators. Delegating allows object permissions to be managed in one organizational unit of the domain, without requiring multiple administrators for the entire domain. For more information, see the section [Delegating Object Control](#) in [Chapter 11](#).

## Establishing Ownership

The owner of an object controls who can access the object by setting object permissions. By default, the object's owner is its creator. Typically, administrators create most network objects and are responsible for setting the object permissions.

One of the standard permissions associated with all objects is the Take Ownership permission. By granting this permission, the owner allows a user (or member of a group) to assume ownership of the object. Taking ownership can be done through the tool that manages the specific type of object. For example, printers are managed through the interface found under Settings on the Start menu. The Security tab in the Properties dialog box for the printer shows the groups and users for which permissions are set. Clicking Advanced opens the Access Control Settings dialog box. With the correct permissions, ownership can be modified in the Owner tab. Administrators can assume control of any object under their administrative jurisdiction, regardless of the setting of the Take Ownership permission for the object.

## Assigning Permissions

Object permissions are broken down into specific actions that can be performed on that particular object. For registry keys, this includes the ability to create subkeys and set values. For Active Directory objects, permissions include the ability to create and delete children.

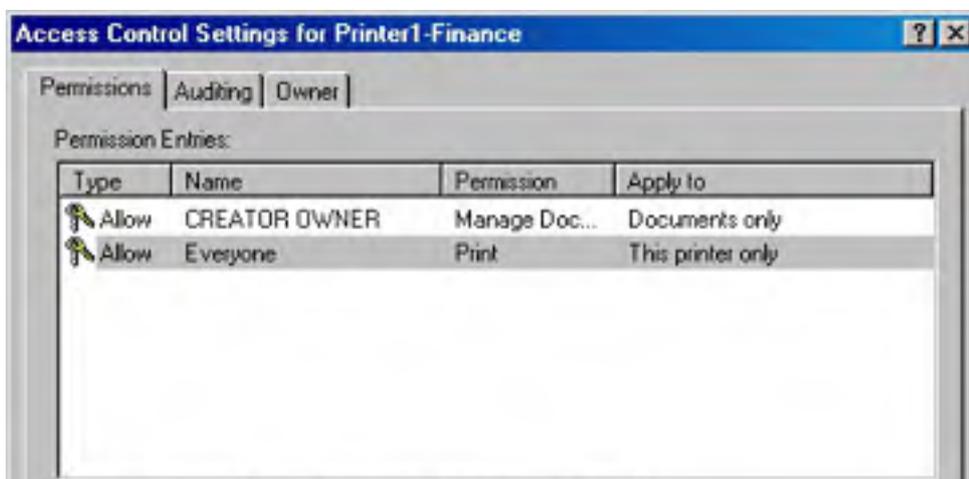

Permissions are set for the specific users or groups who perform actions on a particular object. For a given folder, one group might be granted permissions to create and delete files within that folder. Another group might be allowed only to list the folder's contents. Figure 19-9 shows printer permissions granted to Everyone.

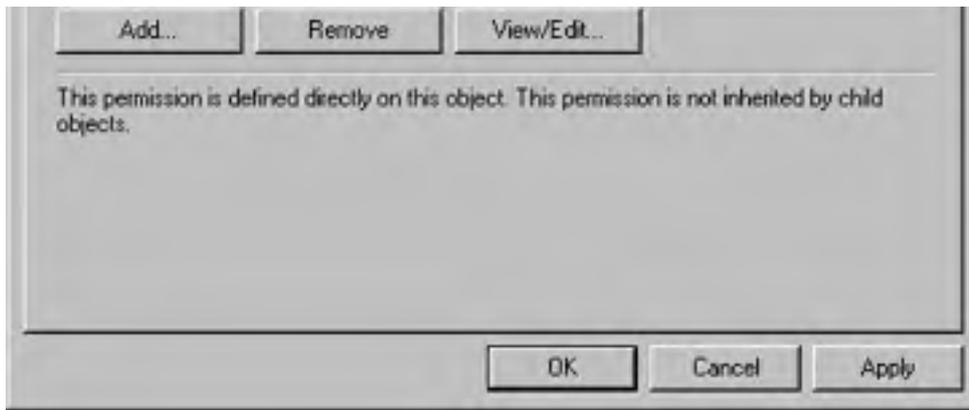

**Figure 19-9.** Printer permissions for the group Everyone.

To display permissions for a user or group, choose an entry in the Access Control Settings dialog box, and click View/Edit. The owner of the object, or a user or group granted Change Permissions permission, can use this dialog box to modify permissions for the user or group. To add a user or group to the access control list (Figure 19-10), click Add and select the user or group to add. Remember to set the appropriate permissions.

The burden of administering a domain of user rights and permissions can be eased by following a few guidelines. First, delegate administration to local authorities whenever closer management of users and services makes sense. Second, assign permissions on a group basis, rather than on a user basis. Third, set permissions at common node points in Active Directory and let them propagate down the tree to lower nodes.

**Figure 19-10.** *The Access Control Settings dialog box.*

## Managing Certificates

Public-key certificates serve as the security medium for many of the Windows 2000 protocols and mechanisms. Network authentication, IPsec, Encrypting File System (EFS), Secure Socket Layer (SSL), and Secure Multipurpose Internet Mail Extensions (S/MIME) all use certificates. MMC provides the Certificates snap-in for the single purpose of managing user, computer, and service certificates.

To add the Certificates snap-in to MMC, run *mmc.exe* from the Start menu. From the Console menu, select Add/Remove Snap-In. Click Add and select Certificates from the list of snap-ins provided. You'll be given a choice of which account to manage certificates for: My User Account, Service Account, or Computer Account. For the service and computer accounts, you can select which computer the snap-in will manage. For the service account, you'll also need to specify which service to manage.

Users can manage only their personal certificates. Administrators manage certificates for computers and services.

The certificate store is made up of five categories: Personal, Trusted Root Certification Authorities, Enterprise Trust, Intermediate Certification Authorities, and Active Directory User Object. Trusted Root and Intermediate CA certificates are preloaded. To view the details of any certificate, double-click the certificate. Figure 19-11 shows the public key of a VeriSign root certificate.

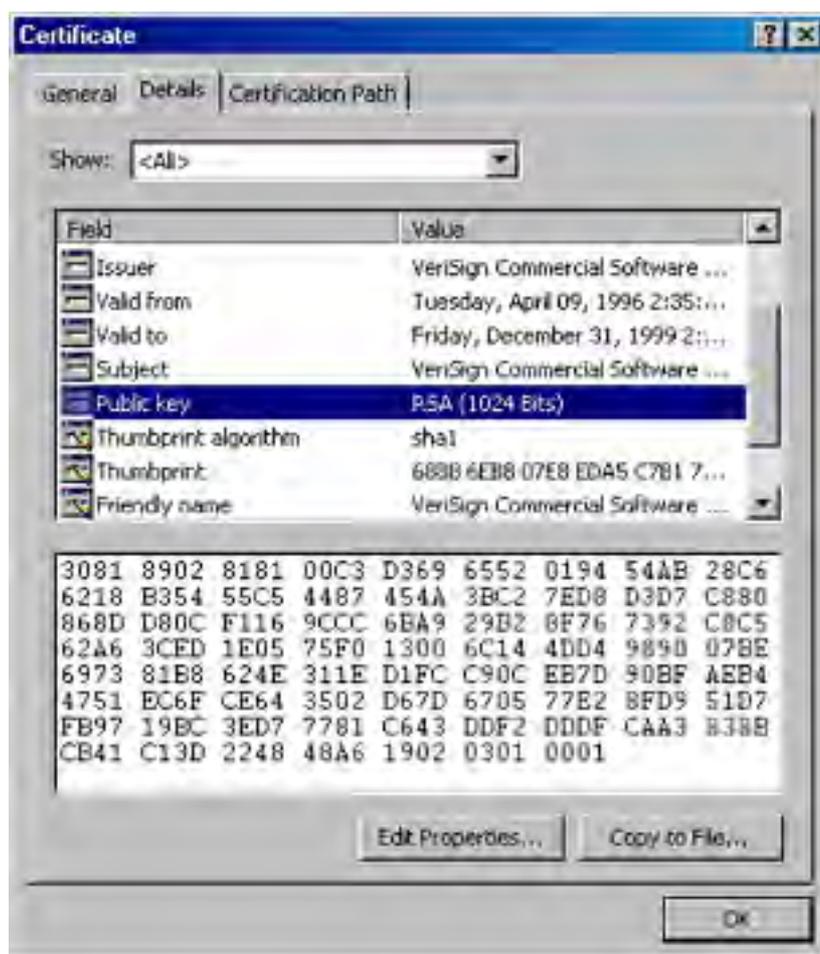

Figure 19-11. The public key of a VeriSign root certificate.

## Exporting Certificates and Private Keys

The Export command in the Certificates snap-in really provides two distinct functions. First, it allows a certificate or certificate chain to be exported for the purpose of sharing it with users or computers that are not privy to a certificate directory. Second, it allows the export of a certificate or certificate chain *along with the associated private key* for cryptographic use on another machine.

By default, only private keys for basic EFS and EFS recovery agents are marked as available for export. This keeps all other private keys from being unnecessarily exposed. Certificates and keys that are meant to be exported can be marked during certificate request.

You can export any type of certificate, including those in root CAs. Naturally, only certificates with available private keys (that is, personal certificates) that are marked as exported can be exported together. To export a certificate, follow these steps:

1. Find the certificate in the Certificates snap-in and right-click the entry.
2. Point to All Tasks and choose Export. You'll be welcomed to the Certificate Export Wizard.
3. Make your way through the wizard, choosing whether to export the private key (if available).
4. Choose the format for storing the certificate. DER Encoded Binary and Base 64 Encoded are single-certificate formats. With the PKCS #7 format, you can include the full certificate chain. Private-key combinations are stored in a PKCS #12 file and are password protected; you'll need to specify a password for the file.
5. Enter a target path and filename for the exported certificate.

With a highly populated certificate database, finding a particular certificate for exporting or enabling may be difficult. Use the Find Certificate command, found by right-clicking the Certificates snap-in, to locate certificates by issuer (Issued By), subject (Issued To), fingerprint (SHA1 Hash or MD5 Hash), or serial number.

## Importing Certificates

Users can import certificates into any one of the certificate categories found in the certificate store. In the Certificates snap-in, right-click the certificate category to which you want to import the certificate, point to All Tasks, and choose Import. Enter the certificate filename, which should have a standard certificate format extension (.PFX, .P12, .CER, .CRT, .P7B, .STL, .SPC, .CRL, or .SST). For PKCS #12 files, which contain private keys as well as certificates, you'll need to enter the password used to protect the file.

Root certificates are the basis of trust for certificate verification. Be extremely careful when importing a root certificate. Ensure that the certificate was received from a trusted source and that the certificate thumbprint matches a trusted publication.

## Requesting Certificates

Before using any application that relies on the public-key infrastructure, you'll need a certificate. [Chapter 20](#) covers how to configure and install Microsoft Certificate Services. Certificate servers configured to be enterprise CAs can request certificates using the Certificates snap-in.

Using Internet Explorer version 3 or later, you can request certificates from Microsoft Certificate Services, running in either standalone or enterprise mode, through the Web interface.

The certificate request process involves first generating a key pair consisting of a public key and a private key. The private key is stored and protected on the local computer. The public key, along with information identifying the user, is sent to the CA as a certificate request. If the CA determines that the user, device, or service is authorized for the certificate being requested, the CA generates and signs the certificate. The certificate can then be retrieved with the Certificates snap-in and placed in the local certificate store.

To request a certificate, right-click the Certificates folder under the Personal certificate store. Point to All Tasks, choose Request New Certificate, and follow the instructions in the Certificate Request Wizard. You'll need to choose a certificate type (the purpose for which the certificate will be used), a friendly name for the certificate, and the CA that will issue the certificate, if more than one is available. To allow you to download the certificate once the CA has issued it, the Certificate Request Wizard provides the Install Certificate option.

The advanced options of the Certificate Request Wizard allow private keys to be exported. Be extremely judicious when selecting this option. Exported private keys can allow other users to read your encrypted data.

## Enabling Certificates for Specific Purposes

Certificates can be issued for specific types of uses. These uses are programmed directly into the certificate, using a certificate extension field. For example, the Key Usage certificate extension tells whether a certificate can be used for data signing, certificate signing, nonrepudiation, or other functions. The Enhanced Key Usage extension extends this property to other uses, such as time stamping or file recovery.

Certificates can also be enabled for certain purposes on an account basis. That is, a user or administrator can decide which certificates to allow or disallow for specific uses. Although the actual certificate can't be modified, the attributes in the certificate store can be configured. For example, a certain certificate might have no internal key usage restriction. However, a user might want to enable that certificate only for code signing and secure e-mail.

To set certificate purposes, right-click the certificate and choose Properties. The three choices for enabling certificate purposes, as shown in Figure 19-12, are Enable All Purposes For This Certificate, Disable All Purposes For This Certificate, and Enable Only The Following Purposes. Choose the third option and select the purposes you want that certificate used for. Remember that only purposes allowed by the actual certificate or certificate path appear in the list.

---

**Figure 19-12.** *Options for enabling certificate purposes.*

## Using Internet Protocol Security Policies

IPSec provides end-to-end security for network communications—in the form of confidentiality, integrity, and authentication—using public-key technology to protect individual IP packets. [Chapter 18](#) provides a description of this protocol. This section covers the MMC snap-in for IPSec configuration, IP Security Policy Management.

To add the IP Security Policy Management snap-in to the MMC, select Add/Remove Snap-In from the Console menu. Click Add and select IP Security Policy Management from the list of available snap-ins. The dialog box that appears allows you to select the range of management: the local computer, the local computer's domain, another domain, or another computer.

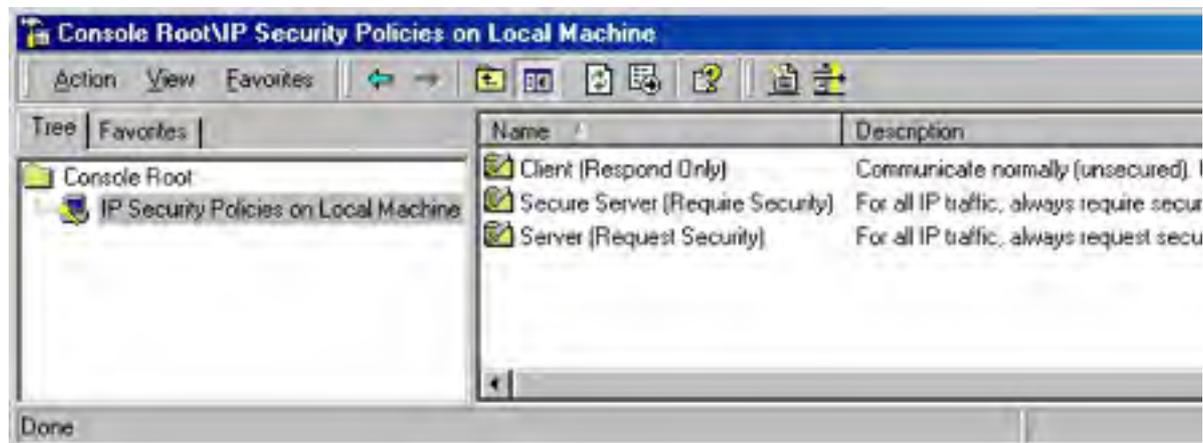

### Defining IPSec Policies

An IPSec policy is passed from the policy agent to the IPSec driver and defines proper procedures for all facets of the protocol, from when and how to secure data to what security methods to use. Policies can get a bit involved. Before jumping into the actual configuration, let's go over some terminology by defining the components of an IPSec policy:

- **IP filter** A subset of network traffic based on IP address, port, and transport protocol. It tells the IPSec driver what outbound and inbound traffic should be secured.
- **IP filter list** The concatenation of one or more IP filters, defining a range of network traffic.
- **Filter action** How the IPSec driver should secure network traffic.
- **Security method** Security algorithms and types used for authentication and key exchange.
- **Tunnel setting** The IP address or DNS name of the tunnel endpoint (if using IPSec tunneling to protect the packet destination).
- **Connection type** The type of connection affected by the IPSec policy: remote access, LAN, or all network connections.
- **Rule** A composite of the components: an IP filter, a filter action, the security methods, a tunnel setting, and a connection type. An IPSec policy can have multiple rules to protect each subset of network traffic differently.

### Using Predefined IPSec Policies

Three basic predefined policies are available for immediate use or as a starting point for more involved IPSec policies. Figure 19-13 shows the predefined policies.

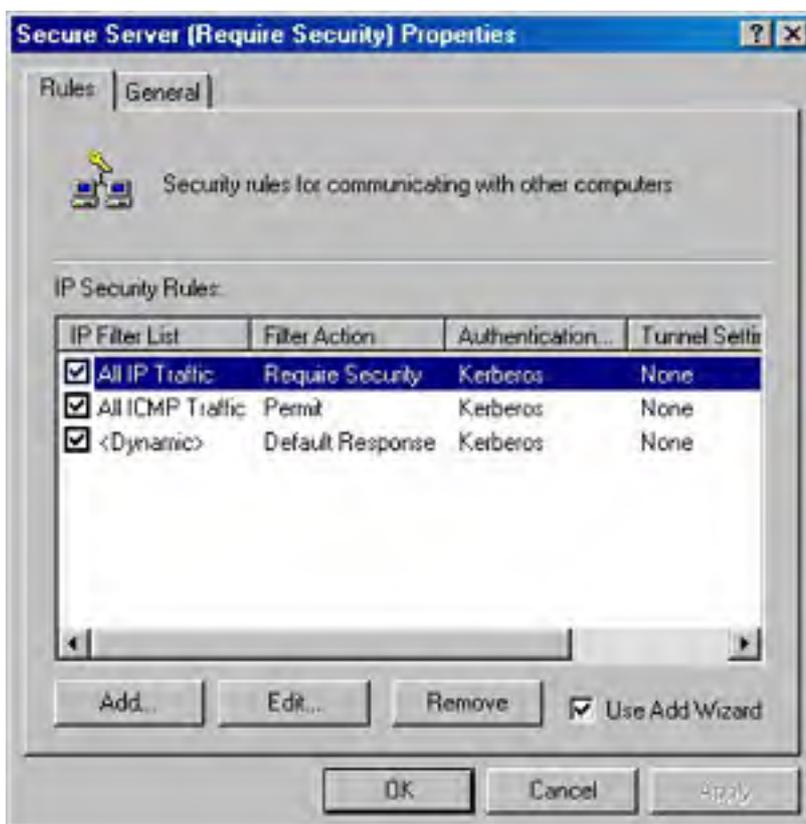

**Figure 19-13.** The three predefined IPSec policies.

The Client (Respond Only) policy should be used on computers that normally do not send secured data. This policy does not initiate secure communications. If security is requested by a server, the client responds, securing only the requested protocol and port traffic with that server.

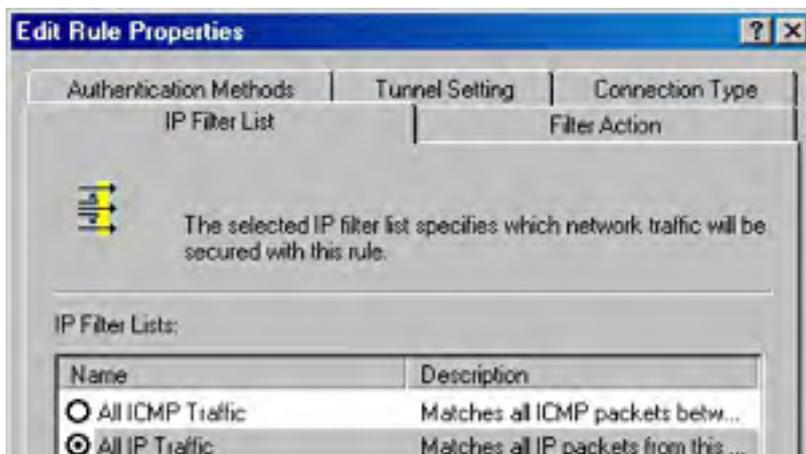

The Server (Request Security) policy can be used on any computer—client or server—that needs to initiate secure communications. Unlike the Client policy, the Server policy attempts to protect all outbound transmissions. Unsecured inbound transmissions are accepted but not resolved until IPSec requests security from the sender for all subsequent transmissions. The strictest of the predefined policies, the Secure Server (Require Security) policy neither sends nor accepts unsecured transmissions. Clients attempting to communicate with a secure server must use at least the Server predefined policy or an equivalent.

The section that follows demonstrates how to generate an IPSec policy from scratch. Let's first peruse one of the predefined policies to get our feet wet. Right-click the Secure Server policy and choose Properties to bring up the Secure Server (Require Security) Properties dialog box, with the Rules tab in the foreground, as shown in Figure 19-14.

**Figure 19-14.** The Secure Server (Require Security) Properties dialog box.

This policy has three rules, all activated, as indicated by the check marks. The first rule has an IP filter of All IP Traffic, a filter action of Require Security, an authentication method of Kerberos, a tunnel setting of None, and a connection type of All. A rule can be added or removed from this list with the appropriate buttons. Clicking Edit brings up an Edit Rule Properties dialog box with five tabs, one for configuring each field of the rule (Figure 19-15).

**Figure 19-15.** *The Edit Rule Properties dialog box.*

We'll explore these configurations in the next section. Back in the Secure Server (Require Security) Properties dialog box (Figure 19-14), you can view the general properties of the policy—including a policy description and minute intervals at which to check for policy change—by clicking the General tab.

Clicking Advanced in the General tab displays a Key Exchange Settings dialog box, shown in Figure 19-16. This dialog box allows you to specify the life of a key in minutes or sessions. Using a short key lifetime makes transmission more secure by increasing the number of keys that an attacker would have to break, but it adds overhead to transmission time. Selecting the Master Key Perfect Forward Secrecy check box ensures that existing keys cannot be reused to generate additional keys. This option should be used with caution, as it adds significant overhead. Clicking Methods allows you to select security methods and preference order. A security method includes an encryption and integrity algorithm, along with a Diffie-Hellman group, which affects key generation.

**Figure 19-16.** *The Key Exchange Settings dialog box.*

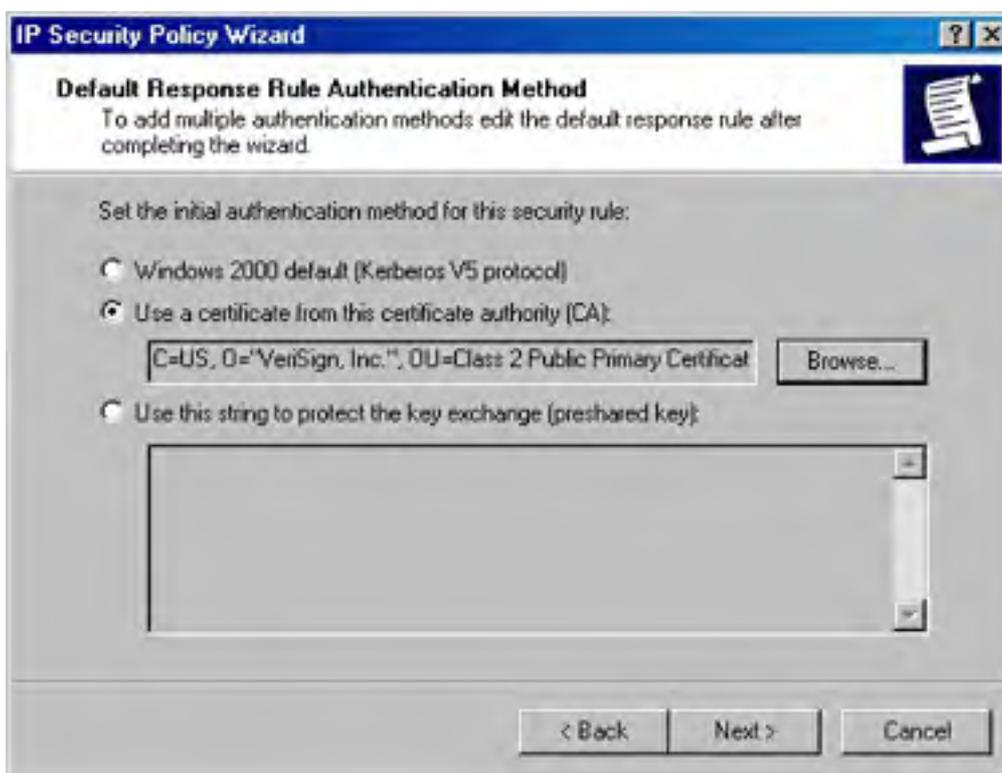

## Creating an IPSec Policy

In addition to using a predefined IPSec policy as a template, an administrator can generate policies from the ground up with the IP Security Policies item in the MMC. A custom policy can be restrictive or permissive, simple or powerful, depending on the function of the machine, the environment in which it operates, and the types of systems it communicates with.

To add an IPSec policy, right-click the IP Security Policies item in the MMC and select Create IP Security Policy. You're presented with the IP Security Policy Wizard. The following steps guide you through this wizard:

1. Click Next at the welcome screen.
2. In the next screen, enter a meaningful policy name and description and click Next.

3. Select or clear the Activate The Default Response Rule check box, based on whether the policy should allow negotiation with computers that request IPSec. Clearing this check box adds an inactivated response rule to the policy. Click Next.
4. If you selected the Activate The Default Response Rule check box in the previous step, you see the dialog box shown in Figure 19-17, in which you choose the authentication method. Kerberos version 5 is the Windows 2000 default protocol but is allowed only on machines that are members of a domain. The second choice, Use A Certificate From This Certificate Authority (CA), promotes public-key authentication. You'll need to choose a certificate authority that is appropriate for the certificate to be used. The third and final option allows you to type a preshared key to be used for key exchange. This string must also be known by the requesting computer for successful exchange. Click Next when you've made your choice.
5. Select the Edit Properties check box if you want to display the policy's Properties dialog box. You can also display this window by right-clicking the policy once it's listed and choosing Properties.

**Figure 19-17.** Choosing an authentication method for the Default Response rule.

### Editing an IPSec Policy

The previous section showed how to create an IPSec policy, but to really add functionality to your policy, you'll need to edit it. (To do so, right-click the policy and choose Properties.) Figure 19-14 in the previous section shows the Properties dialog box for an IPSec policy. A newly created policy contains only one default response rule, which will be activated—or not activated—depending on the choices you made in the wizard during policy creation.

You add functionality to an IPSec policy by creating rules that govern when and how security should be supplied. Each combination of a filter list, filter action, authentication method, tunnel setting, and connection type is a separate rule.

Rules can be added manually or with the Add Wizard; both accomplish the same thing, but the wizard is a bit friendlier. We'll turn off the Add Wizard by clearing the Use Add Wizard check box in the lower right corner of the Properties dialog box for the policy. Doing so allows us to explore each aspect of a rule in its native dialog box. Editing rules after they're created will be done through this interface as well.

With the Add Wizard turned off, click Add. You're presented with the New Rule Properties dialog box, which, except for the title, is the same as the Edit Rule Properties dialog box shown in Figure 19-15. The dialog box has five tabs, one for each element of a rule. We'll look at each of the tabs in turn.

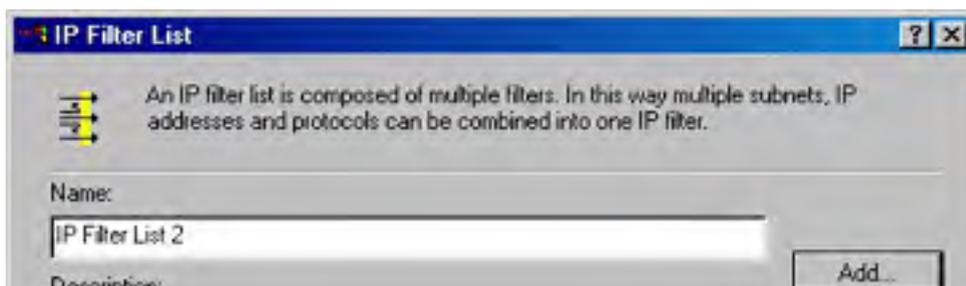

**IP Filter List** The IP filter list is made up of one or more filters that specify which network traffic to act on. As shown in Figure 19-18, the All IP Traffic and the All ICMP Traffic filter lists are added by default but are not activated. In the figure, a third filter list has been added and activated by clicking its option button.

**Figure 19-18.** The IP Filter List tab of the New Rule Properties dialog box.

Clicking Add brings up the IP Filter List dialog box, which allows you to specify filters to include in a customized filter list. Figure 19-19 shows a filter list under construction. Here, if you click Add with the Use Add Wizard check box selected on, the IP Filter Wizard starts, which allows you to construct a new filter based on the following categories:

- **Addressing** Filters the source and destination addresses specified by IP address (My IP Address, Any IP Address, Specific IP Address, or Specific IP Subnet) or a specific DNS name.
- **Protocol** Filters by protocol type, such as TCP, and source and destination ports.

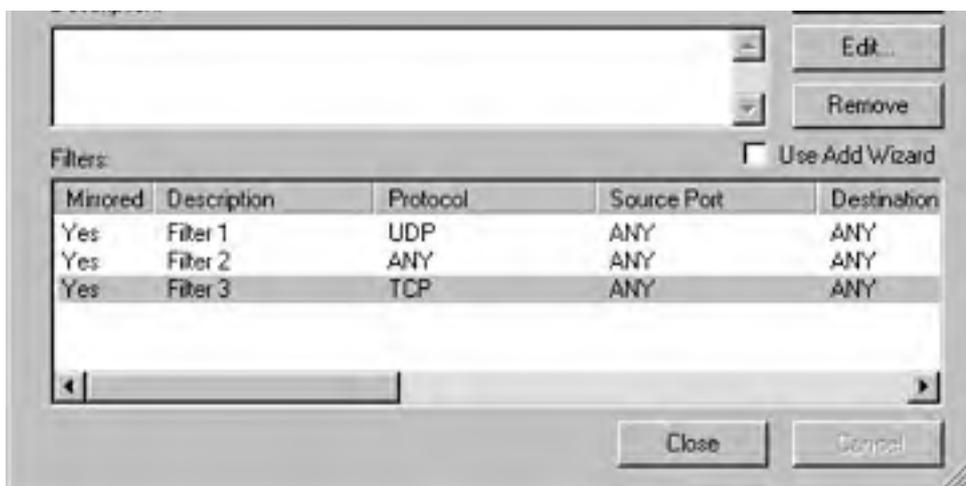

Figure 19-19. The IP Filter List dialog box.

**Filter Action** The filter action determines how the IPsec driver responds to those computers represented by entries in the filter list and what security methods to use. You can choose one of the supplied actions shown in Figure 19-20 by selecting it, or you can add your own action.

The Request Security action causes the driver to attempt to establish secure communications with the client, but if this is unsuccessful it communicates without security. The Require Security action requires clients to establish trust and security methods. The Permit action allows unsecured IP packets to pass through.

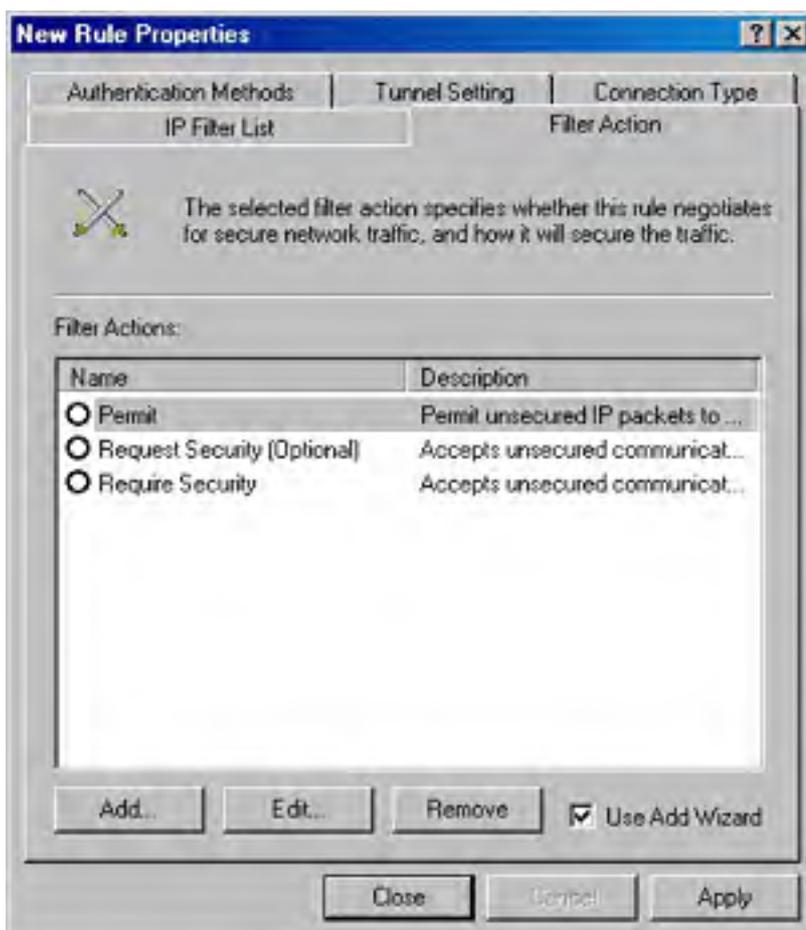

Figure 19-20. The Filter Action tab of the New Rule Properties dialog box.

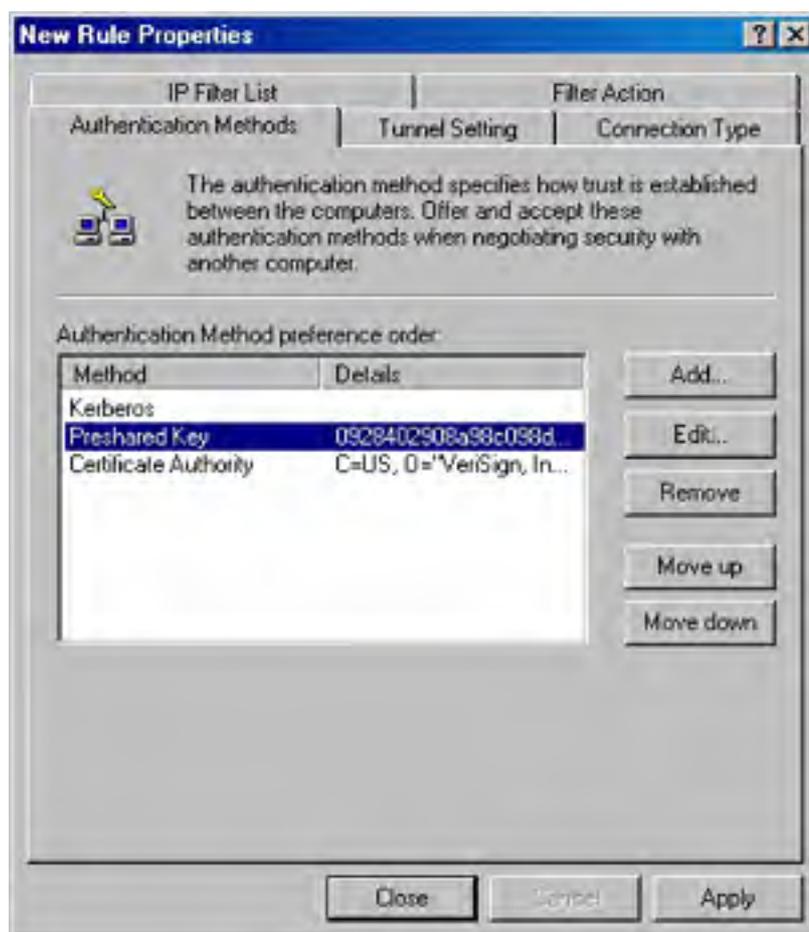

Adding an action involves choosing a filter name, a description, and general behavior that either permits communications, blocks communications, or negotiates security. If you choose to negotiate security, you'll need to configure two other areas. Under Handling Non-IPSec Clients, you choose either not to communicate with computers that don't support IPSec or to allow unsecured communication.

You also select a Security Method: high (encrypted, authenticated, and unmodified), medium (authenticated and unmodified), or custom. For the custom security method, you'll choose encryption and integrity algorithms and specify session key settings, such as how often to generate new keys.

**Authentication Methods** The authentication method specifies how trust will be established with the remote computer. You can specify one or more methods to use when requesting secure communications or when being asked for secure communications. Figure 19-21 shows three allowable authentication methods, listed in order of preference. Change the priority of a method with the Move Up and Move Down buttons. The Add button provides you with three choices for a new method:

- **Windows 2000 Default (Kerberos V5 Protocol)** This option provides the easiest configuration as long as all clients are running the Kerberos V5 protocol and are members of a trusted domain.
- **Use A Certificate** This option uses public-key certificates for authentication. You'll need to specify the certificate authority of users or entities to authenticate. To allow authentication for users under separate CAs, add a separate authentication method for each.
- **Use This String To Protect The Key Exchange** This option uses a preshared key that you specify in the box provided. You can use multiple preshared keys by adding other authentication methods.

**Figure 19-21.** The Authentication Methods tab of the New Rule Properties dialog box.

**Tunnel Setting** The Tunnel Setting tab allows you to specify a tunneling endpoint if you choose to

invoke IPSec tunneling. The endpoint can be specified as a DNS name if you're running the DNS service on your network, or it can be in the form of an IP address.
